Preface

"Quiet the little feet that trod
So merrily the floor
The little hands that clasped my neck
Will clasp my neck no more.
Ah! Children mine and yet not mine
For a few years were given
And then recalled to draw my heart,
Nearer to God and Heaven."

Henry Whinery, who drove the stage coach between San Jose and Santa Cruz, California saw two of his children Harry F. Whinery, (age 5 yrs, 9 mo) and Martha Whinery (age 7 yrs, 5 mo) die of Diphtheria on December 6, 1876.

Vaccines have had a greater impact on human health than any other biomedical development. Over the past three centuries vaccines have facilitated the eradication of one infectious disease, smallpox, and have limited the scourge caused by more than 25 enteric, respiratory, genitourinary and zoonotic and vector-borne pathogens including measles, polio, hepatitis B, yellow fever, and *Haemophilus influenza* type B. Despite the successes there remains enormous work to be done. Infectious diseases continue to be the number one cause of death globally claiming 20 million lives yearly. Old threats such as malaria, dengue, and syphilis have yet to be tamed. Over the past 25 years there has been a dramatic increase in newly recognized or emerging pathogens including human immunodeficiency virus, hepatitis C virus and *Helicobacter pylori*; however the development of successful vaccines has not kept pace with the discovery of these new perils. Increases in international travel and migration have made re-emerging diseases such as tuberculosis and influenza global menaces. As the world strives to achieve the ambitious Millennium Development Goals, resource poor countries struggle to overcome the burden caused by neglected diseases like trypanosomiasis and hookworm. In addition, the risk of microbes as biothreat agents, such as smallpox, anthrax and plague, continues to present a danger to mankind in the 21st century.

This comprehensive new textbook authored by leading authorities is intended to inform researchers, clinicians, public health specialists and policy makers regarding the current state of development of vaccines for emerging and neglected diseases and biothreat agents. Detailed information regarding epidemiology, clinical disease, management, immunology, pathogenesis, as well as vaccinology is presented for each pathogen. The book also provides in-depth information regarding the processes that are critical to the generation of these vaccines to the marketplace. This includes chapters on vaccine platforms, preclinical development, regulatory approval, clinical trials, manufacture and post licensure issues.

The editors would like to thank our many colleagues whose outstanding contributions made this book a reality. We would also like express our appreciation to Lisa Tickner and Carrie Bolger of Elsevier for their able and professional assistance.

Foreword

Rino Rappuoli
Global Head of Vaccines Research, Novartis
Vaccines & Diagnostics, Sienna, Italy

Vaccination is the medical practice that together with clean water had the greatest impact on human health during the 20th century. Thanks to vaccines, devastating diseases that had been responsible for much of the morbidity and mortality recorded were eliminated. These include smallpox, poliomyelitis, tetanus, diphtheria, pertussis, hepatitis B, *Haemophilus influenzae*, measles, mumps, and rubella, which killed or disabled millions of people. Meningococcal meningitis, perhaps the last disease that can attack in a few hours and kill healthy children and young people, is also on its way to being conquered by vaccination. Now that all these diseases have been controlled, is there a role for vaccination in the 21st century?

Clearly the 70 chapters of this book show that we still have a long way to go before we can conquer all the diseases that can be addressed by vaccination. There is increased interest in emerging and neglected diseases, which have not been a priority for vaccine developers, thanks to the technological revolution of the last decades that increased the feasibility of developing new vaccines and the renewed business interest on vaccines that emerged during the last 5 years.

Let us look at the increased feasibility of vaccines first. A recent review of the history of vaccination concluded that the probability of success in vaccine development is highest when protection is mediated by antibodies and antigens that have no or limited antigenic variability (Rappuoli, 2007). In a graph representing the type of immunity and the antigenic variability on the vertical and horizontal axes, vaccines that have the highest probability of success are in the upper right quadrant and the risk in vaccine development increases moving toward the intersection of the two (Fig. 1). Accordingly, vaccines for which T-cell immunity is critical for protection or protective antigens are highly variable have an increased degree of failure during development. In Fig. 1 I have tried to rank the vaccines discussed in this book based on the above-mentioned criteria. From the figure it is clear that the majority of the vaccines reside in the upper right quadrant, which belongs to the pathogens that can be addressed by antigens that meet the validated criteria for vaccine success, that is, they induce an antibody-mediated protection and they are not

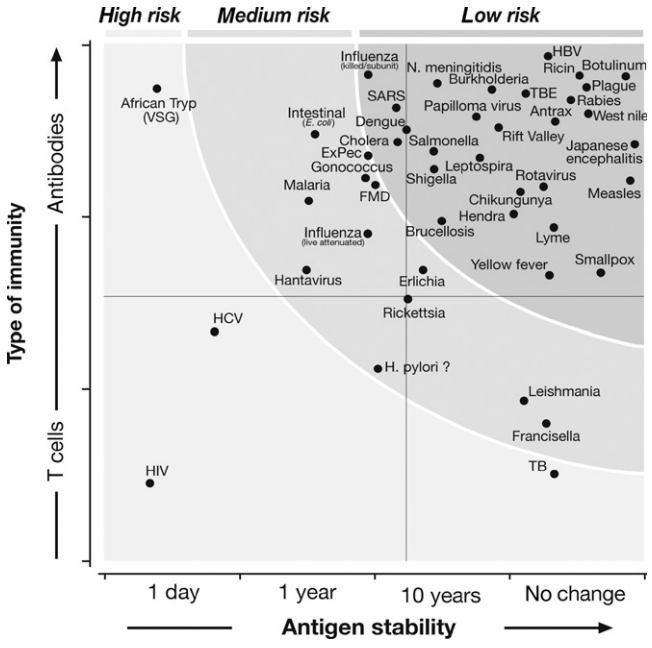

FIGURE 1 Graph representing the type of immunity and the antigenic variability.

highly variable. Therefore, in most cases, vaccines for neglected and emerging diseases can be developed using well-established technologies.

Thanks to technologies such as recombinant DNA, conjugation, genomics, and the increased understanding of the immune system, the feasibility of vaccine development has increased a great deal. Good examples are the several recombinant and conjugate vaccines already licensed, and several vaccines developed using genomics (reverse vaccinology) that are in development. Reverse vaccinology is perhaps the most powerful tool for vaccine development that has become available lately. In fact, the availability of genomic sequences allowed us to use computers to search the entire genetic repertoire for protective antigens, thus increasing by several orders of magnitude the numbers of antigens available for vaccine development. With many more antigens available for each pathogen, it is now possible to select those antigens that respond to validated principles, such as limited or absent antigenic variability and antibody-mediated protection.

An important minority of the vaccines described in this book resides in the middle or left quadrant of Fig. 1. These are the vaccines that are not yet within the reach of today's technologies and developing these vaccines requires bridging science gaps such as learning to develop vaccines based on T-cell-mediated protection. Today these vaccines are mostly addressed by using innovative immunostimulatory molecules and adjuvants, replicating or nonreplicating viral vectors, prime-boost regimens, and so forth. An alternative approach can be to bring them to the comfort zone of upper right quadrant by learning how to engineer immunosilent conserved epitopes to become immunodominant. A good example of this is HIV wherein we know that antibodies such as b12 that recognize the conserved CD4 binding site would be able to protect from infection. However, we are unable to make this epitope immunodominant and therefore we cannot yet make this vaccine. We believe that a systematic approach to the structural properties of immunodominant and immunosilent epitopes can provide the scientific rationale that in the future may allow us to engineer immunodominant epitopes. A rational approach to the 3D structure of antigens (structural vaccinology) is one of the basic aspects of vaccine research that should be a priority.

In conclusion, with a few exceptions, the majority of the vaccines addressed in this book are within the reach of today's technologies; the question is therefore whether or when they will be developed. Unfortunately, technical feasibility is only one of the hurdles in vaccine development. Even more important is often whether there is a market that can justify the huge investment that is necessary to bring vaccines to licensure. Vaccines today are developed by few global vaccine manufacturers that can only afford to invest in those vaccines that have a high probability of success in the market. With few exceptions, most of the vaccines addressed in this book are "neglected" because they do not have a market that justifies their development; as a consequence, the probability that they will be developed is low. In fact, for these vaccines the basic research and initial clinical trials will be carried out in academia and small biotechs funded by the public sector. However, the gestation of vaccines, the phase during which a discovery is transformed into a potential product, is unlikely to happen. As discussed in this book, during this phase of the vaccine development, pathogens (or their genomes) are systematically screened to identify the best antigens, the antigens are prioritized using in vitro assays and animal models that are relevant to making decisions, the selected antigens are engineered and expressed in hosts suitable for industrial scale, and the composition of the vaccine is defined using adjuvants suitable for man. Then, production of the candidate vaccine is adapted to industrial needs; it is scaled up and produced in cell lines suitable for GMP manufacturing. A robust formulation is developed; the vaccine is produced under GMP conditions and tested for stability. Toxicology studies are performed, regulatory documents are submitted to regulatory agencies, and the vaccine is finally tested for safety and for proof of concept in man. Unfortunately, the results of this phase, which is perhaps the most critical for vaccine development, are not suitable for publication in good journals and therefore there is no incentive for people in academia to embark in this area. In addition, the knowledge to do the work required in this phase lacks in academia; it is not even present in most biotechs and vaccine manufacturers in developing countries. However, five or six large vaccine manufacturers have the traditional knowledge and the necessary investment to carry out this obscure but essential part of the work. In fact many of the failures in vaccine development are due to the poor understanding and underestimation of this phase. In order to fill this gap in vaccine development, recently a new institute has been established. This is the Novartis Vaccines Institute for Global Health (NVGH), an institute with a nonprofit mission dedicated to the development of effective and affordable vaccines for neglected infectious diseases in developing countries. By having access to all the know-how and technologies available with a large vaccine manufacturer, and having neglected diseases as a mission, this institute has prospects of being successful in this area.

Despite difficulties in filling technical and structural gaps the field has never been as promising as today. Thanks to the vast progress in technology

and the renewed recognition of the enormous value that vaccines bring to the society, the field of vaccine development is moving beyond its 20th century renaissance. Vaccines today are usually given to prevent diseases that parents and pediatricians have never seen; in their minds vaccines are no longer immediate lifesavers but tools that improve the quality and duration of life. In agreement with this new vision, thanks to the scientific progress, new vaccines target infections such as HBV and HPV that can result in cancer decades after infection; they hold great promise for preventing devastating outbreaks such as pandemic influenza and are being explored for the control of chronic, metabolic, and neurological diseases. Vaccines targeting hypertension, drug addictions, and cigarette smoking are examples of cases that are not traditionally tackled by vaccination. Although some difficult targets such as HIV presently remain beyond the reach of technical feasibility, a new vision is emerging that views vaccines as friendly and safe tools for a global health for all ages and all populations around the world. In this vision, one of the most important missions is to be ready and promptly tackle those diseases that are traditional targets for vaccination, that is diseases caused by emerging infectious agents, traditional infectious agents causing diseases in developing countries that cannot afford the cost of vaccine development, and those infectious agents that have the potential to be improperly used as biological weapons. Although investing in the development of these vaccines is going to be a cost to our society, this can be one of the best investments for improving the quality of life of people globally and for minimizing the risk of biological agents as weapons of terror.

The developmental risk of the vaccines discussed in this book is based on the predicted type of immunity and antigen stability. The graph is adapted from Rappuoli (2007).

SECTION I

BIOTHREATS AND EMERGING INFECTIOUS DISEASES

CHAPTER

1

Agents of Emerging Infectious Diseases

Juan P. Olano and David H. Walker
Departments of Pathology and Microbiology and Immunology, Center for Biodefense and Emerging Infectious Diseases, Sealy Center for Vaccine Development, University of Texas Medical Branch, Galveston, TX, USA

OUTLINE

ABSTRACT

Dramatic improvements in the control of infectious diseases in developed countries owing to socioeconomic changes, vaccines, and antibiotics during the first seven decades of the 20th century led to the mistakened concept that infectious diseases would no longer be a concern. Since the declaration of victory in the war against infectious diseases in 1967, approximately 50 new disease agents have been identified. Nearly every type of etiologic agent and clinical manifestation have been involved including acute respiratory infections (e.g., H5N1 influenza A, SARS, hantaviral cardiopulmonary syndrome, and Legionnaires' disease), central nervous system involvement (e.g., West Nile encephalitis, Nipah virus encephalitis, and prion diseases), enteric infections (e.g., *Helicobacter pylori* gastric and duodenal diseases, cryptosporidiosis, microsporidioses, and Shiga toxin diseases), systemic bacterial diseases (e.g., Lyme disease, six new rickettsioses, three new human ehrlichioses, bartonelloses, and staphylococcal and streptococcal toxic shock syndrome), viral hemorrhagic fevers (e.g., Marburg, Ebola, Lassa, Bolivian, Argentine, and Venezuelan hemorrhagic fevers), human retroviral infections (e.g., HIV1 and 2 and HTLV-I and II), new human herpesviruses (HHV6, HHV7, and HHV8), and the viral agents of hepatitis A, B, C, D, and E.

There are the reciprocal threats that a bioterror agent (e.g., smallpox virus) could cause a newly emerging infectious disease (EID) and that an agent of emerging infections (e.g., SARS-coronavirus or Rift Valley fever virus) could be disseminated by terrorists.

Vaccines offer a critically important potential countermeasure against the effects of these and future EIDs. An aggressive approach to developing prototype vaccines against each new class of etiologic agent must be driven by public health initiatives because commercial interests will not undertake these projects. The microbe must be completely characterized biologically, molecularly, and genetically. An accurate animal model of the human infectious disease should be developed. The mechanisms of vaccine-induced protective immunity must be elucidated and the antigens that stimulate these mechanisms of protective immune memory identified. Preclinical testing of vaccine candidates should then be completed in the animal models.

It would be most effective if subunit vaccine platforms were developed in which new antigen cassettes could be inserted and FDA approval obtained using one or more prototypes. Experience in manufacturing and a track record of effectiveness and safety for vaccines against numerous emerging infectious agents could be achieved for veterinary diseases caused by organisms that also cause emerging human infections (e.g., West Nile virus and ehrlichioses).

In the United States, these approaches are driven currently by individual investigator initiative in pursuing the scientific questions through grants from the National Institute of Allergy and Infectious Diseases. Progress occurs, but not at the desired level. An emerging infection with high transmissibility (e.g., $R_o = 10$) and a case-fatality rate of 15% would cause global devastating effects at a level on the order of magnitude of a nuclear war. Our efforts to prepare for EIDs fall far short of nuclear attack preparedness during the Cold War.

INTRODUCTION

A rather optimistic statement in 1967 from the US Surgeon General proclaimed stated that "the war against infectious diseases has been won." The emergence and re-emergence of infectious diseases during the past four decades has been astounding and has obviously proved this highly publicized statement wrong. A former director of the National Institute of Allergy and Infectious Diseases stated in 1981 that microbial diversity and evolutionary vigor were still dynamic forces threatening mankind. With the advent of revolutionary research tools, our view of the world of microbial diversity continues to expand

astronomically. As an example, a random sample of seawater near Bermuda yielded DNA sequences never known before. The most accepted definition of an emerging and re-emerging infectious disease is "a disease that has newly appeared in the population or has existed previously, but is rapidly increasing in incidence and geographic range." Another widely cited definition is a "new emerging or drug resistant infection whose incidence in humans has increased within the last two decades, or whose incidence threatens to increase in the near future." Strictly speaking all infectious diseases have "emerged" at one time or another. Thus, the definitions are rather arbitrary. The emergence of *Mycobacterium tuberculosis* and *Plasmodium falciparum* as human pathogens probably occurred within the last few tens of thousands of years. Other pathogens required rather large human populations interacting closely so that human–human transmission would occur such as with measles and smallpox viruses. HIV probably made the jump to humans 60–75 years ago. Emerging infections are further classified by others as newly emerging, re-emerging/resurging, and deliberately emerging. The factors involved in the process of emergence and re-emergence are extremely complex and have to do with the microbes themselves, the environment, and the hosts, a triad well known to any scientist who works in the field of infectious agents. The Convergence Model tries to explain all factors that affect the host–microbe interaction. This interaction is affected by interlocking domains, namely genetic and biologic factors, ecologic factors, physical environmental factors, and social, political and economic factors.

EMERGING INFECTIOUS DISEASES SINCE 1967

We have attempted to create a comprehensive list of infectious diseases that fall into this category (Table 1.1). A discussion of the clinico-epidemiological characteristics of the most representative emerging infectious diseases (EIDs) follows. We have classified EIDs based on clinical presentation (syndromes such as pneumonia, encephalitis, systemic bacterial infection, enteric infection, and viral hemorrhagic fever).

EMERGING INFECTIONS CAUSING ACUTE RESPIRATORY INFECTIONS

Acute respiratory infections are the leading cause of mortality from infectious diseases around the world. In 2003, 37 million deaths were due to acute lower respiratory tract infections. Upper respiratory tract infections, although important from the point of view of morbidity, are rarely fatal. In developed countries the main culprits are influenza and bacterial pneumonias. In underdeveloped countries, the highest mortality rates are seen in children less than 5 years of age with viral pneumonia caused by respiratory syncytial virus, parainfluenza viruses, influenza viruses, and adenoviruses. Bacterial respiratory agents include *Streptococcus pneumoniae*, *Hemophilus influenzae*, and *Staphylococcus aureus*.

VIRAL PULMONARY SYNDROMES

Influenza Viruses

These viruses belong to the family Orthomyxoviridae and are enveloped, negative sense, single-stranded, segmented, RNA viruses responsible for recurrent epidemics of febrile respiratory disease every 1–2 years. Influenza viruses are further classified as A, B, and C based on antigenic characteristics. Influenza B and C viruses only undergo antigenic drift as compared with influenza A viruses that can undergo antigenic shift in addition to antigenic drift. Antigenic shifts are responsible for the major pandemics seen with influenza A viruses, three of which occurred in the 20th century, including the highly lethal 1918/1919 pandemic that killed tens of millions of people around the world. Pandemics do not occur with influenza B and C viruses. In fact influenza C causes a mild disease without seasonality, and influenza B causes severe disease confined to the elderly and other persons at high risk. Influenza A viruses are divided into subtypes based on the presence of different hemagglutinin (H) and neuraminidase (N) molecules on their surface. Sixteen distinct hemagglutinins and nine different neuraminidases have been described to date. Influenza viruses are among the most contagious human viruses with attack rates of 10–40% during epidemics. Epidemics are seasonal (winter) in temperate regions and can occur year round in tropical areas. Since the last influenza pandemic in 1968, the predominant virus circulating around the world is the H3N2 subtype that undergoes minor mutations in the H and N proteins and is responsible for yearly outbreaks. In 1977, the H1N1 virus (the same subtype that was responsible for the 1918 pandemic) was reintroduced and is currently co-circulating with H3N2 virus. However, isolated cases of human influenza due to avian viruses such as H5N1 are cause for concern among health professionals around the world because of the high lethality and the possibility that development of efficient

TABLE 1.1 Infectious diseases with agents identified since "The end of the war against infectious diseases" 1967–2004

Year	Agent	Disease
1967	Marburg virus	Marburg hemorrhagic fever
1969	Lassa virus	Lassa fever
1971	JC virus	Progressive multifocal leukoencephalopathy
1972	Norovirus	Norwalk diarrheal illness
1973	Rotavirus	Major cause of infantile diarrhea worldwide
1975	Parvovirus B19	Fifth disease; aplastic crisis in chronic hemolytic anemia; hydrops fetalis; chronic anemia of immunosuppressed patient
1976	*Vibrio vulnificus*	Sepsis and necrotizing fasciitis
1976	*Cryptosporidium parvum*	Human cryptosporidiosis
1977	Ebola virus	Ebola hemorrhagic fever
1977	*Clostridium difficile*	Pseudomembranous colitis
1977	*Legionella pneumophila*	Legionnaires' disease, Pontiac fever
1977	Hantaan virus	Hemorrhagic fever with renal syndrome
1977	Delta viral hepatitis	Hepatitis B virus-associated hepatitis
1977	*Campylobacter* sp.	Enteric pathogens distributed globally
1979	*Cyclospora cayetanensis*	Diarrheal illness
1980	HTLV-I	T-cell lymphoma-leukemia; tropical spastic paresis
1981	*Staphylococcus aureus* toxin	Toxic shock syndrome
1982	*Borrelia burgdorferi*	Lyme disease
1982	*Escherichia coli* 0157:H7	Hemorrhagic diarrhea, hemolytic uremic syndrome
1982	HTLV-II	Associated with neurologic syndromes
1983	HIV-1	AIDS
1983	*Helicobacter pylori*	Gastric and duodenal ulcers
1984	*Hemophilus influenzae aegyptius*	Brazilian purpuric fever
1985	*Enterocytozoon bieneusi*	Microsporidiosis
1986	*Chlamydia pneumoniae*	A major cause of pneumonia
1988	Human herpesvirus 6	Exanthem subitum (roseola infantum)
1989	*Rickettsia japonica*	Japanese spotted fever
1989	Hepatitis C virus	Parenterally transmitted nonA–nonB hepatitis
1990	Hepatitis E virus	Enteric nonA, nonB hepatitis
1990	*Balamuthia mandrillaris*	Leptomyxid amebic meningoencephalitis
1990	Human herpesvirus 7	Another cause of exanthem subitum
1991	Guanarito virus	Venezuelan arenaviral hemorrhagic fever
1991	*Encephalitozoon hellem*	Microsporidiosis
1991	*Ehrlichia chaffeensis*	Human monocytotropic ehrlichiosis
1992	Barmah Forest virus	Febrile polyarthralgia
1992	*Vibrio cholerae* 0139	New strain associated with epidemic cholera
1992	*Bartonella henselae*	Cat scratch disease; bacillary angiomatosis; endocarditis
1992	*Rickettsia honei*	Flinders Island spotted fever
1992	*Tropheryma whippelii*	Whipple's disease
1993	Sin Nombre hantavirus	Hantavirus cardiopulmonary syndrome
1994	*Anaplasma phagocytophilum*	Human granulocytic anaplasmosis
1994	Hendra virus	Acute respiratory syndrome, meningitis
1996	Human herpesvirus 8	Kaposi's sarcoma, Castleman's disease, primary effusion based B-cell lyphoma

(*Continued*)

TABLE 1.1 (Continued)

Year	Agent	Disease
1997	*Rickettsia slovaca*	Tick-borne lymphadenopathy
1999	*Ehrlichia ewingii*	Ehrlichiosis ewingii
1999	Nipah virus	Encephalitis
2001	Human metapneumovirus	Upper and lower respiratory infections
2003	SARS-CoV	Severe acute respiratory syndrome (SARS)
2004	Monkeypox virus	Human monkeypox (USA outbreak)

person-to-person transmission could trigger another pandemic. The first case of human influenza due to H5N1 was described in 1997, and the infection re-emerged in Southeast Asia in 2004. Death rates in domestic birds in Southeast Asia are staggering. Other avian influenza viruses have also emerged in other parts of the world such as H7N7 in the Netherlands causing an outbreak of hemorrhagic conjunctivitis in humans. Influenza A viruses are capable of infecting a wide variety of animals including birds, horses, marine mammals, swine, and humans. The most important reservoir is wild aquatic birds (water fowl, ducks, and shorebirds). These animals can carry different subtypes in their gut, and some viruses are capable of infecting domestic poultry. The ability of avian influenza viruses to infect humans is rather restricted as is the ability for transmission from person-to-person. Because of their segmented genomes, influenza A viruses have the potential to swap or reassort genes when present in the same host or "mixing vessel" such as pigs (these animals have cell surface receptors that allow cellular entry of both bird and human influenza viruses). If the favorable environmental conditions are present, human influenza viruses can coexist with avian viruses in pigs, and new reassortants may be produced with potentially enhanced ability to infect humans.

Clinically, the human disease manifests as a severe febrile illness with abrupt onset, myalgias, severe malaise, dry cough, arthralgias and nasal discharge. Most patients recover from the acute phase of the disease in 3–5 days. Complications include primary influenza viral pneumonitis, which was first well documented in the 1957–1958 pandemic. However, it is widely accepted that this and bacterial superinfections were the causes of death of millions of persons in the 1918 pandemic. These patients progress to acute respiratory failure rapidly, and the main pathologic finding is that of diffuse alveolar damage with a hemorrhagic component. Other complications include secondary bacterial pneumonias.

Severe Acute Respiratory Syndrome (SARS)

An explosive outbreak of severe adult respiratory distress syndrome (ARDS) occurred in residents of Hong Kong and persons who had visited Hong Kong early in 2003. A cluster of cases that had started in November 2002 also occurred in the Guangdong Province of China. After a few months of excellent "detective" work by health agencies and research laboratories worldwide, a new coronavirus was identified as the culprit. Between November 2002 and July 2003, 8096 cases were reported from nearly 30 countries, but the vast majority of cases occurred in mainland China and Hong Kong. The case-fatality rate was between 7 and 17% and approached 50% in the elderly. High mortality rates were also observed in patients with preexisting conditions such as diabetes and cardiopulmonary diseases.

An animal reservoir for SARS-CoV appears likely to be bats, but the virus also has been isolated from civet cats and other wild animals in markets in China where cross-species infections may have occurred. Other coronaviruses in humans have cyclical patterns of circulation. It is suspected that SARS-CoV could reappear in humans. In severe cases, the main finding is diffuse alveolar damage leading to acute respiratory insufficiency. In milder cases, fever, malaise and mylagia are the main manifestations.

Human Metapneumovirus

This viral pathogen was first identified in 2001 in an outbreak of upper and lower respiratory illness in the Netherlands. The agent is a paramyxovirus, subfamily Pneumovirinae in which two genera have been established: Pneumovirus (respiratory syncytial virus, RSV) and Metapneumovirus. The disease spectrum is not completely known but can manifest as severe upper and lower respiratory infections in children and adults especially in patients with previous cardiopulmonary conditions. The disease is similar to RSV

infection and can account for up to 10% of acute upper respiratory tract infections in which another etiologic agent has not been identified. Asthmatic exacerbations have also been related to metapneumovirus infections. Retrospective serological studies have established that this virus has been circulating in humans for at least 50 years.

Hantavirus Cardiopulmonary Syndrome (HCPS)

Sin Nombre virus (SNV) was the first hantavirus in the Americas associated with HCPS. The disease was first described in an outbreak in the Four Corners area of the southwestern US in 1993. SNV belongs to the genus Hantavirus within the family Bunyaviridae. The vast majority of viruses within this family are arthropod-borne zoonoses, with the exception of hantaviruses, which are not vector-borne. Hantaviruses are found in wild rodents, which excrete the virus in urine and saliva for months. SNV is the most important pathogenic hantavirus in North America and causes chronic infections in deer mice (*Peromyscus maniculatus*). In North America, other viruses within the same genus associated with HCPS have been described such as New York virus found in the white footed deer mouse (*Peromyscus leucopus*). In South America, the main representative of the genus is Andes virus, which is responsible for HCPS in Chile and Argentina, and is the only hantavirus for which human-to-human transmission has been documented. In 1978, another hantavirus associated with hemorrhagic fever and renal syndrome (HFRS) in the Korean peninsula was isolated. This infection is endemic across the Asian continent.

The main mode of transmission is through aerosol spread of infected excreta (urine and possibly feces) and less frequently by bites of infected rodents. HCPS is an explosive febrile illness accompanied by myalgias and sometimes abdominal pain. In 4–5 days, respiratory symptoms appear and rapidly progress to severe noncardiogenic pulmonary edema with subsequent hypoxia and shock within hours. Cardiac dysfunction also occurs.

BACTERIAL PULMONARY SYNDROMES

Legionnaires' Disease

An outbreak of pneumonia in 1976 in Philadelphia, Pennsylvania during the state American Legion convention affected 221 people, 34 of whom died from the infection. In 1977, Dr. McDade and Dr. Shepard at the CDC isolated the etiologic agent, a fastidious gram negative organism later named *Legionella pneumophila*. This bacterium has been responsible for subsequent epidemics and sporadic cases, and retrospective studies determined that it had been responsible for outbreaks of pneumonia in the 1950s and 1960s. *Legionella* species are naturally occurring aquatic bacteria that grow in warm water, especially in cooling towers, water heaters and plumbing, hence the propensity to cause nosocomial and community outbreaks (hotels and other facilities). Free-living amebas also support the intracellular growth of *Legionella spp.* More than 20 *Legionella* species have been described affecting humans, thus the general name of legionellosis.

The disease occurs both sporadically (65–75% of cases) and in outbreaks or epidemics. Recent epidemics have occurred in Spain (2001, 700 cases), England (2002, 130 cases), and the Netherlands (1999, 188 cases).

Transmission is by aerosolization of contaminated water sources. Once in the alveoli of the lung, the bacteria are phagocytosed by alveolar macrophages through coiling phagocytosis, and multiplication occurs. The bacteria are then released into the alveolar space by dying macrophages where they can invade other alveolar macrophages. A type IV secretion system is important in promoting intracellular infection including inhibition of phagolysosomal fusion. The lungs reveal patchy-to-confluent bronchopneumonia that may be complicated by pleural effusions or cavitation in a minority of cases. Extrapulmonary infection is rare.

Tuberculosis

Tuberculosis (TB) is as old as civilization itself as demonstrated by evidence of spinal tuberculosis in Egyptian mummies and Neolithic and pre-Columbian bones. However, tuberculosis did not become a major public health problem until the 17th and 18th centuries during the Industrial Revolution. Tuberculosis also ravaged (and still does) the native American populations after Columbus' voyages to the Americas. In the United States, tuberculosis saw a steady decline in the middle part of the 20th century until 1985 when the incidence climbed again principally due to the appearance of HIV. Other factors included deterioration of living conditions, intravenous drug abuse, and underfunding of tuberculosis control programs. However, since the mid-1990s rates have declined and in 2002 reached the lowest incidence in history from the time statistics became available. This control is the result of better anti-HIV therapies, intensified diagnosis, aggressive and monitored anti-TB treatment and prevention efforts. However, not all is good news in

the TB world. The appearance of multidrug resistant strains of *M. tuberculosis* is a challenge recalling the preantibiotic era. In addition, *M. tuberculosis* is the number one killer worldwide (2 million deaths and 8 million new cases diagnosed each year), and approximately 2 billion people are infected.

More than 95% of infections caused by *M. tuberculosis* are acquired by inhalation of aerosols generated from an infectious patient. The initial focus of infection (Gohn's lesion) later develops into Gohn's complex (accompanying infected draining hilar lymph node lesions), and in most cases the infection is contained by the immune system. In the most severe cases, the infection disseminates hematogenously in the lungs and/or systemically leading to miliary tuberculosis. Individuals who control the primary infection may undergo reactivation of the latent infection due to multiple factors including AIDS, malnourishment, alcoholism, and cancer. In these cases, reactivation can involve the lungs (cavitary, endobronchial, pneumonic, and/or bronchopneumonic) and other organs including the spleen, liver, bone marrow, kidneys, CNS, and bones. Primary and secondary mycobacterial resistance to antituberculosis medication in certain subpopulations in New York City and California makes tuberculosis a public health priority. Recent trends have shown that the percentage of isolates with resistance to antituberculosis drugs is decreasing due to vigorous public health efforts.

Viral Hemorrhagic Fevers (VHF)

It is estimated that 75% of EIDs in humans originate in animals, and VHFs are remarkable examples. The etiologic agents of this syndrome are a heterogenous group of RNA viruses belonging to three families, namely filoviruses (Ebola and Marburg viruses), arenaviruses (Lassa, Junin, Machupo, Guanarito, and Sabia viruses), and bunyaviruses (Crimean-Congo hemorrhagic fever and Rift Valley fever (RVF) viruses).

All these viruses have limited geographic ranges due to their specific natural reservoirs and vectors. In all cases, humans are accidental hosts. Pathogenetically, all VHFs lead to dramatically increased vascular permeability systemically with a hemorrhagic diathesis and edema in multiple organ systems, including the lungs and brain. These diseases all occur in localized outbreaks usually with very high case-fatality rates. Clinically, subtle differences exist between the syndromes such as more prominent hemorrhagic manifestations and terminal disseminated intravascular coagulation (DIC) in infections caused by filoviruses and CCHF, and prominent CNS and hemorrhagic manifestations in infections by the New World arenaviruses (Junin, Machupo, Sabia, and Guanarito), and prominent liver disease in RVF.

Rift Valley Fever

This is a mosquito-borne viral disease that affects newborn ruminants, especially sheep. Other affected animals include lambs, calves, goats, kittens, mice, and hamsters. The virus was first isolated in 1930 from sheep in Kenya, and the known distribution was limited to the African continent for decades. However, in 2000, a large epidemic in the Arabian peninsula led to high case-fatality ratios in humans, which had usually been around 5% in previous epidemics. Complications include hepatorenal failure, encephalitis and DIC leading to shock and multiorgan failure. The vector range for the virus is impressive and includes at least 30 species of mosquitoes in eight genera. Transovarial transmission occurs in the mosquitoes. Most outbreaks are related to climatic events that favor floods leading to increased vector populations. Outbreaks in Africa, besides the original one in Kenya, have occurred in Egypt (Aswan Dam construction), Mauritania in 1987 (Diama Dam construction), Kenya and Somalia in 1997–1998 (increased rainfall due to El Niño oscillation), and Kenya in 2007.

Ebola Hemorrhagic Fever (EHF)

Close to 20 outbreaks have occurred in Africa since Ebola virus was identified in 1976 in central Africa. The reservoir has been elusive although human outbreaks are usually preceded by severe primate die-offs. Recent studies of animals in the areas of primate mortality have identified bats as a likely reservoir host. Primary mechanisms of transmission from nonhuman primates to humans include contact with dead carcasses or handling or consumption of bushmeat. The virus has also been linked to lethal outbreaks in duikers, a wild ruminant. Other factors associated with EHF outbreaks include increases in rainfall. The viruses are rather stable genetically, since isolates obtained 20 years apart have limited genetic variation. The disease is rapidly progressive and leads to hemorrhagic manifestations very quickly.

South American Hemorrhagic Fevers

South American hemorrhagic fevers (HF) are caused by arenaviruses whose geographic distribution is limited. Most arenaviruses in Africa and the Americas do not cause human disease. Rodents develop a chronic infection that is most times asymptomatic but with

persistent viremia that can be lifelong. Vertical transmission occurs in mice. Both New World and Old World arenaviruses display a high specificity for their particular host. In the New World, reservoir rodents belong to the family Muridae, subfamily Sigmodontinae (rats and mice). Human infections occur via inhalation of aerosol particles containing infected urine from rodents. Ecologic factors associated with the emergence of these viruses as human pathogens include factors leading to increased rodent populations and increased contact between humans and rodents, e.g., deforestation and encroachment of farming into these areas. Human-to-human transmission is rare but can occur through contact with infected body fluids.

The New World viruses belong to the Tacaribe complex and include Junin (Argentine HF), Machupo (Bolivian HF), and Guanarito (Venezuelan HF) viruses. Few cases of HF due to Sabia virus (including two laboratory infections) have been described in Brazil, but the disease spectrum is largely unknown. Severe systemic disease with hemorrhage and prominent neurologic manifestations are the rule.

Dengue Fever

Dengue virus has been responsible for outbreaks of acute febrile illness (break-bone fever) in the tropics, and for the last 25 years, geographic expansion has occurred due to multiple environmental factors. In the United States, two large outbreaks occurred in Florida (1934) and New Orleans (1945). Four distinct dengue virus species are currently recognized, and the main vector is *Aedes aegypti*. The current geographic distribution ranges between 35° of latitude north and south. A prominent resurgence of dengue virus infections has occurred in the Caribbean basin, where the vector had been eradicated because of extensive campaigns against yellow fever. However, *A. aegypti* was reintroduced to the area, and large outbreaks of dengue fever (DF) and dengue hemorrhagic fever (DHF) have occurred in Cuba, Venezuela, Colombia, Central American countries, Mexico, and the Caribbean islands. A portion of dengue viral infections develop a life-threatening hemorrhagic fever.

EMERGING ENCEPHALITIC SYNDROMES

Nipah Virus Infection

This agent is a recently discovered paramyxovirus that, along with Hendra virus, comprises a new genus (*Henipavirus*) in the family Paramyxoviridae. In 1999, an outbreak of an acute febrile encephalitic syndrome in Malaysia was traced to Nipah virus. The epidemic was preceded by an epizootic of severe respiratory disease in pigs that was terminated after epidemiological control measures were instituted, including the culling of millions of pigs. A total of 283 cases of human encephalitis were diagnosed with a case-fatality rate close to 40%. A relapsing/remitting neurologic syndrome has also been associated with Nipah virus. A subsequent outbreak occurred in Bangladesh, but swine were not associated with this event, suggesting different ecological factors. The natural reservoir is thought to be fruit bats of the *Pteropus* genus. Other animals such as dogs, cats, and horses could also serve as hosts.

Hendra virus was first described in 1994 in Australia during a highly lethal epidemic of acute respiratory disease in horses. The only two human cases that have been associated with Hendra viruses manifested as acute respiratory syndrome and leptomeningitis, respectively. Both cases were fatal. The natural reservoir for Hendra virus is the fruit bat.

West Nile Virus (WNV) Infection

WNV was first isolated from humans in 1939 in Uganda and remained limited to the Middle East, Eastern Europe, and Africa until 1999, when an outbreak occurred in New York. By 2002, WNV spread across North America to the west coast, and annual outbreaks are now the rule. In 2002 and 2003, approximately 4000 and 9000 (case definition was modified in 2003) cases occurred, respectively, leading to CNS disease in 3000 and 2700 cases each year, respectively. Previous outbreaks of West Nile fever have occurred in Israel (1957), South Africa (1974), Algeria (1994), Tunisia (1997), and Congo (1998). WNV circulates enzootically between birds and mosquitoes. At least 300 species of birds and 62 species of mosquitoes can be infected by WNV. Most susceptible birds are the *Corvidae* (blue jays and crows), and the most important mosquito in the enzootic cycle is *Culex pipiens*. Humans and horses are dead-end hosts, both developing febrile and/or encephalitic syndromes. Other forms of transmission are through transplanted organs, transfusion, and breast milk. In fact, blood testing by PCR is now a component of the screening process for donated blood.

Prion Diseases (Transmissible Neurodegenerative Diseases)

Initially known as "atypically slow infections" (Sigurdsson, 1954), the concept of prion (proteinaceous

infectious agents) was first introduced by Prussiner in 1982. Currently a prion is known as "a small infectious pathogen that contains protein and is resistant to procedures that modify or hydrolyze nucleic acids." The pathogenesis of these diseases involves the generation and accumulation of abnormal prion protein from a normal isoform. The common denominator in these diseases in the presence of progressive neuronal degeneration (incubation periods measured in years or decades) accompanied by reactive astrocytosis and absence of inflammation. In most cases, prominent vacuolation of cells or neuropil is observed microscopically. Accumulation of abnormal prions in CNS tissue is present in all cases.

In humans, prions are responsible for several diseases of which Creutzfeldt–Jakob disease (CJD) and its new variant (linked to "mad cow disease" or bovine spongiform encephalopathy) are the most common. Other diseases include kuru, familial fatal insomnia (FFI), and Gerstmann–Straussler–Scheinker syndrome (GSS). CJD has several forms including sporadic (source of infection unknown), familial (mutations in the PrP gene), and iatrogenic (cadaveric grafts from patients with CJD). Kuru was related to anthropophagic practices in isolated tribes in Papua New Guinea, and new variant CJD has been linked to BSE. GSS and FFI are due to genetic mutations in the PrP gene in most cases.

ARTHROPOD TRANSMITTED BACTERIAL DISEASES

Lyme Borreliosis (Lyme Disease)

Lyme borreliosis is a zoonosis transmitted by hard ticks of the genus *Ixodes*. The vector in the eastern United States is *Ixodes scapularis* and in the western United States is *Ixodes pacificus*. *Ixodes ricinus* is the vector in Europe whereas *Ixodes persulcatus* is the vector in Russia and northern Asia. *B. burgdorferi* sensu lato includes *Borrelia burgdorferi* sensu stricto, *B. afzelii*, and *B. garinii*. The latter two are responsible for most cases of Lyme borreliosis in Europe, Russia, and northern Asia. Lyme disease has not been documented in tropical areas. The main hosts of *B. burgdorferi* in nature are rodents. Larval forms of ticks acquire the infection from small mammals, and the spirochetes are transmitted transtadially to nymphal and adult ticks. Human infections usually occur secondarily to nymph bites that go unnoticed very easily due to their small size.

Lyme borreliosis is a disease with an acute phase characterized by erythema migrans and nonspecific symptoms such as fever, headaches, myalgias, and arthralgias. The chronic phase (weeks to years) is characterized by oligoarthritis, central and peripheral nervous system sequelae, myocarditis, and other manifestations.

Rickettsioses

Rickettsia are obligately intracellular bacteria with a gram negative cell wall and a characteristic lipopolysaccharide. Their main target is the microvascular endothelium and different cells in their arthropod host/vector (fleas, ticks, lice, mites). Spotted fever group rickettsiae (with the exception of *Rickettsia felis* [fleas] and *Rickettsia akari* [mites]) are transmitted transovarially and transstadially in their tick vector and circulate in nature via small mammals. Fleas and lice host typhus group rickettsiae although they do not transmit the infection vertically to their offspring.

Newly described rickettsioses include *Rickettsia africae* (African tick bite fever), a closely related agent named *Rickettsia parkeri* (clusters of a relatively mild febrile disease in North and South America), *Rickettsia slovaca* (tick-borne lymphadenopathy or DEBONEL [*Dermacentor*-borne necrosis, eschar, lymphadenopathy]), *R. felis* (flea-borne spotted fever), *Rickettsia honei* (Flinders Island spotted fever), and *Rickettsia japonica* (Japanese spotted fever). The geographic distribution of these agents continues to expand. In fact, the distribution of organisms that appear to be variants of *R. japonica* now includes China and Korea. *R. honei* has been described in Thailand, and *R. felis* is probably distributed worldwide.

Ehrlichioses and Anaplasmosis

Obligately intracellular bacteria in the family Anaplasmataceae, which are related to the genus *Rickettsia*, include four human pathogens, *Ehrlichia chaffeensis* (human monocytotropic ehrlichiosis, HME), *Anaplasma phagocytophilum* (human granulocytotropic anaplasmosis, HGA), *Ehrlichia ewingii* (ehrlichiosis ewingii), and *Neorickettsia sennetsu* (mononucleosis-like illness in Japan). *N. sennetsu* is limited geographically to Japan, and its trematode host cycle differs greatly from the other pathogens in this family. The other three agents are tick-borne and have been considered until recently as veterinary pathogens. HME was first described in 1987, followed by HGA in 1994 and ehrlichiosis ewingii in 1999.

HME is predominantly transmitted by *Amblyomma americanum* ticks, and its main mammal reservoir in nature is the white-tailed deer (*Odocoileus virginianus*). Patients develop a febrile illness after a nymphal or

adult tick bite accompanied by headache, myalgias, malaise, and other nonspecific symptoms. A maculopapular skin rash is present in only 30–40% of cases. Common laboratory findings are the presence of leukopenia and/or thrombocytopenia during the acute phase of the disease. Complications include meningoencephalitis, hepatitis, and diffuse alveolar damage.

HGA is transmitted by *I. scapularis* ticks in the eastern United States and *I. ricinus* in Europe. The clinical picture is similar to HME although the case-fatality ratio and complications are less severe. The target cell of *A. phagocytophilum* is the polymorphonuclear neutrophil as compared with monocytes and macrophages for *E. chaffeensis*. The main reservoir in the eastern United States is the white footed mouse.

Ehrlichiosis ewingii caused by *E. ewingii* is the least known of the human ehrlichioses. It is transmitted by the same vector tick as *E. chaffeensis* and has a milder course. The target cell is the neutrophil. The majority of cases have been diagnosed in immunocompromised patients.

Scrub Typhus

A disease that ravaged American troops in the Pacific and Southeastern Asia during World War II is re-emerging in southern India, Sri Lanka, the Maldives, and Micronesia. The agent is *Orientia tsutsugamushi*, an obligately intracellular bacterium formerly known as *R.ickettsia tsutsugamushi*. The disease is transmitted by chiggers in their larval stage and occurs mostly in tropical Asia, the western Pacific islands, northern Australia, and temperate zones in Kashmir, Korea, Japan, and the lower Himalayas. In nature, wild rats maintain the chigger population (*Leptotrombidium* spp.), and *Orientia* is transmitted transovarially and transstadially. However, rats are not reservoirs for *O. tsutsugamushi*.

The disease is characterized by fever, headache, malaise, and a variable incidence of eschar formation at the bite site, lymphadenopathy, and a transient maculopapular rash. Severe manifestations include diffuse alveolar damage and meningoencephalitis. Poor responses to conventional treatments (tetracyclines and chloramphenicol) have been described in Thailand.

Bartonelloses

The genus *Bartonella* contains five recognized human pathogens: *B. bacilliformis* (Oroya fever and verruga peruana transmitted by sandflies of the genus *Lutzomyia*), *B. quintana* (trench fever, bacillary angiomatosis, and endocarditis transmitted by the human body louse, *Pediculus humanus corporis*), *B. henselae* (cat scratch disease, bacillary angiomatosis, and endocarditis transmitted by cat fleas and cats), and *B. elizabethae* and *B. vinsonii* (endocarditis, transmitted possibly by fleas and ticks).

The reservoir host for *B. bacilliformis* is humans who reside in endemic areas in Peru, Ecuador, and Colombia. Clinically the disease has an acute phase in which the main manifestation is severe hemolytic anemia followed by a chronic phase in which lesions composed of prominent capillary proliferations are present on the skin.

Trench fever affected millions of soldiers during World Wars I and II, and infections continue to be diagnosed worldwide especially in patients with HIV or malnourished, homeless alcoholics.

The feline ectoparasite flea *Ctenocephalides felis* is the vector of *B. henselae,* and humans acquire infection from contact with flea-infested cats. Endocarditis is a serious form of infection that can occur with *B. quintana*, *B. henselae*, *B. elizabethae*, and *B. vinsonii*. The epidemiology of the latter two infections is largely unknown.

EMERGING ENTERIC PATHOGENS

Cholera

Vibrio spp. are gram negative, oxidase positive, free-living bacteria found in warm, salty waters around the world. In these places, *Vibrio* is usually isolated from shellfish, and their concentration in the tissue is far greater than in the surrounding waters. *Vibrio cholerae*, *Vibrio vulnificus*, and *Vibrio parahemolyticus* are all associated with acute enteric infections in humans although the only one causing epidemics or pandemics is *V. cholerae*. The latter two are also associated with wound infections in warm salty waters or ingestion of raw shellfish with involvement of subcutaneous tissue and skeletal muscle and septicemia. Infections caused by *V. parahemolyticus* and *V. vulnificus* are more severe in immunocompromised patients and in persons with underlying diseases such as cirrhosis, hemochromatosis, and diabetes.

V. cholerae is classified by O antigens (>150), biotypes (classical and El Tor), and serotypes (Ogawa, Inaba). Six of the seven pandemics since the 19th century have originated in the Bengal basin, and the seventh pandemic began in 1961 in Indonesia. In 1991 this pandemic extended to Peru and other countries on the South American Pacific coast. In the US, the rare cholera cases have been linked to consumption of raw oysters or undercooked crab. All cases of *V. cholerae* infection were caused by O1 strains, but since

1992, 0139 strain has been isolated from clinical cases of cholera in the Indian subcontinent. Other non-O1 serogroups are sporadically associated with acute gastroenteritis around the world.

The majority of people infected with *V. cholerae* are asymptomatic or mildly ill (75% for the classical biotype and 93% for El Tor biotype). Presentation of the classic illness is explosive after a short incubation period (12 h–5 days) and consists of abundant watery diarrhea that leads to dehydration and circulatory collapse if not treated promptly.

Nontyphoidal Salmonelloses

In the United States, infections caused by nontyphoidal *Salmonella* spp. affect 1.4 million/year and kill approximately 600/year. Most patients are mildly symptomatic or asymptomatic. *Salmonella* are gram negative bacilli, nonlactose fermentors. The classification and nomenclature are extremely complex, but phylogenetic studies based on DNA sequencing reveal that *Salmonella* spp. associated with human illness are considered *Salmonella choleraesuis*, which has approximately 2500 serotypes including Typhimurium and Typhi. The name *Salmonella enterica* has been proposed to replace *S. choleraesuis*.

Virtually all cases of *Salmonella* infection are foodborne and are second only to enteric infections caused by *Campylobacter* spp. in the US. Foods associated with outbreaks in the US include undercooked ground beef, eggs, cheese, ice cream, fresh sprouts, juice, and other vegetables.

Clinical syndromes in nontyphoidal salmonellosis include gastroenteritis, bacteremia/septicemia with or without distant focal infections (infectious endarteritis in arteries with large atherosclerotic plaques, septic arthritis, and endocarditis) and asymptomatic carriage. Patients with immunosuppression of any etiology are at greater risk for systemic illness than immunocompetent patients.

Antimicrobial resistance (ampicillin, tetracyclines, chloramphenicol, streptomycin, and sulfonamides) in nontyphoidal salmonellosis is spreading throughout the world due to a specific phage infecting *Salmonella* type Typhimurium (DT104) that first appeared in 1990. Even more recently, resistance to fluoroquinolones and third and fourth generation cephalosporins has been reported.

Shiga-toxin Producing *Escherichia coli* Infection

The first human cases due to this organism were described in 1982 during two outbreaks of hemorrhagic colitis in the US due to *E. coli* serotype O157:H7. The association of hemorrhagic gastroenteritis due to O157:H7 and hemolytic uremic syndrome (microangiopathic hemolytic anemia, acute renal failure, and thrombocytopenia) was established soon thereafter. More than 30 serotypes of *E. coli* can produce *Shigella*-like toxins, but the vast majority of cases in the US are due to serotype O157:H7. The main vehicles of transmission are contaminated food (hamburgers, uncooked vegetables, and others), water, including swimming pools, person-to-person, and animal contacts.

Clinical presentation is rapid and includes vomiting, diarrhea, and cramping. The diarrhea becomes blood-streaked after a few days. One of the main complications is hemolytic uremic syndrome, mostly in patients under 5 years of age.

Helicobacter pylori Infection

The isolation of *H. pylori* (initially classified as *Campylobacter pylori* or *pyloridis*) from a human with active gastritis represents a turning point in how the medical field views peptic ulcer disease, acute and chronic gastritis, and gastric carcinoma (especially the intestinal variant). *H. pylori* is a motile, microaerophilic, gram negative bacillus capable of surviving in the harsh environment of the human stomach due to its microaerophilicity, capacity to penetrate the mucus layer overlying the gastric mucosa, and production of ammonia from urea via urease to neutralize the low pH in the environment. *H. pylori* infections seem to be limited to humans, but other *Helicobacter* spp. have been isolated from almost every mammal studied. Rates of infection in human populations are very high (in developing countries up to 70% by age 10 and nearly 100% by age 20), but clinical disease is not always apparent. Therefore, microbial and host factors are important in pathogenicity. The so-called *cag* pathogenicity island, the *vacA* gene, and their polymorphisms seem to play important roles in pathogenesis.

Human infections have been present for thousands of years based on studies of *H. pylori* alleles and human migrations. Once infection is acquired it persists for years or decades. Clinical syndromes associated with *H. pylori* infection include chronic diffuse superficial gastritis, intestinal metaplasia and atrophic gastritis, peptic, especially duodenal, ulcers (cagA-containing organisms), noncardiac gastric adenocarcinoma (cagA-containing bacteria), and gastric MALT-type B-cell lymphomas.

Cryptosporidiosis

Crysptosporidium parvum is a protozoan in the phylum Apicomplexa, class Sporozoae, subclass Coccidia.

Recent molecular studies have shown that *C. parvum* (the species thought to cause most human infections) contains various genotypes. In humans two genotypes cause infection: bovine and human genotypes. The name *Crysptosporidium hominis* has been proposed for the human genotype. The first human case was described in 1976, and the first outbreak of cryptosporidiosis in the US was documented in 1987 in Carroll County, GA where an estimated 13,000 cases of gastroenteritis were diagnosed. The largest reported outbreak occurred in Milwaukee, WI where there were an estimated 403,000 cases in 1993. *Cryptosporidium* has been described throughout the world. Infection occurs via the fecal–oral route mostly by ingestion of contaminated water. The infectious thick walled oocysts are resistant to chlorination and survive in moist environments for long periods of time. The cycle is completed in the same host, and multiplication is both sexual and asexual. Once inside the host, *Cryptosporidium* organisms invade the microvillous surface of the epithelial cells in the terminal ileum and proximal colon leading to self-limited watery diarrhea in immunocompetent patients and chronic/persistent diarrhea in immunocompromised patients (especially with AIDS).

Microsporidioses

Phylum Microsporidia are spore-forming, obligate intracellular protozoans that reside in the intestine, liver, kidneys, brain, and other tissues of wild and domesticated mammals and several other animal species. Eight genera out of more than 144 (containing more than 1000 species) have been documented as human pathogens which include *Encephalitozoon*, *Enterocytozoon*, *Pleistophora*, *Brachiola*, *Nosema*, *Trachipleistophora*, *Vittaforma*, and *Microsporidium*. The two most common species involved in humans are *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis*. Microsporidioses, in general, are rare diseases in humans that have received attention due to the increased incidence of infections present in patients with AIDS.

Clinical syndromes in immunocompetent patients consist of self-limited diarrhea, ocular infections (keratitis), and meningoencephalitis. In immunocompromised patients (especially with AIDS), persistent watery diarrhea is the most common presentation. Severe CNS infections and disseminated infections have also been described including hepatitis, peritonitis, nephritis, and pneumonitis.

OTHER EMERGING BACTERIAL PATHOGENS

Diphtheria

Disease caused by infection with *Corynebacterium diphtheriae*, a gram positive, pleomorphic bacterium that was kept under good control in most parts of the world until 1990, re-emerged in the form of large epidemics in the former Soviet Union, extending into parts of Eastern Europe and Asia. The epidemic peaked in 1995 when 50,000 cases were reported in the Russian Federation. Vaccination lapses and disarray of the public health infrastructure are to blame for its reappearance. Humans are the only known reservoir of *C. diphtheriae,* and the primary route of spread is via respiratory droplets. Skin infection is less common. Asymptomatic pharyngeal carriers play an important role in maintaining the organisms in communities. The disease is mediated by a toxin encoded by a lysogenic phage. The toxin inhibits elongation factor 2 (EF2) in the ribosomes, thereby impairing protein synthesis. The main target organs are the nerves, heart, and kidneys. Before diphtheria was controlled in the mid-20th century, mainly infants were affected. However, in recent outbreaks young adults are more frequently affected, suggesting that infants in such populations are still somewhat protected.

Bordetella Infections

The main human pathogens in this group are *B. pertussis* (agent of whooping cough) and *B. parapertussis* (the agent of a milder form of whooping cough). Pertussis continues to be a public health problem worldwide with millions of cases reported every year. In the United States approximately 8000 cases occurred in 2002, affecting mostly adolescents and young adults. The disease seems to be largely underdiagnosed in these population groups, who are more susceptible than children because of lack of booster immunization for pertussis beyond childhood. Pertussis starts as an upper respiratory tract infection that progresses in a few days to paroxysmal cough that lasts for weeks or months. The bacterium is not invasive and remains in the respiratory tract. Secondary infections in the form of bacterial pneumonia can occur. Other complications include pneumothoraces, hernias, seizures, and otitis media.

Staphylococcus aureus Infections

This gram positive, aerobic coccus is one of the most ubiquitous microorganisms in human populations and is responsible for a wide spectrum of human diseases that range from simple skin "boils" to life-threatening generalized infections. In the last few decades, new clinical entities associated with *S. aureus* have emerged such as staphylococcal toxic shock syndrome (STSS), which is a potentially lethal disease mediated by a "superantigen" toxin (TSST-1) and is characterized by fever, hypotension, multisystem organ failure, and an erythematous rash that desquamates during recovery. TSST-1 is a nonspecific T-cell mitogen that leads to a dramatic increase of T-cells and subsequent increase in circulating cytokines. This syndrome was initially described in the setting of vaginal colonization by toxin-producing strains and use of superabsorbent tampons in 1978. This type of tampon was withdrawn from the market, and the incidence declined. However, nonmenstrual forms do exist and are associated with nasal packing, surgical wounds, and other focal *S. aureus* infections. A related condition present in neonates has been described recently in Japan and is known as neonatal toxic shock syndrome-like exanthematous disease.

Antibiotic resistance is a major problem in nosocomial infections due to *S. aureus*. Both methicillin-resistant and glycopeptide-resistant strains are a major threat in the hospital setting. *S. aureus* may be part of the normal flora, especially of the nares and skin. Other sites include the genitourinary tract, mucous membranes, GI tract, and upper respiratory tract. In fact, most infections are considered to be endogenous in origin.

Coagulase negative *Staphylococci* have also emerged as human pathogens in the setting of indwelling catheters and bioprosthetic devices. These bacteria are capable of forming extensive biofilms on inert surfaces leading to local or systemic infections.

GROUP A β-HEMOLYTIC STREPTOCOCCAL (GABHS) INFECTIONS

Streptococcus pyogenes Infections

This complex group of bacterial pathogens is responsible for a wide spectrum of infections in humans ranging from focal infections such as acute tonsillitis to the highly lethal streptococcal necrotizing fasciitis (better known as flesh-eating disease). The classification of *S. pyogenes* is based on antigenic properties and presence or absence of hemolysis on blood agar plates.

Classical diseases caused by this group of streptococci include its nonsuppurative complications (acute rheumatic fever and glomerulonephritis), tonsillitis, and scarlet fever. During the last two decades, GABHS have been associated with severe necrotizing fasciitis or streptococcal gangrene and streptococcal toxic shock syndrome. These conditions are associated with highly virulent streptococci capable of producing toxin superantigens (streptococcal pyrogenic exotoxins, SPE-A, SPE-B, and SPE-C) and other virulence factors capable of destroying host tissues. Fortunately, antibiotic resistance is not a major concern in infections caused by GABHS since the strains are still susceptible to most penicillin-related antibiotics. However, resistance to clindamycin and macrolides has been documented. Similar to *Staphylococci*, these organisms are part of the normal flora of multiple body sites including the skin, vagina, and pharynx.

Streptococcus agalactiae Infections

Group B streptococcal (*S. agalactiae*) infections have also emerged as a major cause of neonatal sepsis related to carriage of the bacterium in the vagina of pregnant women. Other conditions include focal and generalized infections in nonpregnant adults. Underlying conditions usually present in these patients are diabetes mellitus, neoplastic diseases, immobility, and chronic liver disease.

EMERGING CHRONIC VIRAL DISEASES

Acquired Immunodeficiency Syndrome

A pathogenic retrovirus infecting one of the most important cells orchestrating the acquired immune response in humans was something no scientist had in mind at the beginning of the 1980s. We now know that human immunodeficiency virus (HIV) infections were probably occurring sporadically for decades before the initial cases of HIV infection/AIDS were documented in the early 1980s. Unfortunately, HIV infection turns out to be one of the worst epidemics in modern history with more than 42 million people currently infected, most of whom live in sub-Saharan Africa (cumulative

number of cases since the epidemic began is approximately 70 million). AIDS has already claimed at least 25 million deaths around the world, and although major therapeutic advances have been made, the possibility of a vaccine or a cure remains elusive.

An evolving problem within the HIV emergence as a pathogen is viral resistance to antiretroviral drug therapy. Due to the high rates of recombination and mutation in HIV genes, drug resistance is very common in patients receiving only one anti-HIV medication. Therefore, treatment regimens usually employ multiple medications. Even so, development of resistance still occurs. Rates of resistant infections vary from 3 to 4% in Australia to 23% in some areas of the United States.

HIV infection is transmitted sexually, through exposure to infected blood (intravenous drug use and accidental exposures) or vertically from mother to fetus. Virus gains access to target cells via the interaction of viral glycoprotein gp120 and the cellular receptor CD4 and chemokine receptor CCR5, both present in macrophages and CD4+ T-cells. During the acute infection some patients develop a flu-like illness that is in some cases accompanied by a maculopapular rash. Viremia is then reduced dramatically after a few weeks by both neutralizing antibody and cytotoxic T-cells. A variable latency period then ensues and ranges from years to decades during which there is progressive deterioration of the immune system due to declining levels of CD4+ T-cells. As the population of CD4+ T-cells declines, the occurrence of opportunistic infections and certain neoplasm increases, marking the appearance of AIDS per se.

HIV-2

This virus entered human populations more recently than HIV-1 and came directly most likely from sooty mangabeys. The virus is most prevalent in west Africa. Transmission from such animals probably occurs through bites and scratches or contact with infected tissues by hunters. Viremic levels in patients with HIV-2 infections are lower than HIV-1 patients, and the proportion of nonprogressers is higher.

HTLV-I and II

HTLV-I was isolated from a patient with a T-cell leukemia/lymphoma and was the first human retrovirus that was associated with human neoplasia. A few years later, HTLV-II was isolated from a patient with hairy cell leukemia, an association that has not been observed subsequently. HTLV-I is endemic in Japan (Okinawa), East Asia, Papua New Guinea, and the Caribbean basin. Routes of infection include sexual intercourse, vertical transmission from mothers to offspring, blood transfusions, and use of contaminated needles. Typically, patients with adult T-cell lymphoma/leukemia have hypercalcemia. Tropical spastic paraparesis (Caribbean) and HTLV-associated myelopathy (Japan) are associated with both HTLV-I and HTLV-II.

Human Herpesvirus (HHV) Infections

These agents are large, enveloped, double-stranded DNA viruses that infect a wide variety of species. So far, eight herpesviruses have been associated with human illness, namely herpes simplex viruses I and II (HHV1 and 2, respectively), varicella-zoster virus (HHV3), Epstein–Barr virus (EBV or HHV4), cytomegalovirus (CMV or HHV5), human herpesvirus 6 (HHV6), human herpesvirus 7 (HHV7), and Kaposi sarcoma virus (HHV8). The common denominator for all human herpesvirus infections is lifelong latent infection. Clinical syndromes are varied. The main pathogenic mechanisms include direct cytotoxicity, immunopathologic responses, and neoplastic transformation of host cells (HHV4 and HHV8).

Hepatotropic Viruses

Well-defined viral pathogens causing acute and chronic hepatitis belong to different families including hepatitis A (Picornaviridae), hepatitis B (Hepadnaviridae), hepatitis C (Flaviviridae), and hepatitis E (Hepeviridae).

Hepatitis A is transmitted by the fecal–oral route and is a common cause of acute hepatitis in developing countries. Chronicity does not occur, and most patients recover from acute infections. In fact, the majority of patients are anicteric during the acute infection. An effective parenteral vaccine is currently available.

Hepatitis B virus currently infects more than 500 million people worldwide with the highest incidence in the Far East. Routes of transmission are varied and include vertical (prenatal and perinatal) and horizontal (unprotected sex, intravenous drug use, exposure to contaminated fluids and blood products). Infection in humans ranges from asymptomatic carriers to late complications including cirrhosis and hepatocellular carcinoma. In between, patients can develop acute and chronic hepatitis. Some patients develop extrahepatic manifestations, which are immune-mediated including glomerulonephritic syndromes, vasculitides, and

polyarthritis. An effective vaccine is available and has controlled the incidence and prevalence of hepatitis B infections in the industrialized world.

Hepatitis delta virus (HDV) is a satellite virus known as delta (δ) hepatitis virus that requires hepatitis B virus to complete its life cycle in the eukaryotic host cell. HDV replication needs HBsAg for packaging of the HDV genome. The exact classification of the virus remains elusive, but it is related to viroids, plant satellite viruses, and simple infectious RNA molecules. The current classification is that of Deltaviridae family. Infection with HDV occurs either as a co-infection with HBV or a superinfection in a patient already infected with HBV. When both viruses are present, the risk of severe disease is fourfold when compared to patients infected with HBV alone. The spectrum of disease ranges from asymptomatic to end-stage liver disease (cirrhosis). In addition, superinfected patients are at higher risk for developing fulminant acute hepatitis.

Hepatitis C virus is an enveloped, positive-stranded RNA virus that has become one of the leading causes of chronic hepatitis, cirrhosis and hepatocellular carcinoma in the world. The virus has recently been cultivated in cell lines in vitro, and animal models of infection are available. A sensitive diagnostic test based on antibody detection in serum and RT-PCR detection of the viral RNA revolutionized diagnosis of hepatitis C infection during the mid- to late-1990s. Most cases develop chronicity leading in many patients to subsequent fibrosis, cirrhosis, and an increased risk of hepatocellular carcinoma. However, even among patients with chronic hepatitis C viral infections, only 5–20% develop cirrhosis. Clearly, several host and viral factors are in play. Consumption of alcohol is a synergistic factor in developing complications such as cirrhosis. Other factors include viral genotype, HIV co-infection and HLA phenotypes. Transmission is through percutaneous exposure and transfusion of contaminated blood products, although the latter is rare in countries where blood products are tightly regulated. Sexual and vertical transmission is rare. Current estimates suggest that the virus has infected 170 million people worldwide and close to 4 million persons in the US.

Hepatitis E virus is responsible for enteric non-A, non-B hepatitis epidemics in developing countries (especially in Southeast and Central Asia, Middle East, and North Africa). Outbreaks have also been described in Mexico. However, infections are mostly endemic. The disease is transmitted through the fecal–oral route, and the disease is a self-limited acute hepatitis with no known chronicity. In pregnant women, the incidence of fulminant hepatitis is high. HEV is a non-enveloped, single-stranded, positive-sense RNA virus, formerly known as enterically transmitted non-A, non-B hepatitis virus. The viral genome was cloned in 1990. Morphologically, the closest related viruses are those of the family Caliciviridae. However, the genomic organization is closer to the rubella virus which is in the family Togaviridae genus *Alphavirus*.

BIOTERRORISM AS A MECHANISM OF EMERGENCE OF INFECTIOUS DISEASE

For most potential bioterror agents such as *Bacillus anthracis*, humans are a dead-end host. However, some viruses and bacteria that are considered in the high priority categories for use in bioterrorism have the capability for establishment in the human population via person-to-person transmission or in zoonotic cycles. These diseases could spread widely geographically and affect many persons, creating public terror as the perpetrators intended. Although smallpox was eradicated nearly 30 years ago, Soviet scientists in the mammoth Biopreparat program weaponized variola virus and produced tons of the agent. If even a single person were infected with smallpox by a terrorist, there would be the potential for widespread transmission around the world where vaccination ceased decades ago. The outcome of re-establishment of a viral agent that is transmitted from person-to-person by aerosol and small droplet spread is evident in the reintroduction of influenzavirus A H1N1, the origin of which some sources attribute to release from a Russian laboratory. This virus that had ceased to circulate after the H2N2 influenzavirus A pandemic in the late 1950s is now co-circulating with the 1968 pandemic H3N2 influenzavirus A. Intentional release of agents capable of person-to-person transmission could result in their emergence or re-emergence.

The potential for establishment of an agent introduced into widely geographically dispersed zoonotic cycles from which transmission to humans occurs is exemplified by the events after the appearance of WNV in New York City in 1999. Although there is no evidence that WNV was introduced into the US by a terrorist, it could have been done, and there are other potential bioterror agents that could be brought to the US and become established in expanding zoonotic cycles. These include other mosquito-borne viruses such as RVF virus and Venezuelan equine encephalitis virus. These would threaten both domestic animals and humans. Other agents of bioterror such as foot and mouth disease virus or *Ehrlichia ruminantium* could target our food animals and ruin our livestock

industry. Food and mouth disease and heartwater do not occur in the US, and their establishment would be catastrophic, particularly if wild ruminants became reservoirs of infection.

The recent occurrence of global SARS and domestic monkeypox epidemics demonstrate the capacity of EIDs to be used in the future for bioterrorism. These viruses exist in natural cycles in Southeast Asia and Central and West Africa, respectively. SARS-coronavirus is a particularly serious threat because of person-to-person spread and significant mortality. Strains of monkeypox virus from Central Africa also cause significant mortality, and the danger of its intentional establishment in a wildlife reservoir such as prairie dogs would create prolonged terror. Thus, EID agents could be used for bioterrorism, and agents of bioterror could become emerging infections.

RATIONALE FOR VACCINES AGAINST EMERGING INFECTIOUS DISEASES

The rationale for not developing vaccines against EIDs and not developing platforms that can be rapidly applied to newly emerging infections is that apparently small problems will not grow and that what we do not know will not hurt us. The fallacies of these concepts are quite evident in the ongoing tragedy of HIV/AIDS.

Vaccines are the province of industry. The sole rationale for commercial vaccine development is profit calculated as return on investment to stockholders. A particular vaccine would have to be more profitable than a particular drug in order to have resources for development and manufacture devoted to it. Successful vaccines from the perspective of preventive medicine are given only once and induce lifelong protection, translating as a single sale per customer. Drugs for prevalent chronic diseases require enormous numbers of doses for decades. The money and effort invested in development of a vaccine that could have produced a blockbuster drug represent lost opportunity cost to the pharmaceutical enterprise. The effects of not developing more effective and safer vaccines against whooping cough and tuberculosis are measured in days of active life lost, medical costs, and deaths that are borne by society, most often in developing countries. The same metrics apply to DF, DHF, Lassa fever, louse-borne typhus, scrub typhus, RVF, Venezuelan equine encephalitis, Ebola HF, Marburg HF, malaria, plague, and leptospirosis.

The development of vaccines against newly emerging infectious agents demands initiation of the project at the time of the first appearance of the emerging infection, well before the problem has reached significant public health attention. It would be logical to establish research programs to elucidate the principles of stimulating protective immunity against each family of pathogens. The goal would be to develop a prototype vaccine before the disease became a public health catastrophe. Ideally platforms for vaccines would be developed that stimulated memory cells to produce each of the components of immunity that are critical to protection against the particular agent, e.g., Th_1 antibodies or CD8 cytotoxic T lymphocytes. The new infectious agent could be characterized rapidly and the components predicted to be protective used with the appropriate vaccine platform. A disease with high lethality, rapid efficient transmission, and no treatment might justify manufacture and deployment of the vaccine with field use evaluation of safety and efficacy. Of course, preclinical animal testing for safety and efficacy and accelerated phase 1 and 2 trials would be preferred.

The principles that would determine the priority of development of vaccines would more logically be driven by public health concerns than merely financial return on investment. At the top of the list of criteria would be the severity of illness and incidence or threatened increase in incidence of the disease. Consideration of the severity of illness would include the ratio of symptomatic to asymptomatic infections, case-fatality ratio, incidence and nature of permanent sequelae, duration and medical costs of the illness in survivors, and other societal and economic impacts of the disease. Some diseases that would merit consideration for vaccine development on the criteria of disease severity and incidence include infections that currently occur nearly exclusively in developing countries such as Lassa fever, RVF, Ebola HF, louse-borne typhus, scrub typhus, leptospirosis, and Venezuelan equine encephalitis.

Other pathogens for which effective vaccine development effort should be undertaken are agents for which antibiotic resistance is a significant threat, potentially water-borne agents that are resistant to control by chlorination, and agents of veterinary diseases that would be potential agents of devastating agroterrorism. The rising problem of bacterial antimicrobial resistance is evident to all, particularly for nosocomial infection. What is generally ignored is the creation of weapons for biowarfare or bioterrorism that are resistant to antimicrobial treatment. For example, the confidence that rickettsial diseases respond well to early treatment with doxycycline should be reconsidered in light of the development of tetracycline-resistant *Rickettsia prowazekii* in a Russian laboratory. Similarly contamination of municipal

water supplies with chlorine-resistant organisms such as *Cryptosporidium parvum* would cause severe havoc. After several widespread outbreaks, the public would be receptive to prevention by an effective vaccine.

Development of veterinary vaccines is an important goal on its own merit. The lessons that would be learned by the development of vaccines against foot and mouth disease virus, *E. ruminantium*, and *Burkholderia mallei* would have additional impact on human diseases caused by related agents. Other veterinary pathogens such as Venezuelan equine encephalitis virus, *Brucella melitensis*, *Brucella abortus*, *Brucella suis*, and RVF virus are also human disease agents.

Respiratory diseases deserve special consideration for preparation for prevention by development of vaccines. The potential reappearance of SARS-coronavirus should energize efforts to produce an effective vaccine. The threat of pandemic influenza A combines nearly every reason that could be marshaled for all agents together to create a system for rapid vaccine formulation, testing, and manufacture.

THE CHALLENGE OF DEVELOPING VACCINES AGAINST EMERGING AND RE-EMERGING INFECTIOUS DISEASES

The development of a new vaccine is not easy by any means. Even when the pharmaceutical industry recognizes the market potential of a vaccine against an emerging pathogen, such as HIV or hepatitis C virus, there are many difficult steps between the desire to develop the vaccine and its availability for purchase. There are more steps from the discovery of a newly EID agent to the availability of a vaccine against it than for a pathogen that has been studied for decades or more than a century. First, the pathogen must be characterized at the levels of biology, molecular composition, and its genome. Even well into the contemporary molecular, proteomic, and genomic era, knowledge of the proteome and genetic sequence provides no more complete understanding of the agent than possession of an encyclopedia, which written in a language that has been translated only partly, would impart omniscience. Second, appropriate animal models that adequately mimic the pathology of the human disease, anatomic distribution of the agent, and the human immune response to the infection must be developed. There are numerous agents that are so highly adapted to humans that no adequate animal model exists. Other models utilize animal species that do not permit effective analysis of the protective immune response owing to lack of reagents to evaluate the immune cells and proteins and absence of animals that are genetically inbred or have knockout of specific genes. Third, studies of animal models and of humans and their cells, cytokines, and antibodies are employed to elucidate the mechanisms of protective immunity. Development of a vaccine that stimulates the presence of memory cells that generate the immune components required to kill the invading pathogen rapidly requires determining which elements (e.g., antibodies, CD4, and/or CD8 T lymphocytes) are critical. Fourth, the antigens of the particular infectious agent that stimulate the protective memory immune components must be identified. For subunit vaccines, some antigens stimulate protective responses, and others suppress protective immunity. Fifth, the animal models are utilized to develop and test vaccine candidates that stimulate protective memory immune responses without harmful side effects. At the point of the primary identification of the etiology of the emerging infection, it would be unlikely that any of these five steps would have been addressed.

Because many emerging infections are zoonotic diseases that have naturally occurring animal counterparts, a strategy of developing related veterinary vaccines on the pathway toward future development of a vaccine for humans may be feasible owing to financial and regulatory considerations. Imagine how much better off we would be today if an effective vaccine against a simian immunodeficiency virus had been produced in the 1970s or a changeable molecular cassette subunit vaccine had been approved for avian influenza viruses a decade ago. The crucial message regarding vaccines for emerging infections diseases is that it is never too early to support research to achieve the five steps outlined above.

CHAPTER

2

Bacterial Biothreat Agents

Richard W. Titball
School of Biosciences, Geoffrey Pope Building, University of Exeter, Exeter, Devon, UK

OUTLINE

ABSTRACT

A range of bacterial pathogens might be used illegitimately to cause disease in humans or animals. The properties of these pathogens are dissimilar. Much of our information on the properties of these pathogens comes from past programs to develop biological weapons. In principle, disease caused by bacterial biothreat agents could be prevented or treated using antibiotics. However, there are limitations associated with the use of antibiotics in this way. Against this background vaccines will play a key role in protecting vulnerable populations from bacterial biothreats.

INTRODUCTION

One simple definition of a bacterial biothreat agent is a bacterium that is used to deliberately cause disease in human, animal, or plant populations to the economic or social detriment of the host nation. Based on this type of definition there are a number of published lists of bacterial biothreat agents, ranging from those that inform export controls, such as the Australia group list, to those compiled to protect the U.S. Agricultural industry from disruption (Table 2.1). The differences in threat agents of concern reflect the difficulties in devising a single definitive list of biothreat agents. For example, agents that are likely to cause disruption of the agricultural industry are not necessarily those which would be used against a human population. Similarly, agents which would be used against civilian populations would not necessarily be used to attack the armed forces.

Despite these differences, there are some agents that consistently appear on all of the lists. The observation

that these agents are of concern to such a wide range of authorities clearly suggests that these pathogens would be preferred for vaccine development and licensing.

This chapter highlights the ways in which bacteria might be used to deliberately cause disease and reviews the utility of vaccines for the prevention of disease. Finally, the prospects for improved vaccines against bacterial biothreat agents are considered.

PAST USES OF BACTERIAL PATHOGENS TO DELIBERATELY CAUSE DISEASE

There are a number of reported examples of the use of bacteria to deliberately cause disease in humans or animals, although most of these involve small-scale and relatively localized incidents. A review of 270 cases of alleged bioterrorism until 2001 has been compiled by Carus (2001). In addition to these incidents, there are a number of proven or suspected uses of biological agents during warfare, either against civilian or military targets.

Arguably, the program that resulted in the greatest number of human casualties involved the Japanese Army (Unit 731) during the 1930s and 1940s and was the creation of the bacteriologist General Ishii Shiro (Mangold and Goldberg, 1999; Guillemin, 2004). It is reported that human trials were carried out with a wide range of potential biothreat agents (Table 2.2). Many of the casualties occurred after prisoners were deliberately exposed to pathogens during trials of biological weapons. For example, one trial used 10 Chinese prisoners who were exposed to a shrapnel bomb containing *C. perfringens* (Mangold and Goldberg, 1999). Reportedly, all of the victims died of gas gangrene within a week (Mangold and Goldberg, 1999). Other trials involved fleas infected with *Y. pestis* which were dropped from aircraft onto Chinese villages. One attack, on the hamlet of Congshan, reportedly resulted in an outbreak of plague that killed one quarter of the population (Mangold and Goldberg, 1999). In spite of this significant military program, which continued for a decade, several reports indicate that the Japanese program failed to devise a range of effective biological weapons which could be used for large-scale attacks on military or civilian populations (Mangold and Goldberg, 1999; Guillemin, 2004). In part, this reflects the difficulty of moving from the observation that pathogens cause disease to the large-scale production and successful weaponization of these bacteria.

B. anthracis is one of the bacterial pathogens that is frequently cited as a likely biological warfare or bioterrorism agent, and there is a significant body of information supporting this suggestion. In the past both the United Kingdom and the United States developed weapons containing this bacterium. In trials on Gruinard Island off the west coast of Scotland during the 1940s *B. anthracis* spores were tested as means of inducing pulmonary anthrax in sheep (Manchee et al., 1981, 1982). These trials demonstrated the feasibility of such a weapon but left the island contaminated. Subsequently, a major exercise during the 1980s resulted in the decontamination of the island (Manchee et al., 1983) which was then returned to grazing use (Aldhous, 1990). The programs to develop biological weapons in the United Kingdom and the United States ceased in the mid-1950s and late 1970s, respectively. However, there is evidence that other nations continued to develop anthrax as a biological weapon (Inglesby et al., 1999). An outbreak of human anthrax in Sverdlosk in the former Soviet Union was originally attributed to the ingestion of anthrax-contaminated meat (Sternbach, 2003; Meselson et al., 1994). However, subsequent investigations by a team of U.S. scientists revealed the cause to be the accidental airborne release of anthrax spores from a military facility (Meselson et al., 1994). This resulted in the largest outbreak of human inhalation anthrax documented with at least 79 cases of anthrax and 68 deaths (Inglesby et al.,

TABLE 2.2 Examples of the alleged use of biological agents to deliberately cause disease

Agent	Year	Location	References

1999). Additional cases of anthrax occurred in livestock outside of the city limits (Meselson et al., 1994).

B. anthracis has also attracted the attention of terrorist groups. During the early 1990s the Aum Shinrikyo group attempted to release significant quantities of *B. anthracis* spores over Tokyo. The failure of these attacks to cause disease has been attributed both to failures of the dissemination system and the mistaken use of the attenuated vaccine strain of *B. anthracis* (Kaplan and Marshall, 1996; Carus, 2001). However, more recently, *B. anthracis* has been used in the United States to cause a number of cases of disease. During 2001, *B. anthracis* spores were released into the U.S. Mail system resulting in 22 cases of anthrax (Jernigan et al., 2002). Of the 11 cases of inhalation, 5 were fatal. The high fatality rate for these inhalational cases of disease reflects the difficulties of treating symptomatic inhalation anthrax (Inglesby et al., 1999).

Other reported examples of the use of bacteria to deliberately cause disease involve minor events. For example, 12 cases of shigellosis occurred in laboratory staff working at St Paul's Medical Center Hospital in Dallas, Texas (Kolavic et al., 1997). Reportedly these were the result of the deliberate contamination of pastries with *S. dysenteriae* type 2 by one of the laboratory staff. These pastries were offered to other laboratory workers and 11 consumed them between 07.15 a.m. and 13.30 p.m. One victim became ill after consuming a contaminated pastry that was taken home by one of the laboratory staff. All of the individuals developed shigellosis within three days of consuming the pastries. Subsequent investigations showed that the organism was stored in the laboratory on coated beads within a vial, and that some of the beads were missing. The perpetrator of this crime was identified as one of the laboratory staff and subsequently sentenced to 20 years in prison. This crime is very similar to the so-called "sponge cake incident" which was reportedly carried out in 1964 in Japan, when a physician contaminated a cake with *S. dysenteriae* and offered it to four colleagues who became ill and required hospitalization (Carus, 2001). The perpetrator of this crime was eventually charged with 13 incidents of deliberate infection of a total of 66 individuals with *S. dysenteriae* or *S. enterica* serovar Typhi.

The examples cited above illustrate the ways in which bacterial pathogens might be used to cause disease in humans. However, the possibility that pathogens might be used to cause disease in animals should not be overlooked. For example, during World War II the United Kingdom produced cattle cakes containing *B. anthracis*, as a potential weapon against German domesticated livestock. This weapon was never used; however, there is evidence that during World War I *B. mallei* (formerly *Pseudomonas mallei*) was used to cause disease in horses that were essential to the Allied supply chains (Wheelis, 1999; Geissler et al., 1999). Although it is documented that outbreaks of disease did occur in horses, the precise incidence of disease caused by the deliberate release of agent is not known (Wheelis, 1999).

POTENTIAL FOR AIRBORNE BACTERIAL PATHOGENS TO CAUSE DISEASE

Most of the examples of the illegitimate use of bacteria to cause disease involve the relatively small-scale release or use of bacterial pathogens to cause disease. However, the scenario that is of greatest concern involves the airborne release of a bacterial agent over an area of high population density.

There are little data on the likely incidence of disease following the airborne dissemination of a pathogen. However, a report from the WHO during 1970 (Anon, 1970) made an attempt at predicting the numbers of casualties caused by the release of 50 kg of dried biowarfare agent released as a line source upwind of the population. The study considered six different targets. Three typified economically developed cities with populations of 500,000; 1,000,000; and 5,000,000. Three typified cities with similar populations but in economically developing areas of the world.

The estimation by the WHO made several assumptions. With the exception of the spores of *B. anthracis*, bacterial biological agents are generally unstable in the airborne state and especially when exposed to UV irradiation. The attacks were therefore assumed to be carried out at night with dried bacteria mixed with stabilizing compounds to limit the extent of airborne decay. It was assumed that the agent was dispersed from an aircraft at a height of 10 m above ground and over a distance of 2 km upwind of the target site. The wind speed was assumed to be 2.5 m/s. Under these conditions, the number of casualties was related to the infectious dose of the pathogen and the stability of the bacterium in the airborne state. Therefore, agents that are aerosol stable and have a low infectious dose caused the greatest numbers of casualties (Fig. 2.1). However, caution should be exercised when viewing these estimates of casualties—changes to any of the variables outlined above, such as height of release, time of release, wind speed, or the properties of any stabilizing agent could impact significantly on the number of predicted casualties.

Notwithstanding these concerns, and the issues highlighted above concerning the technical challenges

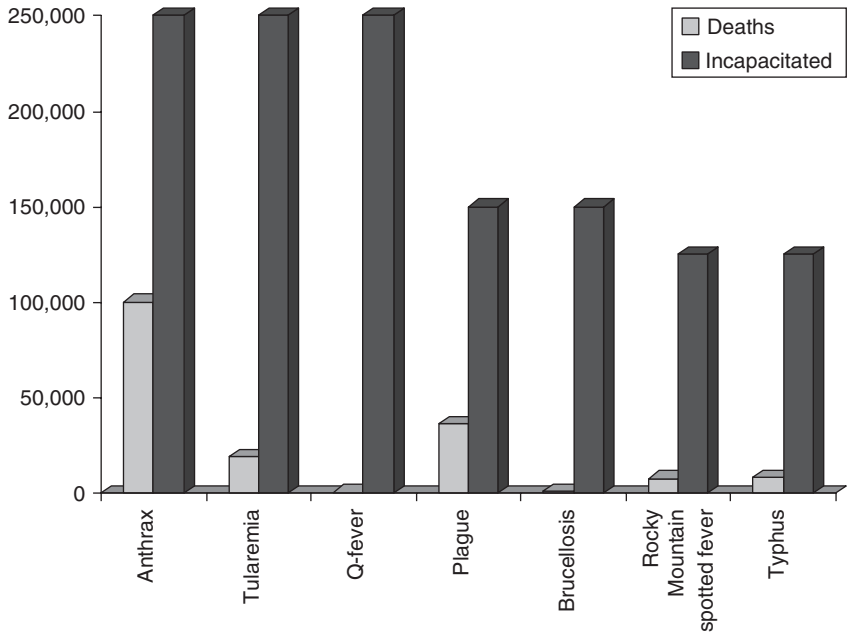

FIGURE 2.1 Predicted numbers of casualties following the airborne release of selected bacterial pathogens over an area of high population density (5 million) in an economically developed country.

associated with mounting such a large-scale attack, the exercise carried out by the WHO does illustrate the different properties of different bacterial agents. For example, not all of these pathogens would cause significant numbers of deaths. Some like *Brucella* sp. causes severely debilitating diseases, which would likely place significant requirements on the healthcare systems. Some agents cause diseases that are transmissible from person to person (for example, plague), meaning that there would be a need to restrict the movement of individuals within the area covered by the agent. Others like *B. anthracis* spores would leave the environment contaminated for long periods of time, requiring costly and technically challenging decontamination processes.

VACCINES AND ANTIBIOTICS FOR THE PREVENTION AND TREATMENT OF DISEASE

Both antibiotics and vaccines have been proposed to have a role to play in the prevention or treatment of disease caused by bacterial biothreat agents. In principle, antibiotics might be used either prophylactically or therapeutically but surprisingly their effectiveness in either scenario is not certain. The use of antibiotics for the treatment of disease is especially problematic because of the acute nature of many of the infections which occur after the inhalation of bacteria (Inglesby et al., 1999, 2000; Dennis et al., 2001). By the time most individuals are symptomatic the effective treatment of disease is difficult, and for diseases with a high mortality rate, many of these symptomatic individuals will die even with aggressive antibiotic therapy and other interventions. The problems of treating inhalational anthrax with antibiotics were clearly highlighted during the 2001 mail-associated outbreak of disease. Of the 11 cases of inhalational disease, 5 died. In contrast, there were no deaths in the 11 individuals who contracted cutaneous anthrax (Jernigan et al., 2002).

The prophylactic use of antibiotics also presents some significant problems, which were again highlighted during the mail-associated outbreak of anthrax in the United States. It is estimated that 32,000 individuals initiated antibiotic prophylaxis (Jernigan et al., 2002). However, the numbers of individuals who completed the recommended 60-day course was relatively low. In some cases termination of the course was the appropriate course of action when the full extent of the risk to the individual was quantified (Jernigan et al., 2002). An alarming number of individuals failed to complete the course, even though they were considered to be at a significant risk of contracting the disease (Stein et al., 2004). In a more detailed study, Shepard et al., (2002) found that the proportion of individuals who completed a 60-day course of antimicrobial prophylaxis ranges from 21 to 64% depending on the site (Fig. 2.2). Adverse events were the most frequently

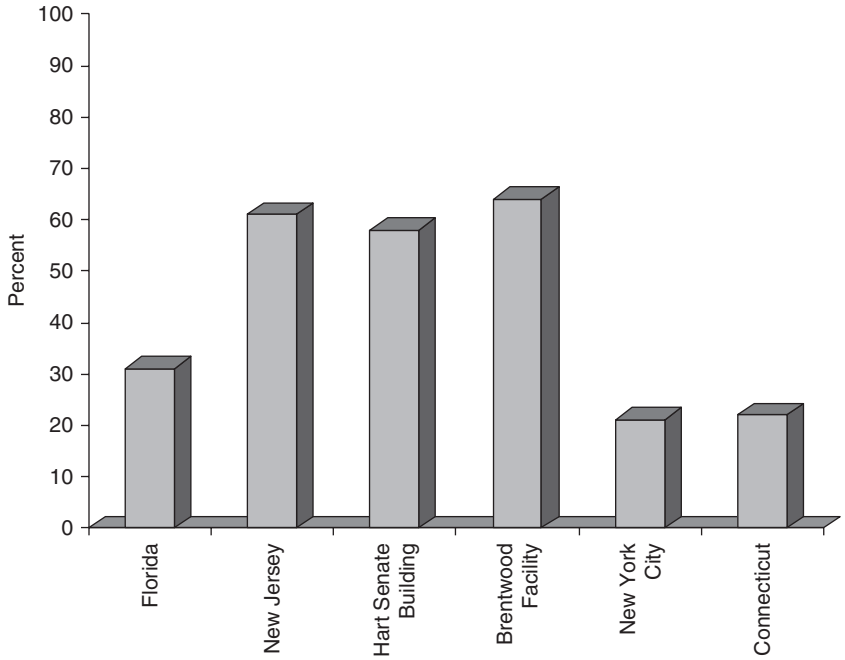

FIGURE 2.2 Percentage of individuals completing at least 60 days of antimicrobial prophylaxis following possible exposure to *B. anthracis* spores in the United States during 2001. Total numbers of individuals at each site were as follows: Florida, 1082; New Jersey, 1402; Hart Senate Building, Washington, D.C., 600; Brentwood facility, Washington, D.C. 2743; New York City, 2259; Connecticut, 1217.

cited reason for failing to complete the course of antibiotics. These ranged from gastrointestinal disturbances to seizures (Shepard et al., 2002)—although the proportion of these adverse events which are definitely attributable to antimicrobial prophylaxis is not known. Overall, it is clear that the prophylactic use of antibiotics may not be an effective way of protecting target populations from disease caused by the deliberate release of a bacterial pathogen.

Against this background, the use of vaccines to protect target populations appears to be an attractive proposition. However, the concept of use for these vaccines is not yet established. It may be possible to include vaccines against biothreat agents in childhood immunization programs. However, the cost of such an immunization program may be prohibitive. Alternatively, vaccines against bacterial biothreat agents may be given only when the risk of an attack is judged to be high. Vaccines used in this way might need to rapidly induce protective immunity.

AVAILABLE VACCINES AGAINST BACTERIAL BIOTHREAT AGENTS

Bearing in mind the ways in which bacterial biothreat agents might be used to cause disease, the suitability of existing vaccines against bacterial agents can be assessed. Clearly, for the majority of agents these vaccines need to provide good protection against an airborne challenge. For pathogens which might be used to contaminate food or water supplies vaccines must protect against this route of infection. Ideally, vaccines should result in the induction of protective immunity after a single dose. In some scenarios it may be desirable to immunize large numbers of individuals within a short period of time. Finally, these vaccines should have been tested according to national or international guidelines for pharmaceutical products. With reference to the possible biothreat agents as shown in Table 2.1, it is clear that relatively few commercially available or fully licensed vaccines exist (Titball and Williamson, 2003) (Table 2.3). In addition, some of the available vaccines do not meet the criteria outlined above (Titball and Williamson, 2003). The performance of some of these vaccines are detailed in subsequent chapters in this book.

The limited availability of vaccines can be ascribed largely to the minimal investment in this area of research during the past 50 years. The costs associated with working with dangerous pathogens under containment level 3 or 4 conditions are significant. Not only are the costs of construction of suitable laboratory facilities high (typically $50 million–$100 million) but the costs of operating these facilities is likely to be several million dollars per year. Much of this cost is

TABLE 2.3 Licensed/commercially available vaccines available in Europe and N. America against bacterial biothreat agents

Pathogen	Composition
B. anthracis	Live attenuated Sterne strain (for veterinary use only) or live attenuated STI-1 strain (used only in humans in the former Soviet Union (Brachman et al., 2004)
B. anthracis	Anthrax vaccine adsorbed (Brachman et al., 2004)
B. abortus	Live attenuated strain 19 (veterinary use only) (Schurig et al., 2002)
B. melitensis	Live attenuated strain Rev. 1 (veterinary use only) (Schurig et al., 2002; Blasco, 1997)
B. melitensis	Live attenuated strain RB51 (veterinary use only) (Schurig et al., 1995; Schurig et al., 2002)
S. enterica serovar Typhi	Killed whole cell (Levine, 2004)
S. enterica serovar Typhi	Live attenuated (TY21a) (Levine, 2004)
S. enterica serovar Typhi	Capsular polysaccharide (Vi) (Levine, 2004)
V. cholerae	Killed whole cell (injectable) (Sack and Lang, 2004)
V. cholerae	Killed whole cell+CTB (oral) (Sack and Lang, 2004)
V. cholerae	Live attenuated (oral) (Sack and Lang, 2004)
Y. pestis	Killed whole cell (Titball et al., 2004)

related to the regular servicing of laboratory air and water handling systems and the cost of heating air for laboratory ventilation systems which is eventually lost to the atmosphere.

These problems are compounded by the relatively low level of financial return on the sale of vaccines. Bacterial biothreat agents do not normally cause significant disease in the developed world and there is a small market for these vaccines outside of the biodefense arena. In addition, the commitment of nation-states in the developed world to purchase stocks of vaccines is not yet determined. Against this background we cannot assume that the commercial sector will bear most of the risks and costs associated with the development of biothreat agent vaccines.

NEW VACCINES AND NEW VACCINE TECHNOLOGIES

During the past decade there has been a marked increase in the level of government-funded research into improved vaccines against bacterial biothreat agents. This work can broadly be divided into four areas: studies on mechanisms of virulence of pathogens, studies on the host response to bacterial pathogens, work to develop and test vaccine candidates, and work to devise and evaluate new vaccine delivery platforms. There is every reason to believe that this initiative will be successful and that a suite of vaccines will become available over the next two decades. However, the development of vaccines against biothreat agents does present some significant technical challenges (Titball and Williamson, 2003).

Firstly, there is a paucity of data on mechanisms of virulence or biochemical makeup of many of these pathogens. For other pathogens this basic information has often been the starting point for the development of vaccines. Although some of the research currently underway will address these questions, it is unlikely to be mature enough in the near future to be directly exploitable. One alternative strategy might be to exploit genome sequence information to kick-start vaccine development programs (Titball and Williamson, 2003). This information might be used to support whole genome mutagenesis approaches to identify virulence determinants, predict metabolic pathways, identify targets for the construction of rationally attenuated mutants, and identify candidate protein antigens using "reverse vaccinology" (Titball and Williamson, 2003; Capecchi et al., 2004; Masignani and Rappuoli, 2004; Plotkin, 2005; Rappuoli and Covacci, 2003; Hensel et al., 1995; Hou et al., 2003). Fortunately, genome sequences are now available for almost all of the bacterial agents of concern (Table 2.4).

The technology of reverse vaccinology merits particular comment, since this approach has been successfully used to identify candidate vaccine antigens from a range of pathogens including *Helicobacter pylori* (Lissolo and Quentin-Millet, 2000), *Neisseria meningitidis* (Pizza et al., 2000), *Porphyromonas gingivalis* (Ross et al., 2001), *Streptococcus pneumoniae* (Wizemann et al., 2001), and more recently *B. anthracis* (Ariel et al., 2002, 2003). The approach relies on the assumption that vaccine antigens are located on the surface of the bacterial cell. Therefore, the predicted proteome of the pathogen of interest is screened to identify proteins that possess motifs indicating that they are destined for a cell surface location. The most frequently used algorithm is PSORT (http://psort.nibb.ac.jp/) which provides an integrated software package for this purpose. This conceptually simple approach does have some limitations. Although programs such as PSORT are excellent for the prediction of proteins which are exported via the type II secretion pathway, they are much less effective at predicting proteins exported via other pathways, and potential vaccine antigen might not be identified using this approach. In addition, the

output from PSORT is a list of proteins with the potential to be located on the cell surface. Each of these proteins must be produced and tested.

Even when vaccine candidates are identified, produced under manufacturing conditions, and tested in animal models of disease, the licensing of vaccines for use in humans may be a difficult process. It is certainly possible to gain data on the safety of these vaccines via human clinical trials. However, with the exceptions of some pathogens that cause relatively mild diseases, efficacy studies in humans are not feasible. In these cases it will be necessary to gain significant information on mechanisms of protection in different animal models of disease, and to then show that similar immune responses are induced in immunized human volunteers.

CONCLUSIONS

It is clear that vaccines are likely to play a major role in plans to limit the impact of biothreat agents on human populations, and they are especially valuable when airborne releases of significant quantities of the pathogen are anticipated. However, currently there are few commercially available vaccines that are

suitable for the immunization of at-risk populations. This situation is likely to change over the next decade—there are already improved vaccines against some biothreat pathogens which are in the advanced stages of development. The greatest challenge today is the development of appropriate plans for the effective use of these vaccines. Should they become part of the normal childhood vaccination program or should they be used only when the likelihood of an attack is considered to be high? Should a prime-boost strategy be adopted where individuals are primed to allow the rapid development of protective immunity on boosting? These are important questions because they might drive not only the selection of vaccine antigens but also the selection of appropriate vaccine delivery systems.

Finally, we should not lose sight of the fact that many of the diseases caused by bacterial biothreat agents are a significant cause of morbidity and mortality in economically deprived areas of the world. The vaccines that are developed to protect against biothreat agents are likely to find additional utility in the protection of these disadvantaged populations of humans.

CHAPTER

3

Viral Biothreat Agents

Kevin Anderson
National Biodefense Analysis and Countermeasures Center, Science and Technology Directorate, U.S. Department of Homeland Security, Frederick, MD, USA

OUTLINE

ABSTRACT

The risk posed by viruses as biological threat agents is discussed primarily from a public health perspective, with the potential occurrence of significant morbidity and mortality as a result of infection via natural or intentional exposure. Parameters of risk associated with the spectrum of viruses considered as biological threat agents are discussed, to include examples of intentional use. In consideration of the threat posed by viruses, mitigating illness and preventing death are the principal goals of medical countermeasure development efforts. The existence of safe and efficacious vaccines is critical to establishing a robust posture of preparedness to address the spectrum of viral threat agents.

INTRODUCTION

Given the primary focus of this text is on vaccines, the term biological threat will be defined primarily from a public health perspective. Therefore, viruses as biological threat agents are defined as those that cause harm to public health as manifested by significant morbidity and/or mortality, which can occur via natural or intentional exposure.

Natural exposure to viruses that cause human disease can occur via direct or indirect contact. Direct

contact would include person-to-person spread, such as with community-acquired viral infections; animal-to-person spread, as with viral zoonoses; and spread to an unborn child from its mother, also known as vertical transmission. Also, viruses can be transmitted directly by vectors, such as mosquitoes and ticks. Indirect contact would include environmentally acquired viral infections (via food, water, air, or fomites) that are not spread by close contact. Infectious viral diseases can be spread through the air either by direct or indirect contact via droplet or particle transmission, respectively.

Intentional exposure to viruses resulting in human disease would include biowarfare, bioterrorism, and biocrimes (Swearengen, 2006). Biowarfare is defined as the military use of biological agents, where targets of agents are predominately military personnel, government officials, or resources that might hinder a nation's ability to attack and/or defend itself. Bioterrorism is defined as the threat or use of biological agents by individuals or groups motivated by political, religious, ecological, or other ideological objective. Viruses of concern from a biowarfare or bioterrorism perspective represent a major theme of this chapter. A biocrime is defined as the threat or use of biological agents for individual objectives such as revenge or financial gain. Use of viruses in biocrimes against people have been documented, with sources limited primarily to clinical samples containing viruses such as HIV-1 and hepatitis A (Carus, 2001). Viruses have also been used to reduce animal populations unlawfully and by definition, such action would be categorized as a biocrime (Carus, 2001).

The extent to which particular viruses are considered as biological threats is largely dependent on the risk they pose. The risk posed by a virus is defined as the probability of it causing infections of significant consequence, with high morbidity and mortality, as a result of either naturally occurring epidemic or pandemic disease, or malevolent intent, in the case of biocrime, bioterrorism, or biowarfare.

Viruses as credible, high-impact threats are defined by the properties or characteristics of the virus, the vulnerability of those subject to exposure and also, in the case of malevolent use, the capability and intent of perpetrators. Credible, high-impact threats include viruses that could inflict harm by either natural exposure, in which parameters of risk include agent characteristics and vulnerabilities, or intentional exposure, in which adversary capability and intent also become factors to consider (Fig. 3.1). Parameters of risk associated with properties or characteristics of viruses would include high infectivity, high morbidity and mortality, environmental stability, airborne transmissibility, and high contagiousness. Parameters associated with vulnerabilities include limited or unavailable medical countermeasures, such as vaccines and therapeutics, with cost and increasing public resistance to vaccination as contributing factors, limited or unavailable means to detect and identify viruses, and the ability of a virus to cause disease that is difficult to treat. Parameters of risk associated with adversary capability and intent include ease of acquisition, production, and dissemination of viral agents; and evidence of prior research and development as a biological weapon (Center for Biosecurity, UPMC, 2008).

In human history, the consequences of natural exposure to viruses have been much greater with respect to morbidity and mortality than those realized by intentional release, as depicted in Fig. 3.1. With the exception of smallpox, which some experts speculate is responsible for more deaths throughout modern history than all other infectious diseases combined, the greatest human and economic consequences derived from virus infections via natural exposure have been realized from emerging diseases, all of which have been derived from infected animals via zoonoses. For example, influenza pandemics that occurred in 1918 (H1N1), 1957 (H2N2), and 1968 (H3N2) resulted in approximately 40–50, 2, and 1 million deaths worldwide, respectively (World Health Organization, 2008). It is thought that the 1918 H1N1 virus was an avian virus that was introduced into pigs, and subsequently transmitted to human carriers, which spread the virus along trade routes and shipping lines resulting in a global pandemic (Taubenberger and Morens, 2006). In the past 25 years, approximately 60 million people have been infected by HIV-1, resulting in greater than 25 million deaths (Avert, 2008). HIV-1 most likely originated in wild chimpanzees living in

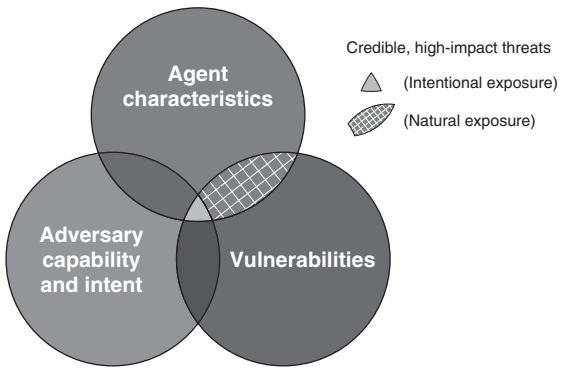

FIGURE 3.1 Parameters of risk.

tropical rain forests of equatorial Africa, with infection of humans likely occurring during the French colonial period from 1919 to 1960 (Keele et al., 2006).

THE SPECTRUM OF BIOLOGICAL THREATS

Although the societal effects of emerging infectious diseases continue to shape the landscape of medical preparedness, the proliferation of biological materials, technologies, and expertise has increased the potential for adversaries to use viruses for biological attacks. Not only does society have a need for developing vaccines, therapeutics, and diagnostics to counter naturally occurring and emerging infectious diseases, but countermeasures must keep pace with potentially devastating adversarial efforts to subvert developing or existing biomedical technologies. Moreover, caution must be exercised to prevent biomedical advances that benefit mankind from being applied to create enhanced or advanced viral threat agents generated through the use of these technologies (Petro and Carus, 2005).

The spectrum of viruses considered as biological threat agents resulting from intentional exposure encompasses four categories as shown in Fig. 3.2, each of which presents unique challenges and significant opportunities for development of medical countermeasures (Bush, 2007). Traditional agents would include viruses that could be disseminated to cause mass casualties in susceptible populations. Although risk posed by traditional viral agents is significant, a finite number of viruses fit in this category. Of particular concern are variola virus (smallpox) and viruses that cause hemorrhagic fever such as filoviruses (Lake Victoria marburgvirus and ebola viruses), arenaviruses (Lassa, Junin, Machupo, Guanarito, and Sabia viruses), bunyaviruses (hantaviruses, Rift Valley fever virus, and Crimean-Congo hemorrhagic fever virus), and flaviviruses (yellow fever virus, tick-borne encephalitis virus, and dengue viruses) (NIAID, 2008). These viruses can be easily disseminated or transmitted from person-to-person, resulting in high case-fatality rates and have the potential for major public health impact (Peters, 2002); might cause public panic and social disruption; and require special action for public health preparedness (Centers for Disease Control and Prevention, 2008; WHO, 2005). Therefore, the development or existence of targeted medical countermeasures against these agents will reduce the current risk posed or the likelihood of mass casualties resulting from intentional use.

Emerging agents would include those viruses which undergo rapid co-evolution with their hosts and the environment. Emerging viruses are for the most part, zoonotic in nature and spillover via natural exposure to humans as incidental hosts: examples of which are SARS coronavirus and avian influenza virus. Improved disease surveillance, to include early detection, is essential for containing the spread of an outbreak and is dependent on strong, flexible public health systems at local, state, and federal levels (Centers for Disease Control and Prevention, 2008).

Enhanced agents would include selection of naturally occurring viruses to enhance their virulence or host range or to facilitate their delivery beyond parameters that define natural exposure. For example, viruses used in an aerosol attack may exhibit altered patterns of infectivity, resulting in a different outcome than that observed in naturally occurring outbreaks. Enhanced viral agents may also be capable of producing disease with a more rapid onset of symptoms, making timely diagnosis, treatment, and containment more difficult (Schmaljohn and Hevey, 2005). Increasingly, medical countermeasure development

Traditional	*Enhanced*	*Emerging*	*Advanced*
Naturally occurring microorganisms (e.g., viruses) or toxins with the potential to be disseminated to cause mass casualties.	Traditional agents that have been modified or selected for enhanced ability to harm human populations or circumvent current countermeasures.	Previously unrecognized pathogens that might be naturally occurring and present a serious risk to human populations.	Novel pathogens or other materials of biological nature that have been artificially engineered to bypass traditional countermeasures or produce a more severe or enhanced spectrum of disease.

FIGURE 3.2 The spectrum of biological threats.

strategies should include protection against agent enhancements, such as aerosol exposure as mentioned above.

Advanced agents would include viruses that have been artificially engineered in the laboratory to circumvent countermeasures or produce a more severe or enhanced spectrum of disease. Of particular concern have been examples of viruses engineered to contain host biological response modulators, which in animal models have demonstrated an ability to circumvent levels of protective immunity obtained from prior vaccination, a primary example being ectromelia virus engineered to express IL-4 (Jackson et al., 2001).

Given the challenges of developing medical countermeasures against enhanced, emerging, and advanced agents, which are confounded to a great extent by unknowns, a posture of preparedness is largely based on the ability to rapidly identify and characterize the agent, understand the extent of exposure, and to evoke appropriate levels of patient care and social distancing to limit the spread of infection (World Health Organization and Robinson, 2004).

VIRUSES OF CONCERN

Several lists of threat agents, which include viruses, have been generated by groups or agencies within governments for a variety of purposes, including relative risk, biosecurity, and export control (select agents), as shown in Table 3.1. Although all of the agents listed represent traditional or emerging agents, the likelihood of their use for intentional exposure is a key consideration for prioritizing development of biodefense medical countermeasures, including vaccines.

Smallpox is a bioterrorism threat due to its potential to cause severe morbidity in a nonimmune population and because it can be transmitted via inhalation, ingestion, abrasion, or injection (Darling et al., 2005). A single confirmed case of smallpox identified anywhere in the world would be considered a public health emergency (Saks and Karras, 2006).

The first documented attempt to use variola virus as a biological weapon occurred during the French and Indian Wars (1754–1767) in North America. Blankets from smallpox victims were given as gifts to susceptible North American Indians, resulting in epidemics among native populations leading to case-fatality rates approaching 50% in some areas. During World War II, the Japanese Military conducted experiments with variola virus for use as a biological weapon. The former Soviet Union conducted biological weapons programs to include large-scale industrial production of variola virus that was stable in an aerosol and was claimed to be deliverable in warheads (Alibek and Handelman, 1999).

Subsequent to the World Health Organization (WHO) declaration of the eradication of smallpox in 1980, member nations agreed to destroy all laboratory stocks of the virus and/or provide them to one of the two officially sanctioned WHO reference laboratories: The Centers for Disease Control and Prevention in Atlanta, GA, or the Institute of Virus Preparations in Moscow, Russia. Although remaining stocks at these laboratories were scheduled to be destroyed in 1996, the World Health Assembly subsequently accepted a recommendation to retain the remaining stocks and to review a decision to destroy them on a periodic basis. Should the existing repositories be destroyed, other potential sources of smallpox may exist. Conceivably, sources of the variola virus may include unknown stores, cadavers in permafrost, and recreation of the viral genome or strains in laboratories utilizing genetic engineering, recombination, and data from published genomic sequences as a basis for design (Darling et al., 2005).

In addition to variola virus, a number of other viruses have been weaponized or studied for possible use as biological weapons against humans by state programs, including Lake Victoria marburgvirus, Venezuelan equine encephalitis virus, ebola viruses, Junin virus (Argentinian hemorrhagic fever), Machupo virus (Bolivian hemorrhagic fever), yellow fever virus, Lassa virus, Japanese encephalitis virus, and tick-borne encephalitis virus (Alibek and Handelman, 1999). Most of these viruses can be readily acquired from naturally occurring outbreaks and can be grown in the laboratory to high titers. The hemorrhagic fever viruses associated with this group are notorious for causing aerosol-mediated laboratory infections with case-fatality rates as great as 30% (Peters, 2002).

A number of viruses of concern are viewed primarily as threats to agriculture and their introduction to domestic livestock would have devastating effects such as reduced food production, economic loss in food and farm sectors, export embargoes, destabilization of markets, and loss of public confidence in the safety of the food supply (CIDRP, 2008). Such viruses would include foot-and-mouth disease, Rift Valley fever, Venezuelan equine encephalitis, and other viruses that may employ invertebrate hosts as vectors, from which virus can be subsequently amplified in animal hosts and also can be transmitted to humans. In addition, Nipah and Hendra viruses have been transmitted from domestic animals or livestock to

humans leading to high case-fatality rates and therefore, are of concern from both an agricultural and a public health perspective.

PREPAREDNESS

Biodefense vaccine development represents, in part, a defensive strategy to protect the public from biological terrorism through the development of safe and effective countermeasures to mitigate illness and death, protect critical infrastructure, and minimize economic consequences (Gay et al., 2007). The need to accelerate and expand development of current and new vaccines to prepare for intentional introduction or natural occurrence of catastrophic human and zoonotic diseases is reflected by the list of vaccines shown in Table 3.2. In summary, licensed vaccines exist for only a few viruses of concern and are of limited supply in case of catastrophic need (Schmaljohn and Hevey, 2005). For other viruses, vaccines are available under investigational new drug (IND) status, which have not been licensed for a variety of reasons, primarily the lack of market incentive to develop through to licensure (Schmaljohn and Hevey, 2005). In light of the paucity of medical countermeasures effective against viruses of concern, subsequent chapters of this text are devoted to review of vaccine development efforts against biodefense, emerging and neglected diseases.

Adoption of a national strategy to rapidly develop effective biodefense countermeasures, which includes safe and efficacious vaccines, requires periodic threat and risk assessments to understand the evolving biological threat (Bush, 2002). Such assessment must be performed to define gaps in knowledge or vulnerabilities in our preparedness posture, thus guiding prioritization of investments in biodefense-related research, development, planning, and overall preparedness. Vaccines represent a necessary component of biodefense countermeasure development to prepare for and to minimize the consequences of a biological attack. Risk assessments have provided a means of identifying and prioritizing vaccine research and development efforts for biological agents capable of being used in biological attacks. In support of vaccine research and development, current biodefense strategies include the development of an enduring infrastructure to test and evaluate existing, proposed, or promising countermeasures, assess their safety and effectiveness, expedite their development, and ensure rapid licensure (Gronvall et al., 2007c; NIAID, 2008; U.S. Department of Health & Human Services, 2008).

Response to bioterror events involves rapid agent detection and diagnosis, implementation of exposure control measures, and use of vaccines, when appropriate, to minimize consequences to human and animal health (Gronvall et al., 2007b). Current approaches to biodefense vaccine development include use of existing applications for development and manufacturing, and development of new technologies to rapidly design, test and evaluate, and manufacture desired products. Given the urgency with which vaccines designed to minimize consequences of bioterror events are needed, new technologies and infrastructure are mandated to shorten timelines for their development. New technologies applicable to the design of vaccines would include rapid methods for the identification and selection of protective immunogens, and the development of vaccines that allow for differentiation of vaccinated hosts from those infected by exposure to virus, with options to employ improved adjuvants that stimulate innate immune responses and/or promote adaptive immune responses (Capua, et al., 2004). New infrastructure would include biocontainment facilities to increase current capacities for vaccine testing and evaluation, to optimize vaccine dosage and delivery in conjunction with routes of exposure, and enhance manufacturing capacities to ensure availability of a minimum number of doses for intervention and reduce average cycle times to manufacture vaccine lots. Rapid deployment of biodefense vaccines will require both infrastructures, to include facilities for storage of vaccine stockpiles, and technologies that ensure validated storage conditions for such stockpiles (Gronvall et al., 2007a).

CONCLUSIONS

Programs to develop better medical countermeasures against viruses must increasingly reflect the potential use of enhanced, emerging, or genetically engineered viruses as biological weapons and scenarios that require countermeasures to provide broad-spectrum coverage to prevent illness postexposure. Support for research and development of biodefense countermeasures, including vaccines, should result in improved methods for vaccine discovery and development, and enhance preparedness against viruses, as biological threats, to the benefit of public and animal health.

ACKNOWLEDGMENTS

Many thanks to David Hodge, Sara Klucking, and Jens Kuhn for critical review and to Ed Marino and Cynthia Sheffield for exceptional technical assistance in preparation of this chapter.

OUTLINE

ABSTRACT

The process to develop a vaccine becomes longer and more complex each year due to the many steps required to prepare and get a product licensed. Here, we overview the complex pathway that is needed to develop a vaccine. The process starts with basic science/discovery, proceeds through preclinical development, to clinical trials, manufacturing, registration/licensure, implementation, and finally post-marketing surveillance.

INTRODUCTION

Development of a vaccine is a very complex process involving multiple steps and a long period of time. It has been estimated that it takes 15 years for a vaccine to move from the initial discovery through to licensure. Why does it take so long? This can be explained by the need to have a vaccine that is both safe and efficacious. In the 20th century the focus was on preventing infectious diseases while in the 21st century,

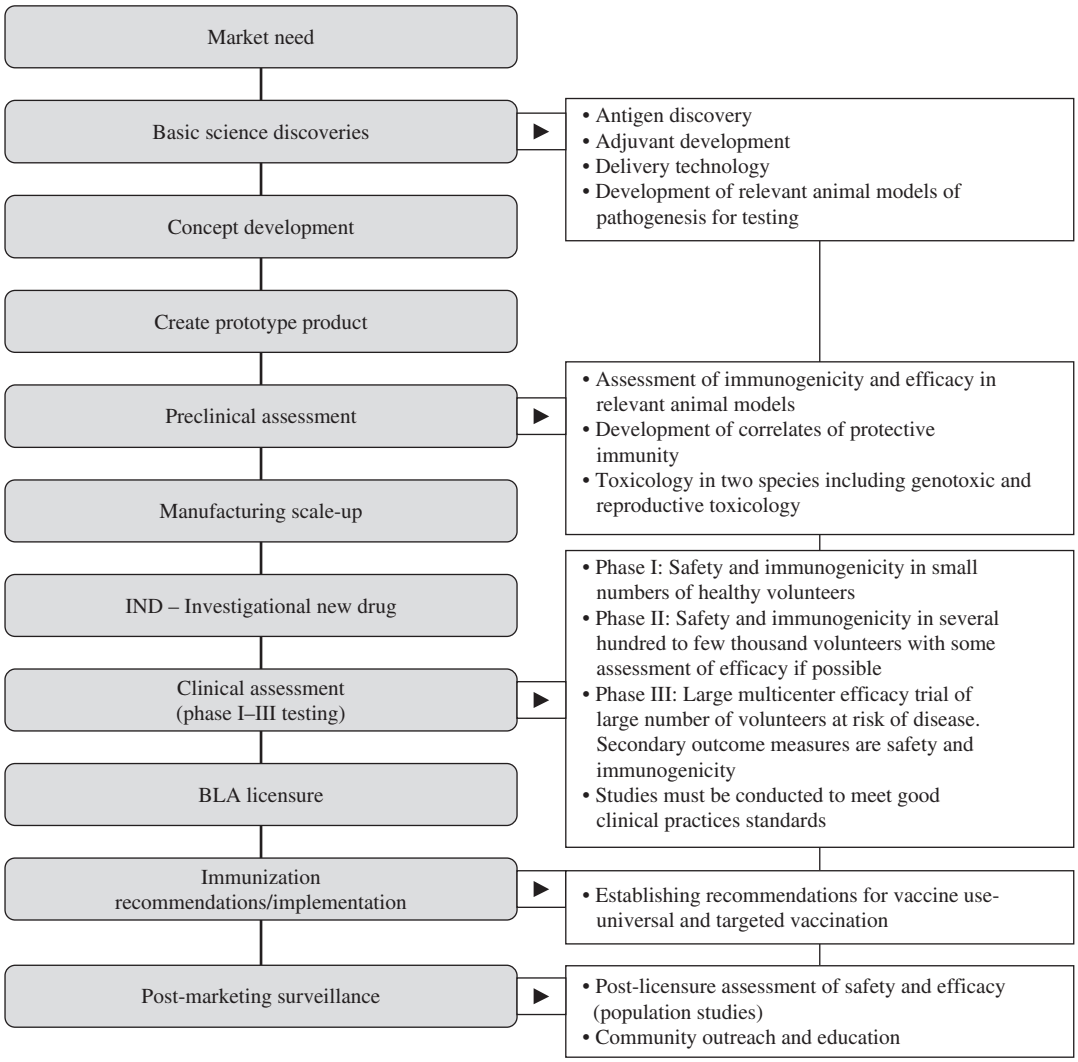

FIGURE 4.1 The vaccine development pathway.

society has changed its views on vaccines and now focuses on the need to have a vaccine that is 100% safe. In part, this is due to the successes of science and public health in the 20th century where many of the major infectious diseases have greatly reduced in incidence and rarely seen in developed countries such that the vaccine is now considered to be a potential cause of disease. Thus, in general, the steps to develop a vaccine fall into three categories: financial, scientific, and regulatory. The pathway is illustrated in Fig. 4.1.

MARKET NEED

The first step in vaccine development is determination of the need for the proposed vaccine (Batson, 2002). Need is not simply based on the number of people who might benefit from the product but rather it is based on the number of people who likely could pay for the vaccine (or have it purchased on their behalf). Consequently, estimates of market need are then influenced by the anticipated vaccine purchase price. Although there may be more individuals in a developing country that would benefit from a vaccine there may be fewer financial resources available to buy the product and hence the market need may be perceived as insufficient to support the product development, i.e., the vaccine producer has to recover the costs of research and development plus the costs involved in manufacturing and marketing, and also make a profit for shareholders. While scientific feasibility, and political and marketplace issues, heavily influence the decision to develop a vaccine, it is economics that ultimately drives the decision. The investment

costs required for development, manufacturing, and product distribution are weighed against anticipated revenue to determine the potential financial return on investment. The development of a vaccine may take more than 10 years and cost between $200–500 million (Struck, 1996; Andre, 2002). The decision to proceed with development is influenced by the projected return on investment and by anticipated risks that could impact successful implementation of the vaccine to the general population. Governments that fund the development of vaccines may accept a lower return on investment, or the return may be calculated to include the saving associated with monies required to treat and prevent the disease by other modalities. For example, a mosquito-borne disease such as dengue which has no vaccine currently requires monies to support control of the mosquito vector plus medical support for individuals who have the disease. For vaccines developed in the private sector, the so-called "push and pull" mechanisms can impact the economic formula (Pauly, 2005; Batson, 2005; Grabowski, 2005). Push mechanisms are those that subsidize or reduce research and development costs or risks; e.g., tax credits for working on government targeted diseases. Pull mechanisms pledge purchase of the vaccine once developed and hence reduce uncertainty regarding potential revenue.

BASIC SCIENCE DISCOVERIES

Basic science discoveries are key to the development of new vaccines (Poland et al., 2002). Breakthroughs or insights resulting from fundamental research can inform use-inspired science (The Biodesign Institute, http://www.biodesign.asu.edu/news/New-ASU-Interdisciplinary-PhD-Graduate-Program-in-Biological-Design-Set-for-Launch). Industry-based vaccine scientists constantly monitor the ongoing research at universities and in government, institute and research-oriented hospital laboratories seeking to identify advances that can be applied to vaccine development. Historically, university- and hospital-based researchers have been instrumental in the development of vaccines (Table 4.1). Increasingly, academic and government researchers are focusing more effort in product-oriented research with greater emphasis on protecting the intellectual property developed in their laboratories.

Not all discoveries have an obvious application at the time they are made. Discoveries in molecular genetics that established the field of genetic engineering (Winther and Dougan, 1984) led to the development of recombinant hepatitis B virus (HBV) vaccines (Zahradnik et al., 1987; Kuwert et al., 1985), which replaced a HBV vaccine derived from purification of particles from individuals infected with the virus. The HBV vaccine consists of the viral S protein produced by yeast genetically engineered to express the viral gene encoding the S protein. Examples of other licensed or experimental recombinant vaccines include the human papillomavirus vaccines (Koutsky et al., 2002; Harper et al., 2004), herpes simplex virus (HSV) vaccines (Corey et al., 1999; Stanberry et al., 2002), a malaria vaccine (Polhemus et al., 2007), and a cytomegalovirus vaccine (Bernstein et al., 2002). Advances in genetic engineering, including reverse genetics (see Chapters 6 and 7), have permitted the development of genetically attenuated experimental viral vaccines including vaccines against HSV (de Bruyn et al., 2006), influenza (Leroux-Roels et al., 2007), dengue (Edelman et al., 2003), and chimeric

TABLE 4.1 Examples of university and hospital contributions to vaccine development

Contribution	Investigators	Institution
Growth of viruses in cell cultures	Enders, Weller, and Robbins	Harvard
Inactivated polio vaccine	Salk	University of Pittsburgh
Inactivated influenza vaccine	Frances	University of Michigan
Oral polio vaccine	Sabin	Cincinnati Children's Hospital
Haemophilus influenza type B vaccine	Smith and Anderson	University of Rochester
Measles vaccine	Enders and Katz	Harvard University
Varicella vaccine	Takahashi	Niigata University
Yellow fever vaccine	Theiler	Harvard/Rockefeller Foundation
Rubella vaccine	Plotkin	University of Pennsylvania
Rabies vaccine	Koprowski	Wistar Institute/University of Pennsylvania
Rotavirus vaccine	Bernstein and Ward	Cincinnati Children's Hospital
Papillomavirus vaccine	Fraser	University of Queensland
Rotavirus vaccine	Clark, Offit, and Plotkin	Children's Hospital of Philadelphia
Papillomavirus vaccine	Reichman, Bonnez, and Rose	University of Rochester

vaccines such as ChimeriVax-Den where dengue genes are incorporated into the yellow fever 17D vaccine virus backbone (Guirakhoo et al., 2006). Genetic engineering also permitted the development of vector systems, including vaccinia virus (Smith et al., 1984), canarypox (Taylor et al., 1994), adenovirus (Graham, 1990), yellow fever virus (Galler et al., 1997), and salmonella (Schödel and Curtiss, 1995; Kwon et al., 2007). These vector platforms are being used in a variety of new experimental vaccines against influenza, human immunodeficiency virus (HIV), Japanese encephalitis, and tuberculosis (Russell et al., 2007; Goonetilleke et al., 2006; Van Kampen et al., 2005; Monath et al., 2003; Xing and Lichty, 2006).

The discovery that the intramuscular injection of a DNA plasmid coding for an immunogenic protein could elicit an immune response to the encoded protein (the so-called genetic immunization) led to the development of DNA vaccines (Tang et al., 1992; Ulmer et al., 1993). The application of the DNA vaccine platform to the development of vaccines for biodefense and emerging and neglected diseases is reviewed by Lu and colleagues in Chapter 8. The extension of the discovery of genetic immunization has permitted antigen discovery through immunization with expression libraries of pathogen DNA (Barry et al., 1995).

An early recognition (Avery and Goebel, 1929) that linking a poorly immunogenic carbohydrate antigen to a more potent protein antigen increased the immunogenicity of the carbohydrate antigen formed the basis of conjugate vaccines (Rappuoli, 2001). Application of this discovery has led to the development of vaccines that protect against infections caused by *Haemophilus influenzae* type B (Heath, 1998) and selected serotypes of *Streptococcus pneumonia* (Oosterhuis-Kafeja et al., 2007) and *Neisseria meningitides* (Keyserling et al., 2006).

Recent discoveries in the area of basic immunology concerning toll-like receptors and control of innate immunity (Kopp and Medzhitov, 1999) is providing a framework for understanding adjuvant mechanisms of action (Kwissa et al., 2007) and rational adjuvant discovery programs (Hauguel and Hackett, 2008), which will ultimately lead to vaccines with improved immunogenicity.

CONCEPT DEVELOPMENT

Concept development is a complex and iterative process that examines the technical and marketing issues relevant to a proposed new product. In general, the process should produce a product profile, identify essential technology with assessment of intellectual property issues and evidence supporting feasibility, address manufacturing issues, and examine market need. In general, organizations involved in product development have somewhat different approaches to the process of concept development. This phase of the vaccine development pathway has been described by some as the "Fuzzy Front End," the stage of the development process between when an idea is first considered and when it is determined to be ready for development (Koen et al., 2001).

CREATE PROTOTYPE PRODUCT

The creation of the prototype vaccine is a critical step in the development pathway. This stage not only demonstrates the technical feasibility of producing the product but should also lay the groundwork for meeting the regulatory requirements that will later be required for a U.S. investigational new drug (IND) or European clinical trial application (CTA), and ultimately licensure. Elements considered in prototype development include production of vaccine components and formulation with an eye toward eventual scale-up and manufacturing, and use of components that will meet regulatory requirements such as those outlined in U.S. FDA guidance documents such as, "Characterization and Qualification of Cell Substrates and Other Biological Starting Materials Used in the Production of Viral Vaccines for the Prevention and Treatment of Infectious Diseases" or "Considerations for Plasmid DNA Vaccines for Infectious Disease Indications" (see Chapters 13 and 14). Industry is well attuned to addressing early the regulatory requirements that will delay or derail the downstream product development; academic scientists, however, are generally less aware of the requirements to get a vaccine to licensure and prototype vaccines developed in a research laboratory may lack detailed information on the derivation and passage history of cell cultures, media used, use of materials from bovine sources, testing for adventitious agents, and origin and history of viral or bacterial agents used in the development of the prototype vaccine. Lack of attention to meeting downstream regulatory requirements can be costly both in terms of time and money. Sufficient quantities of the prototype vaccine are prepared, ideally under conditions that meet good laboratory practices (GLP) (US Food and Drug Administration, http://www.fda.gov/ora/compliance_ref/bimo/glp/default.htm) (see Chapter 10), and the prototype vaccine then moves to the preclinical assessment phase.

PRECLINICAL ASSESSMENT

Before entering clinical trials, prototype vaccines are tested to evaluate safety (toxicology), immunogenicity, and, when possible, efficacy. Toxicology testing must be conducted in a GLP-compliant laboratory and ideally the immunogenicity and animal efficacy studies also conducted under GLP. Nonclinical safety assessment includes tests to determine the direct toxicity of the product, the lack of contaminants, impurities, and adventitious agents, and the potential of the vaccine to trigger preexisting conditions (Verdier, 2002). In general, vaccine toxicology is assessed in single- and repeat-dose studies in two mammalian species, typically one rodent and one non-rodent (often a nonhuman primate). The vaccine is usually given by the route of administration planned for clinical use and tested at the maximum proposed human dose. The repeat dose studies typically include one dose more than anticipated for use in humans, e.g., if a three-dose regimen is planned for human studies then animal studies would examine the safety of a four-dose regimen. The repeat-dose studies are aimed at determining a no-observed-adverse-effect-level (NOAEL). The toxicology assessments generally include mortality, clinical signs, food consumption, body weight, clinical chemistry, hematology, gross pathology, and histopathology. Vaccines intended for pregnant women require genetic and reproductive toxicology studies (Verdier et al., 2003). The other product-specific tests may be required such as potential of a live viral vaccine to establish a persistent infection or of a DNA vaccine to integrate into the host genome. With the development of new vaccine platforms, novel adjuvant systems, and unique delivery systems it is likely that expanded safety testing will be required (Brennan and Dougan, 2005). As one might expect, the more detailed the studies, the longer it takes for a vaccine to reach licensure.

Preclinical immunogenicity testing determines the ability of the experimental vaccine to induce humoral and/or cellular immune responses, and this will be developed into correlate(s) of protection. In the case of most vaccines developed to date, this has revolved around neutralizing antibodies. The types of assays to be used may include well-established tests previously used in the development of licensed vaccines or new, yet-to-be validated assays. Ultimately, this will become a surrogate of protection. In general, the animal immunogenicity testing should use the same assays that will be used in the clinical trials.

Demonstration of efficacy in relevant animal models lends strong support for advancing a vaccine to evaluation in humans. Ideally the animal model utilizes the human pathogen and appropriate routes of challenge, e.g., intravaginal or ocular inoculation with HSV rather than injection of the virus into the footpad. It is also preferable that the pathogenesis and outcome measures should reflect what is observed in humans (Stanberry, 1991). Under some specific circumstances, animal studies may substitute for human studies in demonstrating vaccine effectiveness. The FDA Animal Efficacy Rule (the so-called Animal Rule), finalized in May 2002, allows for the development and licensure of products where human efficacy trials are not feasible or ethical. Such circumstances exist for many biothreat agents and emerging and neglected infectious diseases where there are insufficient numbers of cases of the disease to undertake efficacy studies. The rule permits the FDA to rely on evidence from animal studies to provide substantial evidence of vaccine effectiveness when the effect is demonstrated in either more than one animal species expected to react with a response predictive for humans, or one well-characterized animal species model (adequately evaluated for its responsiveness in humans) for predicting the response in humans, and when the animal study endpoint is clearly related to the desired benefit in humans (Food and Drug Administration, 2005). To date, no vaccine has been approved under the Animal Rule but there is optimism that this pathway will facilitate the development of products needed for biodefense and for the control of emerging and neglected infectious diseases (Rosenthal and Clifford, 2002; Gronvall et al., 2007).

MANUFACTURING SCALE-UP AND CURRENT GOOD MANUFACTURING PRACTICES (cGMP)

The small quantities of vaccine material required for preclinical studies are generally produced under GLP conditions in research laboratories or pilot plants. Such materials are currently acceptable for clinical trials, although it is probable that in the future vaccine materials intended for use in clinical studies will be produced according to current good manufacturing practices (cGMP). Transitioning from the production of small lots in the laboratory or pilot facilities to large-scale production in manufacturing plants requires extensive planning and specialized expertise, and is resource intense (see Chapter 11). Also, the large-scale commercial production of vaccines must comply with increasingly complex cGMP regulations (Milstien, 2004). In the United States the Food and Drug Administration has the responsibility

for developing and promulgating the regulations, currently detailed in Sections 210 and 211 and applicable parts of Sections 600–680 of the U.S. Code of Federal Regulations (CFR); in Australia, regulations are developed by the Therapeutic Goods Administration; in Canada, by Health Canada; and in Europe, by the European Medicines Evaluation Agency (EMEA). In general, cGMP regulations require the manufacturer to define and follow the conditions and controls required throughout the production process to consistently produce a safe, pure, and potent product that is free of any environmental contamination. Each step of the production process must be documented and validated. Areas included in cGMP regulations include personnel education and training; facility design and maintenance; equipment design, calibration, maintenance, and operation; raw material sources and specifications; aseptic processing; segregation of pre- and post-inactivation steps; safety/purity assessment; potency assessment; analytical laboratory procedures including instrument calibration and maintenance; packaging procedures; and storage and shipping procedures. Because of the global nature of the vaccine industry, the multiple regulatory bodies and rules present increasing challenges to the development and use of new vaccines. To address this growing problem regulatory agencies and manufacturers in the United States, Europe, and Japan established the International Conference on Harmonization (ICH) (Milstien et al., 2006).

INVESTIGATIONAL NEW DRUG (IND) APPLICATION

In the United States in order to initiate clinical studies of a new experimental vaccine the FDA's Center for Biologics Evaluation and Research (CBER) must review and approve an IND application (see Chapter 14 and 13) (Code of Federal Regulations, 2005; Stehlin, 1996; National Institute of Allergy and Infectious Diseases, 2003; Davenport, 1995). The application must contain detailed information regarding the vaccine including the rationale for the vaccine, its production, characterization, purity, safety, animal immunogenicity and efficacy data and any human experience, clinical trial protocols, an investigators' brochure, and any other data relevant to the review (Table 4.2). Upon receipt, the FDA has 30 days to review the IND application. Under the IND the clinical trial protocols must undergo an ethics review and receive approval from an Institutional Review Board (IRB). In the clinical development pathway the candidate vaccine advances through increasingly complex phase 1, 2, and 3 trials.

TABLE 4.2 Elements of an investigational new drug application

The background and discovery of the vaccine
The chemistry, manufacturing, and controls of the vaccine and information on the final product formulation
Documentation of controlled and validated assay results supporting the product characterization including safety, consistency, stability, potency, and lot release criteria for the vaccine
The results of the preclinical (animal) toxicology and immunogenicity studies to support safety and animal efficacy data if available
Any human experience with either the experimental vaccine or similar products
Detailed clinical trial protocols
An investigators' brochure
Any additional information necessary to facilitate review and evaluation

Source: Adapted from http://www3.niaid.nih.gov/daids/vaccine/Science/VRTT/08_Pre-IND.htm.

As part of the IND process all clinical trials are monitored by the FDA and IRB to ensure safety. If safety concerns develop during a study the FDA can put the trial on hold until the concerns are thoroughly investigated and the issues resolved (Miller and Ross, 2005).

CLINICAL ASSESSMENT (PHASE 1, 2, AND 3 TESTING)

The pre-licensure evaluation of vaccines in humans proceeds in a stepwise manner through an increasingly complex series of clinical trials (see Chapters 12 and 14). The first studies, referred to as phase 1 trials, are safety and immunogenicity studies performed in a small number of closely monitored healthy volunteers. These are generally short-term studies that may examine a range of vaccine dosages. The study design may be uncontrolled open label or more often are randomized, double blind, and placebo controlled. Inclusion of a placebo group is important in assessing adverse events that may occur during the trial. Phase 2 studies involve larger numbers of healthy volunteers, possibly volunteers at risk for the target disease. The design may examine optimum dosage and dosing regimen, and focus on safety and immunogenicity, although depending on the prevalence of the target disease some efficacy data may be collected. These larger sample sizes provide greater power to detect less common adverse events. Phase 2 trials are randomized, blinded, and placebo controlled. Phase 3

trials may enroll hundreds to thousands of individuals depending on the prevalence of the target disease. Generally, thousands of volunteers are included in phase 3 trials in order to assess for rare adverse events. The phase 3 trials must be randomized, double blinded, and placebo controlled. Two large studies, or under some circumstances a single, large, multicenter phase 3 field trial designed to demonstrate the efficacy of the vaccine against the target disease is pivotal for licensure. As was discussed earlier, for target diseases that are rare, or where clinical trials cannot be ethically conducted, the FDA has promulgated an alternative pathway that substitutes efficacy data from relevant animal models but still requires extensive human safety data (Food and Drug Administration, 2005).

Throughout the world, regulatory agencies require that clinical trials be conducted to meet good clinical practice (GCP) standards promulgated by the ICH. GCP is an ethical and scientific quality standard for designing, conducting, recording, and reporting trials that involve the participation of human subjects. The standard was developed to provide the public assurance that the rights, safety, and well-being of subjects participating in clinical trials are protected and that the clinical trial data are credible (FDA (CBER), 1996).

BLA-LICENSURE

Following successful completion of the clinical trial program, the next step in the vaccine development pathway is submission of a Biologics License Application (BLA) (FDA (CBER), 2007). The applications are expected to contain all the information necessary for the FDA's multidisciplinary review team to evaluate the product safety and efficacy so as to make determination of the vaccine's risks and benefits. According to the U.S. federal regulations licensure requires that vaccines demonstrate safety, purity, and potency (see Chapter 14). During the BLA review process, the FDA conducts a pre-approval inspection of the planned manufacturing facility with detailed examination of the manufacturing processes and GLP compliance. In considering the application, the FDA may also conduct audits of the IND clinical studies, including site visits, to evaluate the conduct of studies and to ensure satisfactory record keeping. During the licensure process advice regarding the safety and efficacy of the vaccine for the proposed indication may be sought from the FDA's Vaccines and Related Biological Products Advisory Committee (VRBPAC), an independent panel of 12 experts. Adequate product labeling is a requirement for vaccine licensure. The labeling should permit health care providers to understand the vaccine's proper use, its potential risks and benefits, information to be conveyed to patients and parents, and how to safely deliver the vaccine.

Because the safety of a vaccine may not be apparent until it is used widely in the population, FDA approval of the new product may be contingent upon the conduct of phase 4 studies, also referred to as postmarketing studies.

IMMUNIZATION RECOMMENDATIONS/ IMPLEMENTATION

In the United States, after the FDA has licensed a new vaccine several committees of experts make recommendations to health care providers and public health programs for use of the vaccine. The committees of experts include the Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention, the Committee on Infectious Diseases (COID) of the American Academy of Pediatrics (AAP), and the American Academy of Family Physicians (AAFP) Commission on Clinical Policies and Research (CCPR). These committees independently assess the evidence to recommend what populations should receive the vaccine, at what ages, the number of doses and dosing interval, and precautions and contraindications (National Network for Immunization Information, www.immunizationinfo.org/immunization_policy_detail.cfv?id = 41#3).

The ACIP consists of 15 experts in immunization-related fields. Members are appointed by the Secretary of the U.S. Department of Health and Human Services. Their role is to provide advice and guidance to the Secretary, the Assistant Secretary for Health, and the Centers for Disease Control and Prevention (CDC) on the control of vaccine-preventable diseases. The ACIP is the only entity in the federal government that makes immunization recommendations (Centers for Disease Control and Prevention, www.cdc.gov/vaccines/recs/ACIP/default.htm). The Director of CDC (and/or the Secretary of Health and Human Services) makes immunization recommendations after consideration of the advice provided by the ACIP. These are then published in the CDC publication MMWR. Individual states consider the ACIP recommendations when setting their vaccine policies.

The AAP's COID (also called the "Redbook Committee") develops and reviews policy recommendations on the use of vaccines. Members of the committee are pediatricians selected by the AAP leadership for their knowledge of infectious diseases and

expertise in vaccines. The recommendations by the COID are approved by the AAP leadership before publication in the Report of the COID (also known as "The Red Book" of the AAP).

The AAFP CCPR is a commission whose members are selected by the AAFP leadership for their scientific knowledge of conditions seen in family medicine. The CCPR meeting includes a liaison from AAP's COID. Recommendations by the CCPR are approved by the AAFP leadership before publication and promotion to AAFP's members.

Similar groups of experts advise and assist in the development of recommendations in other counties and for the World Health Organization.

POST-MARKETING SURVEILLANCE

Until a vaccine has been widely used in the general population rare or uncommon adverse events may be unrecognized. In many countries surveillance programs have been developed in order to identify problems that may develop following licensure and marketing. In the United States, the FDA may mandate specific post-marketing studies as part of the licensure agreement. In addition, the U.S. government has developed the vaccine adverse event reporting system (VAERS) and the vaccine safety datalink to identify problems after marketing has begun (Jacobson et al., 2001; National Network for Immunization Information, www.immunizationinfo.org/vaccine_safety_detail.cfv?id = 106; National Network for Immunization Information, www.immunizationinfo.org/vaccine_safety_detail.cfv?id = 35). The effectiveness of the VAERS system is illustrated by its success in detecting unexpected cases of intussusception associated with rhesus rotavirus vaccine, Rotashield®, which were eventually determined to have occurred at a rate of less than 1 in 10,000, and which in turn quickly led to the withdrawal of the vaccine (Centers for Disease Control and Prevention (CDC), 2004).

OUTLINE

ABSTRACT

The use of vaccination as a strategy to reduce the impact of disease on society has a long-standing history of success, particularly for viral and bacterial-mediated diseases. The demand for safe and effective vaccine products is increasing due to the potential use of biothreat agents, and the emergence and reemergence of various pathogens. The implementation and use of vaccines in immunologically naive recipients in outbreak settings places extraordinary demands on the timing of the onset of immunity in a relatively broad population base, including those populations which may not always be ideal for delivery of vaccines (e.g., neonates, pregnant women, and the elderly). Each of these populations has its own unique demands for the induction of protective immunity and safety. For example, changes in immune function are present as the immune system matures or declines in neonates and the elderly, respectively. In addition, alterations in hormonal status and to functional changes necessary to accommodate the developing fetus are factors in the scheme used to promote immediate development of effector cells plus the capacity to induce long-term memory pools in pregnant women.

The development of immunologic memory is the standard for disease prophylaxis and the basis for most protective vaccines with the induction of both T-cell responses (CD4 and/or CD8 responses) and the production of neutralizing antibody. The kinetics of induction of primary adaptive immune responses in immunologically naive subjects is dictated by many factors including cell cycle transit time to increase the frequency of antigen-reactive cells and the relative rate at which effector cells acquire partial or full functional activities. Memory responses in B- and T-cell compartments are influenced by the phenotype, frequency, and persistence of cells over time (Robinson and Amara, 2005). Generation of effector and memory T cells, which contribute to both humoral and

cell-mediated immune responses, requires antigen processing and presentation by cells of the innate immune system on class I or class II major histocompatibility molecules (MHC). In addition, the production of essential cytokines, crucial for early steps in the differentiation of lymphocytes is necessary for the generation of effector and memory T cells. An understanding of how the immune response status is altered from the "normal state" during different physiological states (e.g., pregnancy, lactation, growth), stages of maturity, and nutritional levels is necessary in order to develop effective and safe memory responses.

INTRODUCTION

Vaccination is a low-cost and effective strategy for the prevention and therapeutic reduction of infectious diseases. Protective host responses encompass the spectrum from adaptive humoral and cell-mediated immune responses in concert with a robust innate immune response (Table 5.1). The generation of secondary antibody responses as a result of natural exposure or vaccination can be attributed primarily to distinct populations of cells, short- and long-lived antibody-secreting plasma cells, and memory B cells (McHeyzer-Williams and McHeyzer-Williams, 2005; McHeyzer-Williams and Ahmed, 1999). Both T-dependent (T-D) and T-independent (T-I) pathways may be operational depending on the vaccine type (Table 5.2). T-I responses are generated via B-1, marginal zone cells, and dendritic cells (DC) (Vos et al., 2000; Mond et al., 1995a, b). B-1 responses generate rapid antibody responses and are partially dependent on innate-derived factors such as cytokines and pathogen-associated molecular pattern receptors (PAMPs) (Baumgarth et al., 2005). B-1 cells develop relatively low affinity responses (Herzenberg et al., 2000). Recent studies in mice suggest that B-1a cells account for much of the natural antibody produced as a component of innate defense, and B-1b cells are capable of generating anamnestic responses to vaccination with *Streptococcus pneumonia* (Haas et al., 2005). A linkage between DC and T-I B cell responses reinforces the need to enhance DC targeting for both T-I and T-D antibody responses (Austin et al., 2003; He et al., 2007; Litinskiy et al., 2002). T-I responses in neonates have also been shown to be less robust relative to adults (Adkins et al., 2004). Developments in our understanding of T-I immunity and the potential to generate vaccines that can generate rapid serum neutralizing antibody responses in addition to anticarbohydrate responses would represent major advances in the development of vaccines for biodefense applications and for several pediatric diseases. T-D responses rely on the coordinated interaction of T helper cells and B-2 cells at specific sites within lymphoid tissues (Randolph et al., 1999; Vinuesa et al., 2005; Cyster, 1999, 2003). Human neonates exhibit delayed T-D responses that are both qualitatively (isotype) and quantitatively different relative to adults (Adkins et al., 2004; Elliott et al., 2000; MacLennan et al., 1997; Gray et al., 1994; Inaba et al., 1983).

Studies in the T-cell compartment have shown that the memory population of $CD4^+$ and $CD8^+$ T cells can be subdivided into two populations: (1) effector memory T cells (T_{EM}) and (2) central memory T cells (T_{CM}) (Northrop and Shen, 2004). $CD4^+$ T cells can be subsetted based on surface phenotype, anatomical distribution,

[b] T-dependent antibody response.
[c] cell-mediated immune response conferred by cytolytic T cells.

and immune function. T_{EM} express low levels of CD62L, CCR7, and CD27, and are primarily found in the peripheral tissues such as the lung and liver. T_{CM} express high levels of CD62L, CCR7, and CD27, and are found in secondary lymphatic organs. T_{EM} are capable of producing effector cytokines immediately upon antigen recognition, whereas T_{CM} have greater proliferative potential upon restimulation. It has been hypothesized that T_{EM} confer immediate protection, whereas T_{CM} are a reservoir for generating a large pool of secondary effectors upon a second encounter with the pathogen. As recently reviewed by Reiner et al. (2007), the outcome of T-cell differentiation is dictated by many factors including costimulation, cytokines, antigen concentration, the relative frequency of antigen-specific T cells, and antigen presenting cells (DCs). T effector cells needed for an immediate response post vaccination can also be heterogeneous in terms of their activities, including cytokine production (e.g., Th1, Th2, Th17, or T regulatory cells). Additional cell populations have been defined, including follicular Th cells that produce IL-10 and IL-21 (Vinuesa et al., 2005), and IFN-γ and IL-10 (O'Garra and Vieira, 2007) or IFN-γ and IL-17 (Ivanov et al., 2006).

NEONATAL RESPONSES TO VACCINATION: LESSONS FROM ANIMAL MODELS

It is generally assumed that the immaturity of the neonatal immune system contributes to an increased susceptibility of the young host to infectious disease, limiting its capacity to develop a protective response to vaccination. Several differences between the neonatal and adult immune response have been identified. The mechanisms governing these differences, however, are not yet fully understood. Certain differences that have thus far been characterized include the observation that the neonatal T-cell population is abundant with a greater proportion of naïve T cells that can suppress immunoglobulin (Ig) production (Clement et al., 1990). Neonates also have higher proportions of antigen-presenting cells with defective costimulatory activity (Ridge et al., 1996). Importantly, the neonatal immune compartment is lymphopenic at birth. Lymphocyte development is a relatively late event in murine fetal development. At birth, the murine neonate has substantially fewer T cells in peripheral lymphoid organs including the lymph node and the spleen, and adult percentages of $CD4^+$ T cells are not reached in these organs until day 7 and 15 of age, respectively (Garcia et al., 2000). It has been shown recently that the neonatal environment supports lymphopenia-driven proliferation of $CD4^+$ T cells, resulting in an expansion of $CD4^+$ T cells with memory phenotypic and functional characteristics by the 17th day of life (Min et al., 2003). This lymphopenia-driven proliferation may equip the neonate with a large repertoire of memory cells (Min et al., 2003).

Although maternally derived immune factors, such as immunoglobulin, provide early protection to the neonate, they may interfere with postnatal activation of the neonate's immune system and its capacity to mount a protective response to vaccination or infection (Barrington and Parish, 2001; Endsley et al., 2003; Glezen, 2003; Siegrist, 2003). In humans, inhibition of the infant's responses to vaccination by maternal antibody is B-cell-specific, depends on antibody titer and dose of vaccine antigen, and does not appear to influence T-cell responses (reviewed by Siegrist, 2003). For example, neonatal calves fail to develop Ig responses to *Brucella abortus* if antigen-specific maternal Ig is present at the time of vaccination (Husband and Lascelles, 1975). Colostrum-deprived calves, however, produce relatively robust antibody responses to *B. abortus*. In addition, neonatal calves sensitized to ovalbumin (OVA) (an antigen to which there was no maternal Ig) at birth mount humoral responses similar to older cattle, regardless of colostral status (Husband and Lascelles, 1975). In addition, calves given a bovine viral diarrhea virus vaccine fail to develop a primary humoral response, but do generate memory B cells, in the presence of maternal Ig (Endsley et al., 2003). Likewise, neonatal calves vaccinated with *M. bovis* BCG fail to mount antigen-specific humoral responses, but calves do generate certain in vitro B cell responses to BCG following vaccination (Foote et al., 2007). These results suggest that although maternal Ig may block endogenous Ig production, B cells retain other functional capacities (i.e., differentiation into memory B cells.).

The altered immune reactivity of the neonate may reflect the demands of in utero conditions and the need to avoid unwanted reactivity in this environment (Levy, 2005; Levy et al., 2004). This idea is supported by observations indicating that neonatal immune cells frequently have a reduced ability to produce proinflammatory cytokines. For example, neonatal immune cells produce less TNF-α and IFN-γ in response to lipopolysaccharide (LPS) relative to adult PBMC (Levy et al., 2004; Yan et al., 2004).

Protective adaptive immunity requires an appropriate balance between Th1 and Th2 responses. Th1 cells secrete inflammatory cytokines (e.g., IFN-γ, lymphotoxin, and TNF-α) that activate components of the innate and adaptive immune system to defend against intracellular pathogens. In contrast, Th2 cells secrete cytokines (e.g., IL-4, IL-5, IL-13) that are

generally antiinflammatory in nature and are important for evoking potent humoral (i.e., antibody) immune responses. Neonates are capable of developing mature inflammatory responses characterized by adult-level Th1 and CTL functions following antigenic exposure under potent Th1-driving conditions, such as complete Freund's adjuvant (reviewed in Adkins et al., 2004). More often, however, neonates develop strong Th2 responses to antigenic stimulation (reviewed in Min et al., 2003; Siegrist, 2000; Adkins, 2000). For example, neonatal mice immunized with the protein antigen KLH develop responses characterized with enhanced in vitro production of IL-4 and in vivo production of IgG1 (Adkins et al., 2003b; Adkins and Du, 1998). This phenomenon has been well established for recall responses. Mice initially immunized as neonates mount Th2-dominant memory recall responses as adults. Early development of Th2-dominant primary responses by $CD4^+$ cells likely contributes to observed Th2-dominant memory responses (Adkins et al., 2003a). The mechanisms governing the neonatal Th2 bias are now coming to light. Studies suggest that IL-4 production by neonatal T cells drives apoptosis of Th1 cells, thus skewing the neonatal recall or secondary response to Th2 (Li et al., 2004). In addition, new data suggest that developmental-specific epigenetic phenomena occurring at the Th2 locus contribute to the Th2 bias (Rose et al., 2007). The Th2 regulatory region CNS-1 preexists in a hypomethylated state in neonatal naïve $CD4^+$ T cells and $CD4^+$ thymocytes, suggesting that neonatal T cells are poised for rapid Th2 effector function (Rose et al., 2007).

Data in support of a Th2 bias in human neonates, indicate that human-cord-blood-derived DC, essential for priming and differentiation of naïve T cells into Th1 cells, have a profound defect in the expression of the Th1 cytokine, IL-12 (Goriely et al., 2001). Responses of human infants to viral vaccines are also characterized by reduced IFN-γ secretion and elevated serum antibody titers (Ota et al., 2004; Vekemans et al., 2002). Consequences of a Th2-biased response may include a reduced capacity of the neonate to respond effectively to vaccines that rely on a Th1 response for their efficacy. In contrast, vaccination of human newborns with *M. bovis* BCG, a potent Th1-driving stimulant, induces a potent Th1 response characterized by adult-like IFN-γ responses and reduced secretion of IL-4 and IL-5 by $CD4^+$ lymphocytes (Marchant et al., 1999; Vekemans et al., 2001). Similarly, studies indicate that the dairy calf, like the human infant, can generate an adult-like Th1 response when vaccinated during the first week of life with *M. bovis* BCG (Buddle et al., 2003; Nonnecke et al., 2005). In addition, vaccination of the neonatal calf with *M. bovis* BCG provides protection upon subsequent challenge (Buddle et al., 2003). *M. bovis* BCG is routinely administered to newborns for the prevention of tuberculosis, and human trials will ultimately be conducted in this population. It is therefore essential to determine safety and efficacy of candidate vaccines in this target population. Importantly, the neonatal bovine may provide a useful model for the development of efficacious tuberculosis vaccines.

Studies carried out in newborn mice demonstrate that DNA vaccines induce adult-like, protective $CD8^+$ T-cell responses to LCMV (Zhang et al., 2002). Likewise, DNA vaccination of nonhuman primates induces significant humoral and cellular immunity to influenza (Bot et al., 2001). Thus, genetic immunization is an appealing strategy to both prime and boost immune responses against pathogens in the neonate. A more developed understanding of the immunomodulatory properties of genetic immunization are needed to enhance the prospects of effective vaccines based on this platform in nonrodent species.

Protein-energy malnutrition (PEM) is the major cause of immunodeficiency worldwide (Delafuente, 1991), and is still a major concern in developing countries, particularly in young children. It has negative effects on both innate and adaptive immunity (reviewed by Woodward et al., 1999). Substantial evidence supports the negative effects of PEM on adaptive immune responses. The lymphoid involution (decrease in size and cellularity of secondary lymphoid organs) that occurs in wasting PEM is considered contributory to PEM-associated immunodepression (Woodward et al., 1999; Lee and Woodward, 1996). Lymphoid involution associated with PEM is characterized by drastic decreases in mononuclear cell numbers in blood, spleen, and mesenteric lymph nodes (Lee and Woodward, 1996). A low $CD4^+/CD8^+$ T-cell ratio in the blood has been commonly associated with PEM in humans and weanling mice (Chandra, 2001, 2002). However, imbalances within, rather than between, the two main T-cell subsets may be of greater importance. In mice, wasting PEM is associated with an overabundance of $CD4^+CD45RA^+$ T cells ($CD4^+$ naïve phenotype) and $CD8^+CD45RA^+CD62L^+$ T cells ($CD8^+$ naïve phenotype) that are quiescent compared with $CD45^-$ effector and memory phenotypes (Woodward et al., 1999; ten Bruggencate et al., 2001). In addition, wasting because of severe protein deficiency decreases proliferation and expression of IFN-γ, IL-2, and IL-2 receptor mRNA by splenic mononuclear cells (Mengheri et al., 1992). PEM also affects humoral responses negatively. Mucosal secretory IgA antibody responses are more sensitive to wasting than systemic humoral immunity, leading to the hypotheses that

PEM affects epithelial IgA transport (Chandra, 1991, 1993; Chandra and Sarchielli, 1993).

Obesity also has been associated with decreased immune function. In developed countries, the United States in particular, obesity has become an epidemic, affecting even children. Thirty-eight percent of obese children and adolescents show impairment of cell-mediated immune (CMI) responses including decreased DTH, abnormal lymphoproliferative responses to mitogens, and decreases in bacterial killing by neutrophils (Chandra and Scrimshaw, 1980). Obesity also has been related to elevated leukocyte and lymphocyte subsets (excluding NK and cytotoxic/suppressor T cells), lower T- and B-cell mitogen-induced lymphocyte proliferation, but increased phagocytosis and oxidative burst activity by monocytes and neutrophils (Nieman et al., 1999). An additive negative effect of obesity and old-age on immune function has also been reported (Moriguchi, 1995, p. 169).

Immune responses to vaccination with *M. bovis* BCG have been characterized well in the bovine (Nonnecke et al., 2005; Maue et al., 2004). Sensitization to *M. bovis* BCG and elicitation of recall responses (i.e., IFN-γ and NO) by mycobacterial antigen (i.e., PPD) have been used to model CMI responses in cattle (Fiske and Adams, 1985; Nickerson and Nonnecke, 1986; Nonnecke et al., 1986). Recent studies have investigated the effects of protein and energy status on adaptive immune responses in neonates using this BCG/PPD model in cattle (Foote et al., 2005, 2007).

Neonatal life is a unique period with regard to immune function and development. Additional studies are needed to elucidate what specific immune-related deficiencies exist as the neonate develops, and when each of these components is fully functional. The neonatal bovine may provide a useful model, particularly with regard to development of efficacious tuberculosis vaccines. Vaccination strategies that are designed to boost immunity of neonates must consider that the immune system is continuously changing during development. Strategies to enhance the immune response to vaccination must not only be properly targeted, but also be appropriate for the stage of immune development in order to avoid unwanted effects, such as the generation of an ineffective or negative response (i.e., the potential for development of tolerance or induction of self-reactivity).

CHAPTER

6

Molecular Approaches to Bacterial Vaccines

Vladimir L. Motin and Alfredo G. Torres
Departments of Pathology and Microbiology and Immunology,
Sealy Center for Vaccine Development, University of Texas Medical Branch,
Galveston, TX, USA

OUTLINE

ABSTRACT

Recent advances in molecular techniques provided a whole-genome perspective in designing novel and improving existing vaccines against bacterial infections. However, a tremendous amount of information derived from genome sequencing, comparative genomics, microarrays, proteomics, and other large-scale technologies is still not completely utilized to provide a systematic mining of new virulence determinants and prospective vaccine candidates. Therefore, the major task in coming years will be to develop cross-interacting databases which can quickly translate the functional genomic information into potential vaccines. Yet, in many cases, these approaches have already allowed identification of more promising targets than conventional approaches did in the past decades. The bottleneck for moving forward with vaccine technologies resides in the development of high-throughput systems for testing the properties of selected candidate vaccines. However, the more highly developed systems such as bacterial cell surface

display are continuing to be improved. Together with the traditionally used outer membrane protein, fimbriae and flagella displays, novel platforms using autotransporters and lipoproteins have brought additional capabilities for the carriers to expose foreign molecules on the cell surface. Particularly important has been the creation of "second generation" vaccine delivery vehicles for mucosal immunization by the addition of codisplayed adhesins for targeting cells to specific immunoreactive sites. Bacterial peptide display has successfully competed with other epitope mapping techniques and, in combination with protein arrays, proven useful in identification of the entire set of antigens of the pathogen targeted by the immune system. In addition, the development of novel delivery systems has significantly advanced by using intracellular pathogens for genetic immunization. Delivery of DNA vaccine plasmid and even translation-competent mRNA directly to the cytosol of the antigen-presenting cells can be efficiently achieved by self-destructing live bacterial carriers. A bacterial ghost delivery system has become popular for heterologous antigen presentation, and also has been tested for DNA vaccination. Yet another technique, the use of protein secretion systems such as types I, III, and IV, had opened new horizons of using "inverted pathogenicity" for vaccine purposes. Further, genetic approaches have improved the area of identification of essential genes, characterization of functions required for growth under certain conditions (e.g., in vivo–induced), and importantly, in screening methods of direct selection of protective candidates. Finally, several novel stabilization systems for the foreign genes expressed in bacterial carriers have been generated and tested with different vaccine carriers.

REVERSE VACCINOLOGY

The term "reverse vaccinology" was proposed by Rappuoli (2000) and represents a genome-based approach to vaccine development. In comparison with the conventional approach, which requires a laborious process of selection of individual components important for immunity, reverse vaccinology offers the possibility of using genomic information derived from in silico analysis of sequenced organisms. This approach can significantly reduce the time necessary for the identification of candidate vaccines, and enables systematic identification of all potential antigens of pathogens, including those which are difficult or currently impossible to culture. Of course, in limiting analysis to predicted open reading frames (ORFs) of the microorganism, one has to assume that the pathogen can express any of them at a given time. In reality, the knowledge of whether the antigen is expressed in vivo during infection, its abundance and immunogenicity is crucial for determining the feasibility of using this antigen as a vaccine candidate. Moreover, this approach is limited to the identification of protein antigens, omitting such important vaccine components as polysaccharides and glycolipids. Nevertheless, reverse vaccinology can enable us to systemically classify the potential protective antigens, thereby helping to improve existing vaccines and develop efficient preparations virtually against any pathogen that has had its genome sequence determined. With the number of sequenced genomes progressively increasing every year, this approach, combined with recent advances in bioinformatics, comparative and functional genomics and proteomics, will be the method of choice for vaccinology studies at the beginning of the 21st century. The main limitation of this approach is the lack of a high-throughput system to estimate protective immunity of selected candidates.

According to Rappuoli (2000), reverse vaccinology was first successfully applied in the identification of vaccine candidates against serogroup B meningococcus (MenB). For this study, the entire genome sequence of *Neisseria meningitidis* was available, having been computer-analyzed, and in silico-selected vaccine candidates were expressed in *E. coli* followed by immunization of mice and testing of sera for bactericidal activity in vitro (complement-mediated in vitro killing of bacteria). A total of 600 novel genes were predicted to code for surface-exposed or exported proteins, and 350 of them were successfully expressed, purified, and used for immunization. Finally, 25 novel, surface-exposed proteins were shown to induce bactericidal antibodies, and most of these vaccine candidates had not been discovered by all previously used techniques. The foregoing approach has identified more potential vaccine candidates, including lipoproteins or other types of surface-associated proteins without membrane-spanning domains, than conventional approaches did for the past 40 years. A recent review by a group of scientists from Chiron Vaccine, Italy (Scarselli et al., 2005) contains additional examples of successfully applied reverse vaccinology techniques for *Bacillus anthracis*, *Streptococcus pneumonia*, *Staphylococcus aureus*, *Chlamydia pneumoniae*, *Porphyromonas gingivalis*, *Edwardsiella tarda*, and *Mycobacterium tuberculosis*. The most recent publication on this topic described identification of a universal Group B *Streptococcus* (GBS) vaccine by multiple genome screens. Eight sequenced genomes of GBS strains belonging to different serotypes were analyzed to find the genes shared by all strains ("core" genome), as well as genes that were not present in all

strains ("variable" genome). Then the genes encoding the putative surface-associated and secreted proteins were uncovered within two subgenomes (589 total genes). Of these identified genes, 312 were successfully expressed in *E. coli*, and the antigens were purified in a soluble form and used to immunize animals. Four proteins elicited protection in mice, and their combination was highly protective against 12 virulent strains, which represented the major pathogenic GBS serotypes (Maione et al., 2005). In addition to using such newly discovered antigens for vaccine purpose, it is important to characterize these proteins in terms of their biological function. Therefore, the reverse vaccinology approach provides a powerful tool to discover previously unknown proteins that have a significant role in the biology of the microorganism.

The reverse vaccinology approach is hard to imagine without comparative genomics and structural biology of bacterial pathogens. By comparing whole genomes of pathogens with their less-virulent variants, nonpathogenic relatives, unrelated pathogens, and even commensals, it is possible to identify either unique, disease-related genes or conserved vaccine targets. Comparative genomics also provides crucial insight into the evolution of bacterial pathogenesis, and therefore, the vaccine candidates that are selected could be properly evaluated with respect to their antigenic appearance, e.g., in terms of criteria such as phase variation, gene duplication, and tendency to loss rudimentary functions (Scarselli et al., 2005). Comparison of the three-dimensional structures of the proteins implicated in bacterial pathogenesis can provide additional information on the motifs involved in adhesion and host recognition, as well as the mode of action of enzymatic virulence factors, including toxins (Waksman et al., 2005).

FUNCTIONAL GENOMICS AND PROTEOMICS

Recently developed DNA microarrays (or microchips) provided a powerful tool for understanding the complex regulation of the virulence network and selection of vaccine candidates. Ideally, transcriptome (the complete series of mRNA transcripts of an organism) of both pathogen and host should be determined during the course of natural infection. In reality, researchers use a set of in vitro growth conditions that mimic, to some extent, the environment pathogens encounter in the host, the appropriate in vivo models (cell cultures and/or animals), or expression analysis in clinical samples. Meinke et al., recently provided several examples describing the successful identification of new vaccine targets as a result of the use of transcriptional profiling. Among them were previously unconsidered components required for the hyperinfectious state and dissemination of *Vibrio cholerae*, genes of *Streptococcus pyogenes* encoding proteins that mediate invasion of innate defense mechanisms, and genes of *M. tuberculosis* that were differently expressed under acidic conditions resembling a phagosome environment (Meinke et al., 2004). Another review described the use of gene array technology to search for vaccine candidates and new virulence genes after interaction of *N. meningitidis* to human epithelial cells. A wide range of surface proteins were induced under the experimental conditions, and this approach, in combination with reverse vaccinology, could provide novel candidates for a meningococcal vaccine. This review also contains many other examples of the application of functional genomics to bacterial pathogens, including the interactions between intestinal epithelial cells and *Salmonella*, human promyelocytic cells and *Listeria monocytogenes*, bronchial epithelial cells and *Bordetella pertussis*, epithelial cells and *Pseudomonas aeruginosa*, mouse gastric epithelial cells and *Helicobacter pylori*, HeLa cells infected with *Chlamydia trachomatis*, human macrophage response to infection with *M. tuberculosis*, and the response of human intestinal epithelial cells to *Shigella flexneri* invasion (Serruto et al., 2004).

Recently, DNA gene arrays were used to characterize temporal global regulatory changes occurring in the *Yersinia pestis* genome after a temperature shift from 26 to 37°C. Plague bacilli exist in nature at ambient temperature within the flea vector or in the mammalian host at 37°C, and thermoregulated changes likely reflect introduction into these niches. In addition to numerous global regulators, transport systems, and metabolic genes, modulators of innate immunity (e.g., invasins, adhesins, cytotoxins, and inhibitors of proinflammatory cytokines) were found to be thermoregulated. Therefore, differential transcription during temperature shift identified a useful list of putative virulence-associated genes to examine as novel candidates for future research on the control of this pathogen (Motin et al., 2004). Besides identification of novel vaccine targets, microarray technology could be instrumental in understanding which pattern of host response is correlated with protective immunity. Using gene expression profiling in combination with immunohistochemical analysis, the mechanism of protection of a whole-cell sonicate vaccine of *Helicobacter felis* was unraveled (Mueller et al., 2003).

Although transcriptional profiling can shed light on host-pathogen interaction which occurs during the infection state, there is no direct correlation between the level of the transcript and corresponding amount of

synthesized protein. Therefore, a gene array expression study should be, if possible, accompanied by analysis at the protein level. Recent achievements in combining two-dimensional gel electrophoresis and mass spectrometry made feasible the separation and identification of the proteome, a full set of proteins expressed by a genome (Nilsson, 2002). In addition to the use of proteomics in complementation with gene expression profiling, the combination of proteome analysis with serology have already provided the first vaccine candidate antigens. The significant limitation of such proteome analysis is the production of the complete proteome itself, since not all proteins are expressed at given experimental conditions. This bottleneck might be possible to overcome by using recently developed proteome microarray technology which relies on high-throughput amplification of each predicted ORF by using gene-specific primers, expression in an *E. coli*–based, cell-free in vitro transcription/translation system, followed by direct printing of the crude reactions on the microarray slide. Then the protein microarrays could be probed with the sera derived from vaccinated/infected humans and animals to determine a complete antigen-specific profile (Davies et al., 2005). A novel approach for the identification of bacterial vaccine candidate antigens called antigenome technology was recently applied to several bacterial pathogens of the genera *Staphylococcus* and *Streptococcus*. In order to select immunoreactive proteins, peptides of different sizes derived from the bacterial genome were displayed on the surface of *E. coli* via outer membrane proteins and were followed by screening with serum samples against the target pathogen (Meinke et al., 2005). The typical size of antigenome described in these experiments consisted of approximately 100 antigens, most of them surface and secreted proteins (Meinke et al., 2004). Similarly, another in vitro protein selection method, ribosome display, was employed to comprehensively identify and map the immunologically relevant proteins of *S. aureus* (Weichhart et al., 2003). Thus, together with protein arrays and protein display techniques, serological proteomics will allow identification of the entire set of antigens and epitopes (i.e., the immunome) targeted by the immune system and sufficient for protection (Klade, 2002; De Groot, 2004).

BACTERIAL CELL SURFACE DISPLAY SYSTEMS

Surface display of protein structures has two main applications in vaccine development. First, the use of cell surface–exposed heterologous antigens has been always considered beneficial for the eliciting antigen-specific immune response. Although this may not be an absolute truth, live bacterial delivery systems are traditionally used to fulfill this goal. Live vaccines could be loaded simultaneously with different antigens or their epitopes, receptor-specific ligands to change vaccine-targeting sites, and codisplayed adhesins that may increase the efficiency of the immune response. In general, either attenuated pathogens or nonpathogenic commensal or food-grade bacteria are used as live vaccine carriers. The display of different colonization factors on the surface of nonpathogens could be particularly advantageous for mucosal immunization, since these vaccine vehicles do not invade the host. Therefore, the codisplay of adhesins can increase colonization of mucosal epithelium, leading to better stimulation of the local immune response. Second, bacterial surface display expressing various polypeptide libraries has been utilized for mapping of epitope sequences for the antibodies elicited to the particular antigen(s). The use of these systems represents the frequent alternative/complement approach to phage display of random peptide libraries and synthetic peptide-based techniques traditionally employed for epitope mapping. The most common systems for bacterial cell surface display described in two recent reviews on the topic will be listed below (Samuelson et al., 2002; Wernerus and Stahl, 2004).

Gram-Negative Display Systems

Both Gram-negative and Gram-positive bacteria are used to present foreign molecules on their surface. The systems based on former microorganisms appeared earlier and employed outer membrane proteins as carriers for the heterologous peptides or proteins to be displayed. Since integral outer membrane proteins besides membrane-spanning regions contain surface-exposed loops, the task was to identify the "permissive" sites within these loops that can tolerate insertions without the loss of all biological functions. Therefore, there are limitations both with respect to the size and nature of the foreign part (passenger domain) used to modify the carrier protein. The examples of carrier outer membrane proteins which were used to display the passenger amino acid (aa) sequence of different sizes are OmpA (15–514 aa), OprF (17–43 aa), LamB (11–232 aa), OmpS (38–115 aa), and PhoE (8–32 aa). Most of these carrier proteins were expressed in enteric bacteria, and successfully used to elicit a strong immune response to the foreign part, followed by delivery as a live vaccine.

In addition to the outer membrane protein-based constructs tolerating insertions within an internal

permissive site of the surface loop, a more advanced system termed Lpp'OmpA has been developed. This system utilized the N-terminal part of the major *E. coli* lipoprotein (Lpp) and transmembrane region of OmpA to allow delivery of C-terminal fusions on the surface of microbial cell. The Lpp'OmpA construct could display relatively large inserts (up to 40 kDa), while remaining sensitive to secondary and tertiary structures of the passenger. Another example of outer membrane proteins employed for the bacterial display is invasin of *Yersinia pseudotuberculosis*. A decamer random peptide library expressed as a fusion hybrid with the N-terminal part of invasin residing in the outer membrane was screened against human cultured cells. Several clones were identified for their human cell binding ability to human cells, which was mediated by the surface-displayed peptides. This approach could be applied to select antiadhesion agents to use in antiadhesion therapy of bacterial diseases (Ofek et al., 2003). In addition to outer membrane proteins, surface-exposed lipoproteins were tested as bacterial display. Among them were plasmid-encoded lipoprotein TraT involved in conjugation, the peptidoglycan-associated lipoprotein (PAL) from *E. coli*, and ice-nucleation protein Inp of *Pseudomonas syringae* which is attached to the membrane via the glycosylphosphatidylinositol anchor sequence. The mentioned systems have some advantages such as a very high number of copies (>10,000 for TraT), or ability to display enzymes, single-chain antibodies, and intact antigens (Inp system).

Recently, autotransporters have been employed for surface display. Since the autotransporter is an autonomous structure promoting its own transport by assembling a channel in the outer membrane, the system is capable of translocating relatively large segments. The examples of autotransporters that were used for display of heterologous antigens are the IgA1 protease from *Neisseria gonorrhoeae*, VirG of *Shigella*, and AIDA-I adhesin of *E. coli*. Moreover, the foreign protein expressed on the surface by an autotransporter could be released by autoproteolytic cleavage, if necessary. In addition, other systems have been developed which allow cell surface–bound antigens to be subsequently released extracellularly. One example of such a system is pullulanase from *Klebsiella pneumoniae*, which is released to the medium at the stationary growth phase. Finally, filamentous surface structures, such as flagella (major flagellin subunit, FliC) and fimbriae (P fimbrillin of uropathogenic *E. coli* and subunits of Type 1 fimbriae of *E. coli*), have been used for surface display. The common feature of these systems is that the insertion of foreign antigens should not disrupt the biogenesis of the filamentous structures that put significant limitations on the size and conformation of the passenger domains.

Gram-Positive Display Systems

Gram-positive microorganisms have several advantages for surface display applications, since their cells have only a single membrane, there is a common mechanism for surface anchoring, and bacteria can withstand rigorous manipulation conditions due to the thicker cell wall. The display systems of Gram-positive bacteria may be classified into three groups: cell wall–bound, cell membrane–anchored, and cell surface–associated proteins. The examples of the first group (most commonly used) are protein A of *S. aureus*, which has provided the surface exposure of heterologous proteins of various lengths (15–397 aa) in *Staphylococcus* and *Lactococcus lactis*; M6 protein of *S. pyogenes* successfully used for display of 15–438 aa epitopes in *Streptococcus gordonii* and *Lactobacillus*; the surface protein antigen P1 from *Streptococcus mutans* that expresses surface-located 179 aa antigen in *S. gordonii*; and extracellular cell wall–bound proteinase PrtP of *L. lactis* which tolerates the display of 52 kDa tetanus toxin fragment. The representatives of the second group are lipoprotein DppE of *Bacillus subtilis*, which can express a 192 kDa antigen which, however, was not surface-accessible unless the bacterial cell wall was stripped out; autolysin modifier protein CwbA of *B. subtilis*, exposing large 192–497 aa antigen; and *M. tuberculosis* lipoprotein Mtb19 fused with ~31 kDa outer surface protein A (OspA) of *Borrelia burgdorferi* and expressed on the surface of the *Mycobacterium bovis* strain bacilli Calmette-Guerin (BCG). Examples of the third group are the beta-D-fructosyltransferase Ffts of *Streptococcus salivarius*, which has been expressed as a carrier of heterologous proteins in *S. gordonii* and subsequently released from the surface when desired; and S-layer proteins EA1 and Sap of *B. anthracis* containing S-layer homology motifs (SLH) and stably expressing SLH-fused ~50 kDa antigen on the surface of *B. anthracis*.

NOVEL DELIVERY SYSTEMS

Listeriolysin O (LLO)

A novel approach for eliciting a cytotoxic T-cell response has been developed using *L. monocytogenes* (LLO). LLO is a pore-forming hemolysin which allows *L. monocytogenes* to escape from the phagolysosomal environment into the host cell cytosol by lysis of the

phagosomal membrane. Therefore, the incorporation of LLO into vaccine formulations provides access to the cytosol of professional antigen-presenting cells (APC) by vaccine components, an activity that is crucial for MHC class I presentation of antigen. LLO was tested in combination with purified protein antigens, attenuated bacterial vaccine strains, DNA vaccines, and the contents of liposomes. Coadministration of LLO with the model antigen chicken ovalbumin resulted in efficient presentation of epitopes of this antigen, together with MHC class I molecules. Similarly, LLO introduced the nucleoprotein of influenza virus and beta-galactosidase directly into the host cell cytosol. Introduction of secreted LLO in attenuated live vaccine carriers such as *Salmonella*, mycobacteria (BCG), vaccinal strain of *B. anthracis*, and *E. coli* expressing recombinant antigen stimulated a class I–restricted $CD8^+$ T-cell response (Dietrich et al., 2001).

Genetic Vaccination

Genetic vaccination is a promising new technology that has emerged in recent years. In general, DNA vaccines are composed of bacterial plasmids encoding antigens under the control of strong eukaryotic promoters. Typically DNA vaccines are injected intramuscularly or intradermally in their naked form and induce antigen-specific humoral and cellular immune responses. However, delivery of DNA vaccine plasmids into mammalian cells by intracellular bacteria (bactofection) might allow more specific targeting of a variety of host cells, including professional APCs. In most cases, bacteria used as DNA vaccine carriers are attenuated pathogens which can be classified into three categories: extracellular pathogens (some strains of *E. coli*, *Yersinia* spp.); intraphagosomal pathogens (*Salmonella* spp.); and intracytosolic pathogens (*Shigella* spp., *L. monocytogenes*). *Y. enterocolitica* is an extracellular enteropathogen multiplying in abdominal lymphoid tissue. Normally, the pathogen is resistant to phagocytosis due to the presence of a virulence plasmid-encoding type III secretion system. Nevertheless, a virulence plasmid-cured variant could be phagocytosed by APC, thus providing a basis for the DNA vaccine delivery. *Salmonella* cells can promote their own uptake into phagocytes and avoid the killing mechanism of phagocytes following internalization. Virulent strains will multiply in the phagosomal compartment. However, attenuated live vaccine carriers of *Salmonella* die there, resulting in release of the DNA vaccine vectors into the phagosome and consecutively from the phagosome via phagosomal leakage into the cytosol. Upon invasion of APC, *Shigella* spp., unlike *Salmonella* spp., can rapidly escape from endocytic vacuoles to the cytosol of the mammalian cell. Therefore, attenuated vaccine carriers, which are lysed in the cytosol, can deliver the plasmids directly to this intracellular compartment. *L. monocytogenes*, the only Gram-positive carrier for bacterial DNA vaccine, can multiply within the cytosol and disseminate through tissue by intercellular spread. Like the *Shigella*-based vaccine delivery platform, *Listeria* carriers deliver DNA vaccine to the cytosol of a broad spectrum of host cell types. The nonpathogenic bacterium *Bifidobacterium longum* (found in the lower small intestine of humans) and *Agrobacterium tumefaciens* (soil plant pathogen) are also tested as DNA vaccine delivery systems. It is important to mention that both effective invasion of host cells and escape of the bacterial carrier from the phagosome are crucial for efficient DNA vaccination. When a noninvasive laboratory strain of *E. coli* used for DNA vaccination was modified to express the *inv* gene (invasin) of *Y. pseudotuberculosis*, DNA transfer occurred more efficiently. Likewise, inactivation of *L. monocytogenes* genes involved in invasion led to a reduced ability of the *L. monocytogenes*–based carrier to deliver DNA vaccine. To promote phagosomal escape, *Salmonella* carrier strains were created, either to secrete LLO or to produce a pore-forming hemolysin from *E. coli*, and this alteration improved gene transfer efficacy. Moreover, most of the bacterial carriers for DNA vaccination were designed to lyse when bacteria entered the host cell. The impaired cell wall synthesis (*Shigella*, *Salmonella*, invasive *E. coli* carriers) and production of a phage lysin (*Listeria*) are the common ways to achieve specific autolysis of the bacteria into the cytosol compartment (Loessner and Weiss, 2004; Schoen et al., 2004).

One of the major limiting factors in using bacterial carriers for DNA vaccination is the import of plasmid DNA from the cytosol into the nucleus where the expression takes place. The nuclear membrane represents a significant barrier for efficient gene transfer. Recently, a self-destructing *L. monocytogenes* carrier was used to release translation-competent messenger RNA (mRNA) directly into the cytosol of epithelial cells, macrophages, and human dendritic cells. The transfer of functional mRNA into mammalian cells using a bacterial carrier represents a totally novel delivery system for vaccine development (Schoen et al., 2005).

Bacterial Ghost System

The bacterial ghost (BG) system is another example of a recently developed antigen delivery vehicle. To produce BG of Gram-negative bacteria, the controlled

nondenaturing method of lysis by the PhiX174 bacteriophage protein E was used. Protein E can form a specific lysis tunnel spanning the whole cell wall complex through which the cytoplasmic content of the cell is expelled. The resulting BG is generally free from nucleic acids, ribosomes, and other intracellular components; however, outer and inner membranes largely remain intact. In contrast to heat, irradiation, or chemical inactivation of pathogens for vaccine purposes, BG preserves its native antigenic structure, and LPS and peptidoglycan retain their immunostimulatory activity, while production and storage of BG can be achieved at low cost. This attractive platform has been adapted for antigen delivery by insertion of the antigens into the BG envelope. The BG system has been applied for envelope and/or heterologous antigen presentation of many medically important bacterial agents such as *V. cholerae*, pathogenic *E. coli*, *Salmonella* spp., *Actinobacillus pleuropneumoniae*, *Francisella tularensis*, *Brucella melitensis*, *Bordetella bronchiseptica*, etc. (Mayr et al., 2005). BG has also been successfully tested as a platform technology for DNA delivery following the loading of lyophilized BG in the DNA-containing buffer or by developing a procedure for the targeted immobilization of plasmid DNA in the cytoplasmic membrane of the carrier (Mayrhofer et al., 2005; Paukner et al., 2005).

Inverted Pathogenicity

The "inverted pathogenicity" concept means the use of virulence mechanisms for prevention or therapy of disease. With respect to the development of new bacterial delivery systems, the classical example of inverted pathogenicity is the employment of a type III secretion system (T3SS) for vaccination. T3SS has been identified in a number of Gram-negative mammalian and plant pathogens; its structure resembles the basal body of flagella and forms a "needle complex." This system not only provides efficient secretion of virulence factors by the pathogen but also delivers them directly into the cytosol of eukaryotic cells by the contact-mediated translocation (Hueck, 1998; Cornelis, 2002). Therefore, the ability to inject virulence factors (effectors) could be utilized for the cytosolic delivery of heterologous antigens and their immunorelevant fragments. For this purpose, TTSS of *Salmonella* pathogenicity island 1 (SPI-1) was employed that promotes uptake of the pathogen and formation of a membrane-bound compartment (macropinosome) in which *Salmonella* cells further multiply. Importantly, *Salmonella* continues to translocate type III effectors into cytosol of the host, as it resides in the macropinosome. Insertion of immunodominant heterologous CD8 epitopes into one of the effectors indeed led to the strong induction of specific MHC class I–restricted immune response, followed by immunization with attenuated *Salmonella* live carrier. The T3SS-based delivery system was further improved by using the *Yersinia* effector's YopE secretion and translocation N-terminal sequence, which is functional in *Salmonella* as well, thus allowing the cytosolic injection of significantly larger antigens. Recently, attenuated *Yersinia* and its T3SS were also used for live vaccine delivery which led to efficient antigen-specific CD4 and CD8 T-cell responses (Russmann, 2004). Similarly, the type IV bacterial secretion system of *A. tumefaciens*, which is capable of mediating DNA transfer into human cells, could be used for genetic vaccination (Loessner and Weiss, 2004). Finally, a type I secretion system can be an effective delivery system in virulence-attenuated, Gram-negative bacteria. For example, the use of the alpha-hemolysin secretion pathway provided an export of heterologous antigens from the cytoplasm of bacterial carrier into either the phagosome or the cytosol of infected cells (Gentschev et al., 2002).

GENETIC APPROACHES

The availability of genome-scale sequence data, the development of new tools for high-throughput gene expression monitoring, and improvements in the ability to analyze large data sets have revolutionized the field of vaccine development. In this section, we discuss several high-throughput genomics approaches that have been developed to discover genes whose expression takes place specifically when the bacteria infect their host and which encoded those antigens with potential applications as vaccine candidates.

Identification of Essential Genes: Nontransposon- and Transposon-Based Methods

Nontransposon Methods

A simple way to define an essential gene is derived from the functional analysis of the protein product. While a mutation (transposon-based or not) within a nonessential gene would not be expected to affect the growth rate of the cell, the mutation within an essential gene would probably result in a measurably diminished growth rate or fitness of the mutant compared to the wild-type bacterium (Lehoux et al., 2001). There are several methods to identify essential

genes that do not rely on transposons, including comparative genomics and the directed knockout of genes. More traditional analysis uses the generation of conditional mutations that affect growth, such as temperature-sensitive (TS) mutations (Judson and Mekalanos, 2000). TS mutations are generated by chemical mutagenesis and result in unmarked point mutations that allow the identification of essential genes by growth at a permissive temperature, but not at a nonpermissive temperature. The location of the mutation is determined by a mapping and/or complementation cloning strategy. Another approach that builds on comparative genomics involves the targeted knockout of specific genes after bioinformatics analysis. This approach uses the premise that genes of unknown function that are conserved between organisms are more likely to be essential than nonconserved genes. Gene-by-gene PCR-product design, cloning, and attempted knockout of the gene in question are used to determine if the gene is essential (Judson and Mekalanos, 2000).

Transposon-Based Methods

There are a number of different transposon-based approaches available for defining essential genes (Lehoux et al., 2001). The utility of each approach varies, depending on the type of information one is interested in obtaining and the genetic systems available in the organism of interest. There are two ways to identify essential genes or regions of the bacterial chromosome which can be based on the location of the transposon insertion: the "negative" and the "positive" approaches (Judson and Mekalanos, 2000). A problem in trying to identify essential genes is that a knockout of an essential gene is lethal. Therefore, the use of the negative approach will help with the identification of many regions that are not essential and enable one to say with some certainty that regions in which transposon insertions are not observed are likely to be essential. These types of approaches that allow saturating in vitro transposon mutagenesis of PCR-amplified chromosomal segments of naturally competent organisms, uptake of these mutagenized fragments, and homologous recombination into the chromosome have being used to identify essential genes in *Haemophilus influenzae*, *Mycoplasma*, and *S. pneumoniae* (Judson and Mekalanos, 2000).

The positive approach defines genes that are essential instead of defining genes or regions of the chromosome that are nonessential by generating a conditional mutation and showing that it has a lethal phenotype. This approach defines essential genes by replacing the gene's natural promoter with an inducible one. Transposition with a transposon that has an outward-facing inducible promoter at one end of the transposon into the promoter region of a gene creates a gene in which the function of the natural promoter is replaced by an inducible promoter. If the gene is essential, the bacterial strain is now dependent on the inducer for growth or survival. This approach was first used with Tn*5tac1*, a derivative of transposon Tn*5* that generates conditional mutations, and modified methods have subsequently been used to identify a number of genes with conditional growth phenotypes (Judson and Mekalanos, 2000; Lehoux et al., 2001).

Functional Inhibition of Genes: STM, GAMBIT, TraSH

Signature-Tagged Mutagenesis (STM)

STM is a functional genomics technique that identifies microbial genes required for infection within an animal host, or within host cells, using extensive collections of mutants generated by insertional mutagenesis. DNA tags are usually incorporated into the mutagenesis vector (transposon or insertional mutagenesis plasmid) to label each mutant with a unique identifying DNA "signature-tag." Pools of mutants are then screened through an animal model or cell culture to identify clones in which a mutation has impaired multiplication. Mutants that fail to be recovered after the screen are likely to be attenuated and therefore altered within virulence genes. The presence or absence of individual mutations within a pool of mutants can then be detected by PCR amplification and detection of the signature-tags, and their identification enables negative selection screens to be performed. STM was originally used in the enteric pathogen *Salmonella enterica* serovar Typhimurium, in which the investigators identified known virulence determinants, thus demonstrating the utility of the technique, as well as the identification of a pathogenicity island (*Salmonella* pathogenicity island 2, SPI-2) containing a type III secretion system (Hensel et al., 1995). Since then, STM has been applied so far to a variety of pathogens, including *M. tuberculosis*, *S. aureus*, *V. cholerae*, *Y. enterocolitica*, *S. pneumoniae*, and *N. meningitidis* (Mecsas, 2002).

Genomic Analysis and Mapping by In Vitro Transposition (GAMBIT)

This method is a variation of the transposon-based approaches which use the transposon TnAraOut to perform high-density mutagenesis of restricted regions of the genome (Akerley and Lampe, 2002).

Using this technique, the complete set of genes required by *H. influenzae* for growth and viability in vitro has been identified. Further, genes essential for growth in *Mycoplasma* were defined using the same approach (Hutchison et al., 1999).

Transposon Site Hybridization (TraSH)

The combined use of high-density transposon mutagenesis and microarray hybridization mapping of pools of mutants resulted in the development of TraSH, a method suitable for the rapid functional characterization of bacterial genes required for growth under different conditions (Sassetti et al., 2001). In TraSH, each mutant contains a single transposon insertion, and the bacterial library contains mutations in each gene in the genome. After a growth phase, mutants harboring insertions in genes that are required for survival are lost from the library. The TraSH probe is generated from the selected library, and this "insertion probe" consists only of sequences complementary to genes that contain insertions in the selected library. Randomly labeled chromosomal DNA (genomic probe) will hybridize to every gene represented on the array. Spots that hybridize to the genomic probe, but not the insertion probe represent genes that are required for growth. TraSH has been applied to identify conditionally essential genes in *M. bovis* BCG which represent promising targets for rational attenuation (Sassetti et al., 2003).

Gene Expression In Vivo: IVET, RIVET, DFI

In Vitro Expression Technology (IVET)

IVET is designed to identify bacterial genes that are induced when a pathogen infects its host. A subset of these induced genes should include those that encode virulence factors. The system is based on complementation of a mutation in a biosynthetic gene (auxotrophic mutation) by gene fusion, and is designed to be used in a wide variety of pathogenic organisms (Slauch et al., 1994). The positively selected fusions are then sequenced to identify in vivo–induced genes. The original IVET made use of a *S. typhimurium* library consisting of a promoterless, two-reporter operon fused randomly in the bacterial chromosome (Mahan et al., 1993). One of the two reporters encoded an enzyme whose expression was necessary for survival in mice. In this study, a mouse was infected with the library, and only bacteria containing in vivo–induced fusions survived, since only they expressed the reporter enzyme. Bacteria were then harvested from the animal and grown on laboratory media. At this step, the second reporter gene, e.g., *lacZ*, became important. When the *lacZ* activity of bacteria grown on indicator media is determined, only those fusions with low *lacZ* activity (those with promoters active in the mouse but inactive in vitro) are kept for further study. As indicated, this method requires the existence of an attenuating and complementable auxotrophy, which might not be available in all microbial systems. Variations to the original IVET method have been developed using different reporting systems (e.g., gene fusions to green fluorescent protein and the use of flow cytometry to screen for the promoters; Valdivia and Ramakrishnan, 2000).

Recombination-Based In Vivo Expression Technology (RIVET)

This is a new version of the IVET method, which enables the detection of genes that are transiently turned on during adaptation to a new environment. The RIVET system is based on recombinase gene fusions, which, on induction during infection, mediate a site-specific recombination, the product of which can be screened for after recovery of bacteria from host tissues. RIVET is very sensitive to low or transient expression of in vivo–induced (*ivi*) genes during infection and is therefore capable of identifying members of this potentially interesting class of genes. RIVET is also uniquely designed for the postidentification analysis of *ivi* genes; e.g., it has been used to analyze the temporal and spatial patterns of virulence gene induction during infection and to dissect the regulatory requirements of in vivo induction with respect to both bacterial regulatory factors and host-inducing environments (Slauch and Camilli, 2000). RIVET was first successfully used with *V. cholerae* to identify genes that are induced transcriptionally during infection of the gastrointestinal tract of infant mice. A recent improvement in this technology has allowed the same investigators to increase the efficiency of the screening method and to reduce the frequency of false positives (Osorio et al., 2005).

Differential Fluorescence Induction (DFI)

DFI utilized a fluorescence-enhanced green fluorescent protein (GFP) and fluorescence activated cell sorter (FACS) to separate bacteria or infected cells on the basis of GFP fluorescence (Valdivia and Ramakrishnan, 2000). In the original application, the technique was used to screen a *S. typhimurium* library for promoters that are upregulated at pH 4.5 (Valdivia et al., 1996). Macrophage-like cell lines were also infected with the same library of *S. typhimurium*-bearing

random gene fusions. Using this approach, cells that become fluorescent, due to their association with a *gfp*-expressing *S. typhimurium*, are collected by FACS. Then, bacteria cells are recovered, grown again in the absence of cells, and sampled by FACS. Bacteria that are no longer fluorescent in the extracellular environment are sorted and used for a second round of macrophage infection. *S. typhimurium* present within these fluorescent macrophages contained *gfp* fusions that were upregulated in the host's cell intracellular environment (Valdivia et al., 1996; Valdivia and Falkow, 1997). One of the advantages of DFI is that there is available automation for initial screening compared to manual screening. Another advantage is that DFI allows the study of upregulation, as opposed to on-off types of gene induction.

Capturing Transcribed Bacterial Genes During In Vitro Infection: SCOTS

Selective Capture of Transcribed Sequences (SCOTS)

The differential gene expression in bacteria within infected host cells or tissues has been limited by the low number of bacteria in these systems and the instability of bacterial mRNA. There are also difficulties involved in separating bacterial mRNA from ribosomal RNA and host RNA. Development of SCOTS has allowed identification of bacterial genes that are expressed within macrophages (Graham and Clark-Curtiss, 1999; Morrow et al., 1999). SCOTS allows the selective capture of bacterial cDNAs from total cDNA, prepared from infected cells or tissues, using hybridization to biotinylated, bacterial, genomic DNA. The cDNA mixtures obtained are then enriched for sequences that are transcribed preferentially during growth in the host, using additional hybridizations to bacterial genomic DNA in the presence of cDNA similarly prepared from bacteria grown in vitro.

Antigenomics: Antigenome Technology, IVIAT, ELI

Evaluation of the immune response against any candidate antigen is a crucial validation task and cannot be circumvented. Therefore, techniques using human immunogenicity as their primary screening and selecting parameter on a genome-wide basis seems to be particularly valuable in vaccine development. Moreover, the antibodies that are induced in the host are molecular proofs of the in vivo expression of the corresponding antigenic proteins.

Antigenome Technology

Combining the advantages of full genome coverage and serological antigen identification, antigenome technology is an approach for identification of antigenic protein epitopes from bacterial pathogens. This approach defines the most-relevant antigenic proteins that are targeted by the human immune system, including their antibody-binding sites (Etz et al., 2002), through the use of comprehensive small-fragment genomic-surface display libraries and antibodies from human serum. Antigenome technology offers an integrated approach for antigen validation to select the most-promising candidates for the development of subunit vaccines against targeted bacterial diseases, as selected clones can be used directly for the generation of specific immune sera for surface localization and in vitro functional assays, without the demanding task of high-throughput recombinant protein production.

In Vivo–Induced Antigen Technology (IVIAT)

This antibody-based selection method has been developed to identify those gene products targeted by the host immune system (Handfield et al., 2000). Sera from patients are first pre-adsorbed with cells of the pathogen grown in vitro, to select antibodies recognizing antigens specifically expressed in vitro, then used to probe expression libraries of the DNA of the pathogen to identify antigens expressed specifically during infection, but not during growth in standard laboratory media. Reactive clones are purified and the cloned DNA sequenced to identify the corresponding gene products. This technique does not require direct genetic manipulation of the pathogen or an animal model, but it is necessary that a gene product is immunogenic to be identified. IVIAT has been applied, e.g., for the identification of *Vibrio*, *E. coli* O157:H7, and *Mycobacterium* antigens that are uniquely expressed during human infection (Rollins et al., 2005).

Expression Library Immunization Technology (ELI)

Another major challenge in the development of efficient screening methods is direct selection for protective candidates. The ELI technology is designed to discover vaccine candidate genes, by using the immune system to identify protective antigens from complex organisms such as fungi, protozoa, and ticks (Barry et al., 2004). However, this technology has also been applied, in combination with in vitro assays, to select immunogenic and protective antigens from bacterial pathogens, such as *M. tuberculosis* (Delcayre et al., 2003), *Mycoplasma* (Barry et al., 1995), and recently,

Chlamydia abortus (Stemke-Hale et al., 2005). ELI is based on the idea that pools of genes from a given pathogen could be introduced into the test animal by genetic immunization and then screened for whether they contained one or more protective antigens by directly challenging the host with the pathogen. Although the method represents the most straightforward approach to select protective candidates, it is limited to the study of genes that can be expressed in eukaryotic cells, and necessitates animal models that are suitable for screening purposes.

Stability of Protective Antigen Expression for Recombinant Bacterial Vaccines

Eliciting the desired immune response against a heterologous antigen is influenced by the appropriate levels of antigen expression; insufficient expression levels will abrogate the immune response, but expression levels that are too high might result in increased metabolic load and toxicity problems. One method of avoiding inappropriate high expression levels is chromosomal integration of heterologous antigens (Galen and Levine, 2001). Although this approach has proven successful for some antigens, in other cases it failed to provide the expected protective immune responses. Since in vivo stability of protective antigen expression is important for recombinant bacterial vaccine efficacy, the optimization of carrier strains by using stabilized and antibiotic-resistant free-expression plasmids, capable of expressing high levels of heterologous antigen, is one of most common approaches when developing new bacterial live vaccines (Spreng and Viret, 2005). Further, the use of in vivo–inducible promoters to limit heterologous gene expression has been shown to enhance the stable expression and immunogenicity of foreign antigens, while reducing metabolic load during in vivo propagation (Galen and Levine, 2001). In addition, the plasmid-based expression of heterologous genes provides the flexibility of introducing heterologous expression cassettes into a variety of existing live vectors efficiently, without the need for cumbersome chromosomal integrations for each live vector. In the following sections, we will discuss some of the most popular plasmid maintenance systems used for the stabilization of plasmids in vivo.

Plasmid Maintenance Systems Based on Auxotrophies in DNA and Cell Wall Synthesis

In plasmid-based balanced lethal systems, plasmids express an essential protein required for the bacteria to grow and replicate. The loss of such plasmids destroys the ability of the bacterium to express this protein and results in cell death. This process of segregational plasmid loss is known as "postsegregational killing" (Spreng and Viret, 2005).

One of the first balanced lethal plasmid systems which rely on the ability to complement a mutation in an essential gene (auxotrophic mutation) was developed by Curtiss et al. (1990) and successfully employed in *S. typhimurium*. This system is based on expression of the *asd* gene encoding aspartate beta-semialdehyde dehydrogenase (Asd), which is involved in the biosynthesis of diaminopimelic acid (DAP) from aspartate. Asd is a critical enzyme involved in the synthesis of structural components essential for the formation of the cell wall in Gram-negative bacteria, so that *asd* mutants lyse in a growth medium deprived of DAP. However, cells deleted for the chromosomal *asd* gene, but harboring a complementing Asd^+ plasmid are restored to normal growth, and loss of the plasmid during segregation leads to cell lysis. Since DAP is not prevalent in the animal host, essentially 100% of the surviving avirulent *Salmonella* recovered from an immunized animal host still contains the recombinant plasmid and expresses the foreign antigen (Curtiss et al., 1990). Asd-stabilized plasmid systems encoding heterologous antigens have been widely evaluated in *S. typhimurium* and *S. typhi* vaccine strains (Spreng and Viret, 2005). One drawback from this system is that toxicity has been observed due to the expression of some foreign proteins in live bacterial vaccine carriers, which generally leads to the overgrowth of a plasmid-free bacterial population. This toxicity is believed to be caused by a vastly increased metabolic burden on the cell, and can be exacerbated by the use of plasmids that have high copy numbers. Therefore, attempts to reduce the level of Asd protein and obtain a more balanced expression have been made, e.g., depleting the *asd* −35 and −10 promoter region on the multicopy Asd^+ plasmids still harboring the Shine–Dalgarno sequence for ribosome recognition, which results in a significant reduction in expression of Asd protein and enhance immunogenicity of the foreign antigen (Spreng and Viret, 2005).

Another plasmid system uses the thymidylate synthase (*thyA*), which is an essential gene involved in the de novo synthesis of the DNA precursor thymidine monophosphate from uridine monophosphate. Isogenic *thyA* auxotrophic mutants are incapable of intracellular growth and survival in vitro and undergo so-called thymidineless death. The *thyA* lethal balanced system is a very efficient method to achieve stable plasmid inheritance both in vitro and in vivo, and this plasmid system can easily be adapted to any host–vector combinations, since *thyA* chromosomal

mutations can readily be selected by trimethoprim selection (Morona et al., 1991). Such a stabilization system has been used, e.g., to generate a candidate carrier strain against cholera (Spreng and Viret, 2005).

A third balanced lethal plasmid system, based on the *purB* gene, has been developed for *Salmonella* spp. for the heterologous expression of *H. pylori* urease. The *purB* coding for adenylosuccinate lyase catalyzes an essential step in the de novo synthesis of adenosine monophosphate involved in the purine biosynthetic pathway. Using this system, it was found that despite an almost equal protein expression, the in vitro stability of the urease-encoding plasmid differed markedly between carrier strains, and the level of the immune response induced against the heterologous antigen seems to be conditioned by a stable antigen expression in vivo (Spreng and Viret, 2005).

Plasmid Maintenance Systems Based on Auxotrophies in Biosynthetic Pathways

Genes involved in amino acid and protein synthesis steps have also been employed for the design of balanced lethal plasmid stabilization systems. Glutamine synthetase, encoded by *glnA*, is required for glutamine synthesis, which serves together with glutamate as a primary nitrogen source in bacterial metabolism. For example, a *V. cholerae glnA* mutant was complemented in trans with a plasmid coding for the heterologous *S. typhimurium glnA* gene, and then the strain was used for oral inoculation of germ-free mice. Bacteria were recoverable for 10–12 days from the stools. However, a problem with this approach was that plasmid-free carrier bacteria could be recovered for 8 days after primary inoculation (Ryan et al., 2000).

Other example is the suicide *L. monocytogenes* carrier system developed for bactofection DNA delivery into mammalian cells and which takes advantage of a phage lysin which is specifically expressed once the bacteria enter the host cell cytosol. This results in the complete lysis of the bacteria and in the consequential release of plasmids encoding for heterologous antigens under the control of a eukaryotic promoter (Dietrich et al., 1998). This balanced lethal plasmid system was shown to efficiently stabilize the recombinant plasmid both in vitro and in vivo.

A third plasmid stabilization system has been described for *E. coli* based on the *infA* gene coding for translation initiation factor 1 (IF1), a small intracellular protein essential for cell viability. By deleting the chromosomal *infA* gene and placing it instead on a plasmid, the latter could be kept totally stable for at least 120 generations of growth in the absence of antibiotics. Although developed for large-scale cultures that are usually applied in bioreactors for microbial production of bio-molecules, this system does not seem to be limited to *E. coli*, and further evaluation in attenuated live bacterial carriers may clarify its use for vaccine development (Hägg et al., 2004).

Plasmid Maintenance Systems Based on Toxin–Antitoxin Modules

Toxin–antitoxin systems also known as "postsegregational cell killing" and "addiction" systems ensure plasmid maintenance during replication by conferring an advantage on plasmid-retaining cells due to reduced competitiveness of their plasmid-free counterparts. The best-characterized toxin–antitoxin module is the *hok-sok* locus of *E. coli* plasmid R1. *hok-sok* is a two-component system in which *hok* encodes a lethal pore-forming Hok protein. Hok translation is blocked by binding of the *sok* transcript that is complementary to the 5′ end of the *hok* mRNA. However, *sok* mRNA is highly susceptible to degradation by nucleases, and its protective intracellular concentration must be maintained at a critical level by constitutive transcription from a resident plasmid carrying the *hok-sok* locus. Therefore, the absence of a renewable source of the *sok* antitoxin RNA in bacteria that spontaneously lose such plasmids results in the accumulation of the more stable *hok* mRNA and thereby to the sustained synthesis of the Hok protein and subsequent cell death by cell membrane depolarization (Gerdes et al., 1997). The noncatalytic, postsegregation killing function of the *hok-sok* module has been incorporated in attenuated strains of *S. typhi* and *S. flexneri*, causing an enhanced inheritance of plasmids, but was not sufficient to maintain plasmids coding for toxic proteins (Galen and Levine, 2001). Therefore, plasmid maintenance systems combining a postsegregational system and partition functions significantly enhance plasmid segregational stability and minimize plasmid loss in a population of actively growing bacteria, and are becoming the next generation of plasmid maintenance systems used in bacterial-based vaccine development.

CONCLUSIONS

From the foundation for modern vaccinology established by Edward Jenner in the late 1700s, the field of bacterial vaccines has seen dramatic changes, particularly in recent years, due to tremendous advances in molecular biology, immunology, cell biology, biochemistry, and the use of innovative scientific approaches. The emergence of multidrug resistance of many

clinically relevant bacterial pathogens has renewed an interest in the development of efficient, safe, and affordable vaccines. As presented in this chapter, to date, weakened microbes, killed microbes, inactivated toxins, and purified proteins or polysaccharides derived from microbes, represent some of the most common components used in vaccine development strategies. However, advances in biotechnology linked to the progress in genome sequencing of pathogens and high-throughput screening technologies are aiding the development of a new generation of vaccines, capable of activating the immune system, including eliciting both humoral and cell-mediated immunity against a variety of disease-producing organisms. Despite the progress, bacterial infections are still killing millions of people worldwide. Therefore, there is a need for the development of new and innovative vaccines to prevent the most challenging of diseases and to respond to the threat of bioterrorism.

OUTLINE

ABSTRACT

Traditional vaccine development platforms such as live-attenuated virus, killed virus, or recombinant subunit-based vaccines are often effective in eliciting long-term immunity to a number of infectious human pathogens. However, for many human pathogens, vaccine platforms such as these are unsuitable for human use due to safety concerns, poor efficacy, or simple impracticality. As a result, much work has focused on the use of recombinant virus vectors as a means for vaccination against human pathogens. Viral vectors can express foreign proteins at high levels in host cells, resulting in strong, long-lasting immune responses against the target proteins. This chapter describes the use of virus vectors in the context of vaccination against human pathogens. Various vector platforms are discussed, compared, and contrasted.

INTRODUCTION

Traditional vaccination platforms such as live-attenuated or killed virus vaccines have been used successfully for decades. This approach is applied to many different human diseases including smallpox, polio, measles, mumps, yellow fever, rubella, influenza, varicella, and hepatitis A. This form of vaccine development can be very effective, with particular support demonstrated by the eradication of smallpox and near eradication of polio through global vaccination efforts.

Compared to inactivated/killed virus vaccines, live-attenuated vaccines are generally thought to provide longer-lasting immunity without the need for repeated booster immunizations, and are an economical and simple means for high efficacy vaccine production. However, development of live-attenuated virus vaccines for some human pathogens can encounter safety concerns due to under-attenuation of the virus or even a reversion to its pathogenic state. For example, in efforts to develop HIV vaccines, researchers have investigated live-attenuated simian immunodeficiency virus (SIV) vaccines as proof of principle and found strong levels of protection in nonhuman primates (Johnson and Desrosiers, 1998). Unfortunately, live-attenuated SIV vaccines can also cause AIDS in vaccinated monkeys due to reversion to pathogenic form (Baba et al., 1999; Berkhout et al., 1999), which is a frequent source of controversy for those in the field (Murphey-Corb, 1997). Similar findings are noted for other experimental live-attenuated vaccines. For example, live-attenuated dengue virus vaccines also show protective immunity in animal models (Blaney et al., 2005). However, a Phase I clinical trial involving a live-attenuated dengue virus vaccine formulation was halted due to side effects caused by under-attenuation of the vaccine virus strain (Kitchener et al., 2006). Obviously, there is a fine balance between developing a safe, attenuated virus strain and developing one that maintains a high level of immunogenicity. Unfortunately, the immunogenicity of live-attenuated vaccines is often gained at the cost of clinical safety, and vice versa.

Even licensed live-attenuated vaccines that have been approved and used for decades are not without a risk of vaccine-mediated disease. A classical example of this is smallpox vaccination. In the 19th–20th century, variola vaccinations were traditionally performed using the related but less pathogenic poxvirus, vaccinia virus. However, the early vaccine strains of vaccinia are well known for inducing significant side effects in vaccine recipients, some of which can even be life-threatening (Parrino and Graham, 2006). With the increased threat of bioterrorism, many recent research efforts have focused on developing new vaccine strains of vaccinia with more favorable safety profiles or even alternative vaccine platforms for smallpox vaccination (see Chapter 22). Global efforts for polio vaccinations, either as a live-attenuated oral vaccine (oral polio vaccine, OPV) or an inactivated parenteral vaccine (inactivated polio vaccine, IPV), have nearly eradicated this disease from the planet. Yet, despite the high levels of efficacy, the live-attenuated OPV formulation has been shown to cause paralytic poliomyelitis in some cases (Blume and Geesink, 2000; Henderson et al., 1964).

Some human pathogens, such as the Ebola and Marburg viruses of the Filoviridae family, are so deadly that live-attenuated vaccines are not even considered a possibility, since they would pose too great a risk if the vaccine strain of virus were under-attenuated or reverted to pathogenic state. As a result of constant pressure to find newer, more effective, and safer vaccine platforms, investigators have sought alternative approaches to vaccine development, such as recombinant protein subunit vaccines, DNA vaccines (see Chapter 8), and viral vectored vaccines.

Protein subunit vaccines can be an effective means for generating strong immune responses, such as in the recent anthrax vaccines (Miller et al., 1998) or the traditional hepatitis B vaccines produced by GlaxoSmithKline (Engerix-B®) or Merck (Recombivax HB®). However, subunit vaccines often require inclusion of an adjuvant to increase the immunogenicity (Berthold et al., 2005; Jendrek et al., 2003; Putnak et al., 2005; Qin et al., 2007). Often, the recombinant proteins are synthesized in insect or bacteria cells prior to purification, which can result in different levels of glycosylation, protein folding, and other tertiary modifications that would occur during protein expression in a natural infection. These differences can alter the antigenicity of the recombinant protein so that it differs from the natural wild-type protein. Even recombinant proteins synthesized in mammalian cells, which may be processed correctly, can be damaged during the subsequent purification processes. Thus, when delivered as a vaccine, the immune responses generated against the recombinant proteins can be quite different from those that would be generated against the natural protein of the target pathogen. Finally, the recombinant proteins can be degraded by the host immune system soon after injection into the vaccine recipient, which results in only a brief period of antigen presentation to the immune system. Therefore, while protein subunit vaccines are promising in certain areas of vaccine development, they may not be ideal for all vaccine applications.

DNA vaccines entail delivery of naked plasmid DNA that contains selected gene(s) of the target pathogen.

Upon vaccination, the plasmid DNA is taken up by local cells at the injection site, and the gene(s) are expressed to produce the pathogen's proteins. This form of de novo protein expression eliminates the need for purification of large amounts of the protein, since the actual protein is expressed from the cells in vivo. The potential efficacy of this vaccine platform has been successfully demonstrated for numerous pathogens, including Ebola virus (Vanderzanden et al., 1998; Xu et al., 1998), avian influenza (Kodihalli et al., 1999; Tompkins et al., 2007), dengue virus (Apt et al., 2006), West Nile virus (Bunning et al., 2007), and HIV (Cherpelis et al., 2001). A major limitation of DNA vaccines is the level of expression of the gene(s) of interest. Compared to other means of gene expression, such as that from viral vectors, expression from DNA vaccines is notoriously weak in vivo, resulting in lower immunogenicity of the vaccine. Thus, many DNA vaccine studies in animal models employ a system of DNA vaccine priming followed by a viral vector or protein subunit booster immunization (Kong et al., 2005; Shu et al., 2007; Sullivan et al., 2000; Wu et al., 2005; Zanin et al., 2007).

One of the most promising recombinant vaccine technology platforms is the viral vector. The premise behind using viral vectors as a means for vaccination is to present the naturally occurring form of the target pathogen antigens to the immune system in the absence of the infectious pathogen itself. This process induces an immune response against the target pathogen's antigens, similar to a natural infection, however in the absence of disease. One of the earliest demonstrations of this was in 1984, when scientists at the Wistar Institute engineered a vaccinia virus vector to express the rabies virus glycoprotein, and successfully protected mice and rabbits from lethal rabies virus challenge (Wiktor et al., 1984). This vaccine has since been licensed and marketed as a veterinary vaccine by Merial (Raboral VR-G®), which is commonly used for mass vaccination of certain species of wildlife in order to curtail the spread of rabies in the wild (Mackowiak et al., 1999) (see Chapter 33). As technology advances, so does the list of viral vectors used in experimental vaccines. Vectors based on adenovirus, adeno-associated virus (AAV), vesicular stomatitis virus (VSV), and alphavirus have all been studied on numerous fronts as vaccine tools (Brave et al., 2007). These and others will be discussed in this chapter.

ADENOVIRUS

Perhaps the most widely studied viral vector for vaccines and gene therapy applications is the adenovirus (Goncalves and de Vries, 2006). Adenoviruses (Ad) belong to the family, Adenoviridae, and are double-stranded DNA viruses with a genome size of approximately 36 kbp. Ad infect a wide range of species, but maintain a high level of species specificity. Of the human Ad, there are at least 51 different serotypes identified (Shenk, 2001), of which, the most studied in terms of viral vectors are serotypes 2 and 5 (Ad2 and Ad5, respectively). Ad are common, have well-characterized genomes that are easy to manipulate, can be grown and purified to high titers in cell culture, are able to infect a wide variety of dividing and non-dividing cell types, express high levels of recombinant transgene in infected cells, and have a favorable safety profile. These properties have all culminated in the use of Ad vectors in hundreds of human clinical trials around the world for a variety of medical applications, including cancer gene therapy and vaccine vectors.

Early work in Ad molecular biology found that the viruses were able to package genomes with sizes up to 105% of the wild-type genome length into infectious viral particles. This equated to approximately 1.8 kb of exogenous DNA (transgene) that could be inserted into a wild-type Ad genome (Ghosh-Choudhury et al., 1987; Graham et al., 1977). However, increasing the genome length beyond 105% of the wild-type genome length can result in genetic instability and loss of the transgene (Bett et al., 1993). Researchers quickly discovered that more genome space could be created for larger transgenes by specific deletions of the Ad genome. The first of these deletions were directed toward the Ad early genes E1a and E1b, which also created a replication-incompetent vector as loss of E1 subsequently inhibits downstream transcription of other Ad genes necessary for replication (Jones and Shenk, 1979). E1-deleted replication-incompetent vectors only replicate in permissive cell lines, such as the human embryonic kidney cell line HEK293 (Graham et al., 1977), which provides the missing E1 gene function for the Ad vector in trans. By additionally deleting the E3 region of the Ad genome, ample space exists for inserting foreign DNA sequences. E1/E3 deleted Ad vectors are referred to as first-generation vectors, and usually have 4–5 kb of genome space available for a transgene insert (Ghosh-Choudhury et al., 1987; Graham, 1984). First-generation Ad vectors are effective tools for gene delivery, but the duration of transgene expression is fairly limited due to host immune response against the Ad proteins expressed by the vector (such as E2 and E4 proteins). Therefore, efforts were made to reduce the amount of Ad protein expressed from the vector, while maintaining high levels of transgene expression. This was achieved through partial deletions in the E2 region (Hodges

et al., 2000; Lusky et al., 1998; Moorhead et al., 1999) or the E4 region (Dedieu et al., 1997; Gao et al., 1996) of the Ad genome, which reduced or eliminated the expression of E2 or E4 proteins. These types of Ad vectors are referred to as second-generation vectors, and have an increased transgene insert capacity of approximately 6–7 kb. The transgene capacity can be increased even further in advanced Ad vectors with deletions in E1, E3, and most of E4 (excluding open reading frame 6) (Wang et al., 2006b). Ad vectors with the highest capacity for exogenous DNA are called "gutless" vectors, and consist solely of the exogenous transgene DNA flanked by the Ad inverted terminal repeat (ITR) sequences and the Ad packaging signal. These vectors can accommodate 30–35 kb of foreign DNA (Table 7.1), although they must be propagated using a helper virus to provide the missing Ad genes necessary for replication in the packaging cell line (Kochanek et al., 2001; Kumar-Singh and Chamberlain, 1996; Parks et al., 1996).

Ad vectors have been studied on numerous fronts, such as avian influenza (Gao et al., 2006), Ebola and Marburg viruses (Sullivan et al., 2000, 2003; Wang et al., 2006a, 2006b), West Nile virus (Schepp-Berglind et al., 2007), dengue virus (Holman et al., 2007; Jaiswal et al., 2003; Raja et al., 2007), SARS-CoV (Ma et al., 2006), HIV (Barouch and Nabel, 2005; Catanzaro et al., 2006), and anthrax (McConnell et al., 2007). Additionally, Ad vectors have been studied as potential gene therapy vectors for many types of cancer and other diseases in hundreds of human clinical trials (www.clinicaltrials.gov).

One of the primary criticisms of Ad vector use in humans is the issue of pre-existing immunity. Ad infections are quite common in humans, resulting in 35–55% of the population having neutralizing antibodies, in particular against the common serotype used in experimental Ad vectors, Ad5 (Chirmule et al., 1999; Nwanegbo et al., 2004). It is thought that these circulating Ad-neutralizing antibodies might limit any Ad-based vaccine vector's efficacy by neutralization of the vector prior to efficient transgene expression. Experimentally, this has been shown in various animal models of Ad5 immunity. Most of these studies establish an Ad5-immune animal by inoculating the animals multiple times with high doses of wild-type Ad5 or an unrelated Ad5-based vector. This is followed by vaccination with the experimental Ad5-based vector, which invariably fails due to pre-existing anti-Ad5 immunity (Capone et al., 2006; Hashimoto et al., 2005; Kobinger et al., 2006; Xiang et al., 2003). Most of these studies demonstrate the feasibility of overcoming Ad5 pre-existing immunity by using Ad vectors based on alternate serotypes that are antigenically distinct and thus are not neutralized by the anti-Ad5 immune response. However, conflicting data have been generated from human clinical trials. Phase I/II clinical trials involving Merck's Ad-based HIV vaccine found that while pre-existing Ad5 immunity did limit the vaccine's efficacy at lower vaccine doses, this limitation could be completely overcome by increasing the dose of vaccine (Cohen, 2006). Further support was produced from a clinical trial studying an Ad-based influenza vaccine, which showed no correlation between the levels of Ad5-neutralizing antibodies and the immunogenicity of the vaccine (Van Kampen et al., 2005). Finally, it is suggested that vaccination by alternate routes of administration (such as oral or intranasal) rather than injection can overcome pre-existing vector immunity (Appaiahgari et al., 2006; Xiang et al., 2003), which is supported by data from a human clinical trial (Van Kampen et al., 2005).

TABLE 7.1 Common viral vectors in recombinant vaccine development

Virus[a]	Family	Species	Genome (kb)	Transgene capacity (kb)[b]	PEI[a,b]
Ad	Adenoviridae	Human, chimp	36	7–35	+++
AAV	Parvoviridae	Human	5	5	+++
Alphavirus	Togaviridae	Zoonotic/mammals	11.8	5	+
NDV	Paramyxoviridae	Zoonotic/birds	15	3.2–4.5	−
Vaccinia	Poxviridae	Zoonotic…bovine?	192	25	+++
Avipox	Poxviridae	Zoonotic/birds	260	25	−
VSV	Rhabdoviridae	Zoonotic/mammals	11.1	4.5	+

[a] Abbreviations: Ad, adenovirus; AAV, adeno-associated virus; NDV, Newcastle disease virus; VSV, vesicular stomatitis virus; PEI, pre-existing immunity.
[b] Based on references cited in this chapter.

Pre-existing Ad vector immunity is a source of frequent debate, and is a significant factor for Ad-based vaccine vectors under certain conditions. However, experimental data exist for support on both sides of the argument, and it remains to be seen if the difficulties demonstrated by pre-existing immunity in animal models will translate to actual scenarios of human vaccination. As more data are produced from clinical trials, we will have a better understanding of the true significance of pre-existing immunity for Ad-based vaccine vectors.

ADENO-ASSOCIATED VIRUS

AAV belong to the family, Parvoviridae, and are small, single-stranded DNA viruses with a genome size of approximately 5 kb. There are eight known AAV serotypes, with AAV-2 being the most commonly studied (Chiorini et al., 1999, 1997; Gao et al., 2002; Muramatsu et al., 1996; Rutledge et al., 1998; Xiao et al., 1999). AAV are quite unique in that in order to replicate, they require the co-infection of a helper virus, such as Ad (Atchison et al., 1965) or herpes virus (Buller et al., 1981). In the absence of helper virus, AAV infection becomes latent and does not produce progeny virus. However, a productive infection can be achieved if latently infected cells are subsequently infected with Ad or herpes helper viruses (Berns and Linden, 1995). Wild-type AAV do not cause human disease, giving them an excellent safety profile as a potential therapeutic or vaccine vector. AAV have a broad host range, persistent transgene expression in host cells, and generate very weak antivector immune responses. These qualities have led to the intense study of AAV as tools for human gene therapy and recombinant vaccines vectors. Recombinant AAV vectors have been studied as vaccine vectors against herpes simplex virus type 2 (Manning et al., 1997), human papilloma virus (Liu et al., 2000), HIV (Xin et al., 2001), and cytomegalovirus (Gallez-Hawkins et al., 2004). Each of these studies found the recombinant AAV (rAAV) platform to be an effective means for inducing potent immune responses against the target pathogen.

Due to the small size of the AAV genome, rAAV vectors can only accommodate approximately 5 kb of exogenous DNA. This is usually done by removal of all viral genes between the 5′ and 3′ terminal repeat (TR) sequences and replacing them with the desired transgene(s) (Dong et al., 1996). Since the only viral DNA sequences the rAAV vectors retain are the TRs, the vectors must be propagated in a special packaging cell lines that express the AAV Rep and Cap proteins, in addition to the helper virus co-infection (Vincent et al., 1997). This has both advantages and disadvantages. An advantage of a recombinant viral vector completely void of parent virus genes is the lack of AAV protein expression upon transduction of host cells. This results in low levels of antivector immunity generated after vaccination. However, the disadvantages are the small genome size and requirement for helper virus during propagation. Additionally, AAV infections occurring in the absence of helper virus become latent by integrating the viral genome into host DNA, on specific sites of human chromosome 19 (Cheung et al., 1980; Samulski et al., 1991). Any virus that integrates its DNA into the host genome raises safety concerns as to the genetic consequences of the integration. Integration of viral DNA can be beneficial if the desired transgene is persistently expressed (the desired outcome for gene therapy studies); however, it may also be detrimental to the host if the integration results in mutations or deletions to host DNA (McCarty et al., 2004).

Similar to Ad vectors, a potential pitfall for rAAV vectors is the issue of pre-existing vector immunity. It was initially thought that AAV was nonpathogenic and only weakly immunogenic, thus creating the perfect gene transfer vehicle that is immunologically invisible. These initial suggestions spearheaded the movement for using rAAV vectors in gene therapy and vaccine vector development. However, it is now known that over 90% of humans do indeed have circulating antibodies that cross-react with AAV, and over 30% are seropositive for AAV neutralizing antibodies (Chirmule et al., 1999; Kotin, 1994). Furthermore, the highest level of human AAV antibodies are directed toward the capsid protein of the AAV-2 serotype, which is the most common serotype used as a backbone for vaccine vectors. However, as there are eight different AAV serotypes, using an alternate serotype as the vector backbone may be a means of overcoming the pre-existing immunity hurdle (Davidoff et al., 2005). More human clinical trials data are needed in order to better gauge the significance of pre-existing vector immunity in using rAAV as vaccine vectors.

It should be noted that on July 26, 2007, the U.S. Food and Drug Administration announced the death of a clinical trial participant involving an AAV-based rheumatoid arthritis treatment (FDA, 2007). As of the date of this chapter review, the details of this tragedy have yet to be released by the FDA or the clinical trial sponsor.

ALPHAVIRUSES

The alphaviruses belong to the family, Togaviridae, and are small, enveloped viruses with a single-stranded

positive RNA genome of approximately 11.8 kb. Alphaviruses, which are arthropod-borne viruses (arboviruses), are grouped into six clades based on antigenic homology of the E1 glycoprotein: Barmah Forest (BF), Ndumu (NDU), Semliki Forest (SF), western equine encephalitis (WEE), eastern equine encephalitis (EEE), and Venezuelan equine encephalitis (VEE) (Griffin, 2001). The three primary alphaviruses used as backbones for recombinant vaccine vectors are SF, Sindbis virus (SIN), and VEE (Liljestrom and Garoff, 1991; Pushko et al., 1997; Xiong et al., 1989).

Alphaviruses are known to have a broad host range, and can infect a variety of cell types, including dendritic cells, which are major antigen-presenting cells (Gardner et al., 2000; MacDonald and Johnston, 2000). This is thought to be an important advantage of using alphaviruses as vaccine vectors in that they can directly target dendritic cells in vivo and induce rapid and strong immune responses. The primary method of using alphaviruses as vaccine vectors is to create what are known as replicons. This entails deleting the alphavirus structural genes from the virus genome and replacing them with the transgene(s) of interest. The recombinant RNA molecule must then be co-expressed in packaging cell lines with helper RNA containing the missing structural genes in order to effectively package the recombinant RNA into infectious viral particles (Bredenbeek et al., 1993; Liljestrom and Garoff, 1991). Thus, the replicons are enveloped viral particles containing the recombinant genome that, in transduced cells, expresses the transgene at high levels. Since the recombinant genome lacks the alphavirus structural genes, no progeny virus is produced from the replicon transduction. One pitfall noticed early on in alphavirus replicon development was recombination between the helper RNA (containing the structural genes) and the recombinant RNA (lacking the structural genes but containing the packaging signal) in the packaging cell line, which produced replication-competent alphavirus particles (Berglund et al., 1993). The generation of contaminating replication-competent virus is a serious safety concern for this vaccine vector platform. However, endeavors have been made in designing newer and more advanced helper RNA molecules and packaging cell lines to reduce the possibility of producing replication-competent alphavirus particle contaminants (Polo et al., 1999; Smerdou and Liljestrom, 1999). An additional shortcoming of the alphavirus vaccine vector is the genome capacity for a transgene insert. Despite complete removal of the alphavirus structural genes from the vector genome, a recombinant replicon can only accommodate transgene inserts of up to approximately 5 kb (Smerdou and Liljestrom, 1999).

Alphavirus vaccine vectors have been studied as vaccines for avian influenza (Schultz-Cherry et al., 2000), Ebola virus (Olinger et al., 2005; Pushko et al., 2000), Marburg virus (Hevey et al., 1998; Lee et al., 2006), HIV (Megede et al., 2006), cytomegalovirus (Reap et al., 2007), SARS-CoV (Deming et al., 2006), anthrax, and botulinum toxin (Lee et al., 2006). Additionally, VEE replicons containing HIV genes were tested in Phase I clinical trials and were well tolerated in vaccine recipients, although the immunogenicity was only moderate (Chulay et al., 2006). Other Phase I studies of alphavirus replicons for HIV and cytomegalovirus vaccinations are currently recruiting subjects (www.clinicaltrials.gov).

Alphavirus vaccine vectors must also face the issue of pre-existing immunity, although it is not likely to be as significant a hurdle as for other vectors, such as adenovirus described above. This is largely because the alphaviruses are zoonotic mosquito-borne viruses that are endemic only in certain geographical regions of the world. Furthermore, human alphavirus epidemics occur very infrequently. This suggests that the general population will have little pre-existing vector immunity against an alphavirus-based vaccine vector. However, it was suggested early on that in horses, pre-existing antibodies against one strain of alphavirus can interfere with infection from other alphavirus strains (Calisher et al., 1973). This could pose problems for repeated vaccination in humans using alphavirus replicons. For example, antivector immunity generated after vaccination with a VEE replicon could subsequently impede booster vaccination with the same or even a different alphavirus replicon. Indeed, there is evidence in humans that the immune response generated from vaccination with one alphavirus can interfere with the immune response generated from subsequent vaccinations with different alphaviruses (McClain et al., 1998).

NEWCASTLE DISEASE VIRUS

Newcastle disease virus (NDV) belongs to the family, Paramyxoviridae, and is a zoonotic virus that naturally infects all species of birds. The NDV genome is a nonsegmented single strand of negative-sense RNA of approximately 15 kb in length. NDV is antigenically distinct from any of the human paramyxoviruses, such as human parainfluenza viruses, which has led to interest in its use as a vaccine vector in humans. NDV are categorized into three groups based on their levels of pathogenicity in chickens: the avirulent lentogenic strains, the moderately pathogenic mesogenic

strains, and the highly pathogenic velogenic strains. Lentogenic strains are widely used for NDV live-attenuated virus vaccines in the poultry industry. An outbreak of Newcastle disease can be quite severe in poultry, and is a constant threat to the industry worldwide. However, NDV are nonpathogenic in primates (Bukreyev et al., 2005), which has led to their study as vaccine vectors.

Construction of recombinant NDV vaccine vectors generally entails first modifying packaging cells in culture, either through stable expression techniques (Romer-Oberdorfer et al., 1999) or infection with a helper virus (Huang et al., 2003; Nakaya et al., 2001), to express T7 DNA-dependent-RNA polymerase. These cells are then transfected with a full-length NDV reverse sense cDNA that contains an exogenous transgene, as well as several DNA support plasmids carrying the genes of the NDV transcriptase complex: nucleocapsid protein (NP), phosphoprotein (P), and RNA-dependent-RNA polymerase protein (L) (Huang et al., 2003, 2001; Nakaya et al., 2001). After incubation, the produced recombinant virus is "rescued" and propagated in embryonated chicken eggs. NDV have been studied as recombinant vaccine vectors against SARS-CoV (DiNapoli et al., 2007), respiratory syncytial virus (Martinez-Sobrido et al., 2006), SIV (Nakaya et al., 2004), and influenza virus (Nakaya et al., 2001). Despite the dangers of NDV in poultry, these viruses have a favorable safety profile for use in humans. This is supported by the high levels of attenuation seen in nonhuman primate animal models of vaccination (Bukreyev et al., 2005), as well as the safe administration of oncolytic NDV (PV701) in human Phase I clinical trials (Lorence et al., 2003, 2007). Other paramyxoviruses have also been studied as experimental vaccine vectors, such as Sendai virus (Griesenbach et al., 2005; Takimoto et al., 2005), and simian virus 5 (Parks and Alexander-Miller, 2002).

Since NDV is an avian paramyxovirus, the issue of antivector pre-existing immunity is not considered a significant factor for this vaccine platform, which is a major advantage. Additionally, several NDV strains are licensed for use as veterinary vaccines, making them well characterized and readily available. Most recombinant NDV vectors can be propagated to high titers in chicken eggs and even in some cell lines, although inclusion of even small exogenous transgenes can significantly lower the yield of recombinant virus (Krishnamurthy et al., 2000). Also, the "rule of six," according to Sendai virus studies, indicates that the total viral genome length (transgene included) must be divisible by six in order for proper NP function in the transcriptase complex (Calain and Roux, 1993; Nakaya et al., 2001). This may complicate strategies for vaccine vector construction. Furthermore, NDV vectors may be somewhat limited in their capacity for large transgene inserts. Early studies of Sendai virus indicated a maximum insert size of 3.2 kb without significant genetic instability or reduction of viral yield (Sakai et al., 1999), although more recently Sendai virus vectors have been shown to accommodate 4.5 kb of exogenous DNA (Ferrari et al., 2007).

POXVIRUSES

Poxviruses are large, double-stranded DNA viruses of the family, Poxviridae. Compared to the other viruses mentioned in this chapter, the poxviruses are by far the largest in viron size (350 × 270 nm) as well as genome length, which can reach up to 300 kb in some types of poxviruses. The most notorious (and most virulent) of all poxviruses is variola virus, of the *Orthopoxvirus* genus, which is an obligate human pathogen that causes smallpox. The three other notable orthopoxviruses, vaccinia, monkeypox, and cowpox viruses, are zoonotic viruses and cause less severe disease in humans compared to variola. Vaccinia virus is often considered the prototype poxvirus, as it is heavily investigated in a number of research endeavors, and has thus been well characterized. Much of vaccinia's fame stems from its use as a live-attenuated smallpox vaccine, which, through global vaccination efforts, ultimately led to the eradication of smallpox in 1977.

Poxviruses of the genus, *Avipoxvirus*, receive a great deal of research attention as potential vaccine vectors. These viruses are zoonotic arboviruses that naturally infect birds, and are nonpathogenic in humans. This quality, in addition to their large 260 kb genomes, make avipox viruses attractive research tools. For example, fowlpox and canarypox viruses have been tested in animal models as a vaccine vectors for rabies (Taylor et al., 1991, 1988), H5N1 avian influenza (Steensels et al., 2007), nipah virus (Weingartl et al., 2006), and HIV (Gilbert et al., 2003; Radaelli et al., 2007; Zhang et al., 2007). The safety of avipox virus vectors in humans has been demonstrated in clinical trials as vaccine vectors for HIV (Emery et al., 2005; Russell et al., 2007) and malaria (Walther et al., 2006), as well as numerous cancer gene therapy clinical trials (www.clinicaltrials.gov).

Vaccinia virus has been used for decades as a smallpox vaccine in humans, and while earlier strains of vaccinia were known for significant side effects in vaccine recipients, newer strains have been developed or modified from previously existing vaccine

strains with more favorable safety profiles for human use (Parrino and Graham, 2006) (see Chapter 22). The improved safety profiles of vaccinia virus strains has led to study of their use as vaccine vectors for other diseases. For example, the replication defective vaccinia strain, modified vaccinia Ankara (MVA), has been genetically modified to express genes from HIV (Zhang et al., 2007), herpes simplex virus type 2 (Meseda et al., 2006), rabies virus (Weyer et al., 2007), and cytomegalovirus (Wang et al., 2007). A significant difference between vaccinia and the avipox viruses is the possibility for pre-existing vector immunity. Since the avipox viruses are zoonotic and only naturally infect birds, the general population has little to no pre-existing immunity to these viruses. Like the avipox viruses, vaccinia is also considered a zoonotic virus, possibly distantly related to cowpox or buffalopox viruses (the exact origin is unknown). In contrast to the avipox viruses, however, much of the adult population today is seropositive for vaccinia due to childhood smallpox vaccinations. Data suggest that a vaccinia-based vaccine vector would be ineffective in these individuals due to antivector immunity (Belyakov et al., 1999). It is suggested that vaccination through mucosal routes of administration may be an effective means to overcome vaccinia-directed vector immunity (Belyakov et al., 1999; Naito et al., 2007).

The large genome size of the poxviruses is somewhat of a double-edged sword for vector development. On one hand, there is ample capacity for large transgene inserts, with sizes reaching to at least 25 kb for recombinant vaccinia virus (Smith and Moss, 1983). On the other hand, these vectors express hundreds of native virus proteins in addition to the transgene(s) of interest. This induces a very strong immune response against the vector proteins, which subsequently reduces the capacity for a strong immune response against the transgene product(s) due to an "immune dilution" effect. This could be an explanation for the poor performance of poxvirus vectors in human clinical trials. For example, fowlpox, canarypox, and vaccinia virus vectors have all been tested in humans and found to be safe. However, fowlpox and canarypox vectors containing HIV genes have induced little to no anti-HIV cellular immune responses in humans (Emery et al., 2005; Russell et al., 2007). Similar results were reported for a fowlpox-based malaria vaccine that induced moderate immune responses but showed extremely poor efficacy (Walther et al., 2006). Vaccinia virus vectors have also been documented as inducing weak cellular immune responses. In a direct comparison, a recombinant Ad vector expressing the nucleoprotein gene from Sin Nombre virus (a member of the *Hantavirus* genus) induced much stronger cellular immune responses in mice than a vaccinia virus vector expressing the same transgene (Maeda et al., 2005).

VESICULAR STOMATITIS VIRUS

VSV is a zoonotic arbovirus that belongs to the family, Rhabdoviridae, the same family as the rabies viruses. VSV has an 11 kb genome that consists of a single strand of negative-sense RNA. VSV transmission in animals occurs through insect bites, and can cause severe disease in cattle, horses, and swine with symptoms similar to foot and mouth disease (Rodriguez, 2002). Human VSV infections do occur, although much less frequently than in animals and with much less severe disease symptoms (usually a mild flu-like illness). Many human infections even go unnoticed, as they are completely asymptomatic; however, in rare cases, severe disease has been reported (Quiroz et al., 1988). Recombinant VSV can accommodate a 40% increase in genome size (approximately a 4.5 kb transgene insert) with only a slight reduction in infectivity titer (Haglund et al., 2000). In addition to ease of genome modifications, VSV vectors have an added advantage in that the virus can efficiently incorporate and express foreign transmembrane proteins on the surface of recombinant viral particles (Schubert et al., 1992). This, coupled with its relatively safe background and rare seroprevalance in humans, makes VSV an attractive platform for vaccine vector development.

Concerns for VSV vector safety are related to the possibility of severe human disease (Quiroz et al., 1988) as well as the neurovirulence and 50% mortality rate from experimental intranasal mouse infections (Reiss et al., 1998). Additionally, asymptomatic brain infections have been noted in cotton rats after intransal delivery of a recombinant VSV vector (Schlereth et al., 2003). However, more recent studies have shown that intranasal delivery of VSV did not spread to CNS tissues in nonhuman primates, indicating that these vectors may be safer than initially suggested (Johnson et al., 2007). Thus, recombinant VSV vectors have been studied as vaccines against H5N1 avian influenza virus (Schwartz et al., 2007), Ebola and Marburg viruses (Daddario-DiCaprio et al., 2006; Feldmann et al., 2007; Jones et al., 2005), plague (Palin et al., 2007), hepatitis C virus (Ezelle et al., 2002), and HIV (Haglund et al., 2000, 2002). While VSV vaccine vectors have yet to be tested in humans, results from these and other animal models of vaccination are encouraging.

Pre-existing vector immunity is not thought to be a significant factor for use of VSV vaccine vectors in

humans. Since VSV is a zoonotic virus, human infections are generally limited to isolated geographical regions of the world or to individuals having close contact with infected animals. Thus, the global seroprevalance for VSV is considered to be low. However, animal models show that vaccination with a recombinant VSV vector induces neutralizing antibodies against the VSV envelope protein (Roberts et al., 1999). Therefore, in all likelihood, humans receiving a VSV-based vaccine vector will develop neutralizing immune responses against the viral envelope protein, which would reduce the efficacy of subsequent VSV-based booster vaccinations. Similar to the Ad and AAV vector strategies described above, a serotype rotation of different VSV glycoproteins is reported to bypass any level of antivector immunity induced after the primary vaccination (Rose et al., 2000).

OTHER VIRUSES

In addition to the viral vectors described above, there are several others being investigated for utility in gene therapy and vaccination applications. Herpes simplex viruses (HSV) are double-stranded DNA viruses of the family, Herpesviridae. HSV subtypes HSV-1 and HSV-2 are well known for causing human herpes infections, but have also been studied as vaccine vectors for SIV (Kaur et al., 2007), HIV (Santos et al., 2007), and intracellular bacterial pathogens (Lauterbach et al., 2004).

Measles virus (MV), of the Paramyxoviridae family, is a well-known childhood pathogen that, despite availability of effective vaccines, still causes significant mortality in children of developing countries. By using rescue techniques similar to those described above for construction of NDV vectors, MV vectors have been developed as a number of vaccine candidates. An advantage to MV vectors is thought to be the possibility of multivalence. Vaccination of children with a MV vector expressing genes from other pathogens, such as hepatitis B virus (Reyes Del Valle et al., 2007), West Nile virus (Despres et al., 2005), or HIV (Lorin et al., 2004) could serve as a bivalent vaccine against both MV and the other pathogen. However, much like vaccinia vectors, a major portion of the adult population will be immune to a recombinant measles vector due to childhood measles infections or measles vaccinations.

Polioviruses are members of the Picornaviridae family, the same family containing foot and mouth disease and hepatitis A viruses. Poliovirus is well known for causing paralytic poliomyelitis, which has nearly been eradicated due to development of successful and safe inactivated and live-attenuated poliovirus vaccines. Since the attenuated virus strains are safe for use in humans, researchers have studied possibly using poliovirus as a vector for other pathogens (Andino et al., 1994), such as hepatitis B virus (Yim et al., 1996) or SIV (Tang et al., 1997). However, the vast majority of the world's population has immunity to poliovirus from childhood vaccination, making a poliovirus-vectored vaccine somewhat impractical for adults.

CONCLUSIONS

In conclusion, viral vectors can be very useful for the presentation of naturally formed viral antigens to the immune system. Generally speaking, viral vectors have a more favorable safety profile than many live-attenuated virus vaccines and are more immunogenic than inactivated/killed virus vaccines. Furthermore, viral vectored vaccines present the desired antigens in the natural, correct conformation to the immune system, a process very poorly achieved by recombinant protein subunit vaccines. Finally, viral vectored vaccines express higher levels of foreign genes in vivo and for a longer duration when compared to DNA vaccines.

Three major considerations exist for the use of viral vectored vaccines in humans, the first of which is safety. Some platforms, such as Ad vectors, have been tested extensively in human clinical trials for many years and are accepted as being safe for human use. Other platforms, such as VSV, are still in their infancy and human safety remains an unknown factor. As more clinical trials take place, we will gain a better understanding of these vectors and their performance in humans. The second consideration is pre-existing vector immunity, which varies in significance depending on the vector of choice. For Ad or vaccinia vectors, this may have a serious impact on vaccine vector efficacy in humans; for the zoonotic virus vectors, such as avipox viruses or NDV, pre-existing immunity is not likely to play as significant a role in developmental and clinical applications. Finally, the third consideration for vaccine vector development is the vector's genomic capacity for a transgene insert. Depending on the vector, these exogenous DNA sequences can range in length from less than 1 kb to 35 kb. However, with increased transgene size often comes genetic instability and decreased virus yield in production. These must all be factored together to determine the ideal virus vaccine vector that is suitable for use in humans, but also maintaining a high level of efficacy.

The viral vectors mentioned in this chapter represent a portion of the ever-growing field of viral vector research. Some of these vectors are well characterized from the basic virology of the vector to the complexity of the immune responses elicited after vaccination. Others are still incompletely understood. The study and use of viral vectors has advanced the fields of human gene therapy for genetic diseases, cancer gene therapy, and vaccine development, and will continue to expand the scientific horizon.

DNA Vaccines for Biodefense and Emerging and Neglected Infectious Diseases

Shan Lu, Jill M. Grimes-Serrano and Shixia Wang
Laboratory of Nucleic Acid Vaccines, Department of Medicine, University of Massachusetts Medical School, Worcester, MA, USA

OUTLINE

ABSTRACT

Continued improvements in vaccination technologies have led to remarkable progress in the control of human infectious diseases. Our fundamental view of the nature of a vaccine was changed with the discovery of DNA immunization in the early 1990s when it was determined that the genetic material that encodes for antigens, rather than the actual antigens themselves, can be effective in eliciting an immune response. Given the ever increasing threat of emerging and reemerging infectious diseases and a renewed concern regarding the use of biological agents for bioterrorism purposes, the opportunities that DNA vaccine technology provides could not have come at a more critical time in history. Since its inception, DNA vaccination technology has undergone significant advancements and many candidate human vaccine formulations have already been developed. Improved modes of administration, the use of codon and antigen gene optimization, and the implementation of vaccination DNA prime/boost regimens have led to the quick progression of DNA vaccines from research laboratory benches to human clinical trials. Significant progress has been made in developing DNA vaccines against various biodefense and emerging infectious disease targets, such as HIV-1, influenza, severe acute respiratory syndrome associated

coronavirus (SARS-CoV), Ebola, the viral encephalitides, anthrax, plague, and botulism, among others with some already moving into early phase clinical trials with promising results. Having the ability to respond to a potential bioterrorism threat or to some other emerging infectious disease outbreak is crucial and the advancements associated with DNA vaccination technology will allow us to do so in a prompt and rational matter.

INTRODUCTION

In the early 1990s, several research groups discovered, independently, that the direct inoculation of a DNA plasmid coding for a specific protein antigen could elicit an immune response against that antigen (Tang et al., 1992; Robinson et al., 1993; Ulmer et al., 1993; Wang et al., 1993; Lu et al., 1995). DNA or nucleic acid vaccination is now considered to be the fourth generation of vaccines after live attenuated vaccines, inactivated vaccines, and recombinant protein-based vaccines. This new vaccine technology could not have come at a more important time in history given the increasing threat of emerging and reemerging infectious diseases and a renewed concern regarding the use of biological agents for bioterrorism purposes. The need for immunological protection for large populations would require the production or stockpiling of large quantities of vaccines. Future vaccines need to be effective while maintaining a high safety profile. The designs of vaccines have to be flexible to counter antigen alterations and to protect people from more than one type of pathogen. DNA vaccines are an ideal vaccine system to employ in the face of such challenges.

DNA vaccines utilize a eukaryotic expression vector to express a gene product or multiple gene products in vivo. It is this expression system that serves as a delivery system to produce either secreted or cell-associated antigens with the goal of eliciting optimized antigen-specific humoral and cell-mediated immune responses in the host. Over the past 15 years, DNA vaccine technology has gone through significant improvements. The focus of research has gradually shifted from proof-of-concept studies in animal models to the demonstration of immunogenicity in humans. DNA vaccine technology provided researchers with a unique platform that is effective in achieving three important objectives in the development of the next generation of vaccines against emerging infectious diseases and pathogens that have the potential to be used as bioterrorism agents. First, DNA vaccines are a simple alternative option against those pathogens to which there were effective vaccines in the past but the original manufacturing process is no longer considered safe. Second, DNA vaccines are able to elicit improved cell-mediated immune responses in addition to protective antibody responses, which dominate the design of previous generations of vaccines. Finally, DNA vaccines are an ideal tool to screen for new or optimal protective antigens (PA) to formulate new or improved vaccines against emerging and neglected infectious diseases or bioterrorism.

ADVANCEMENTS IN DNA VACCINE TECHNOLOGY

Since the discovery of DNA vaccines in the early 1990s, it is well recognized that this novel immunization technology possesses the following key strengths: (1) the ease of construction and production of the constructs; (2) the native conformation of in vivo expressed protein antigens including any associated post-translational processing of newly synthesized proteins, such as glycosylation; (3) the flexibility of modifying antigen sequences to match with mutated pathogen genes or to produce optimized "designer's antigens"; (4) the ability to elicit both cell-mediated and humoral immune responses; (5) overall good safety profile; and (6) the potential to deliver multiple antigen genes in one construct or as a mixture of multiple plasmids.

Over the past 15 years, the immunogenicity of DNA vaccines has been further improved through the utilization of several key technological advancements including antigen gene codon and coding sequence optimizations, various DNA delivery methods, and the adoption of "prime-boost" regimens.

Codon and Antigen Gene Optimizations

The critical step for DNA vaccination is to establish a high level of gene expression in a mammalian host. One way to improve the immunogenicity of DNA vaccines is to alter the nucleic acid sequences of the viral DNA so that they better complement the genetic makeup of the mammalian host while keeping the same amino acid—a process called codon optimization. The basis for using codon optimization in DNA vaccine design stems from the idea that many amino acids can be coded by more than one codon and that the frequency by which a mammalian host may use a particular codon may differ from usage by

a virus. Various studies have used this knowledge in order to improve the ability of mammalian cells to express viral proteins (Haas et al., 1996; Andre et al., 1998; Kotsopoulou et al., 2000; Liu et al., 2004; Apt et al., 2006; Wang et al., 2006a, 2006c). It is this method of altering the genetic sequence that has proven to be effective in increasing the immunogenicity of various DNA vaccines against human immunodeficiency virus (HIV) (Haas et al., 1996; Andre et al., 1998; Kotsopoulou et al., 2000; Liu et al., 2004; Wang et al., 2006a), influenza virus (Wang et al., 2006c), and dengue virus (Apt et al., 2006) due to increased overall antigen production as a result of enhanced mRNA stability (Wang et al., 2006a) and better utilization of host-cell tRNAs (Haas et al., 1996). Due to the adaptation of codon optimization, an otherwise low efficient DNA expression vector can achieve high-level antigen expression (Wang et al., 2006a).

The efficacy of DNA vaccines can be further optimized if the antigen genes are modified. The full-length gene sequences of some candidate antigens cannot be directly used as the antigen gene inserts of the DNA vaccine and may require modification in order to achieve a high-level expression of functional antigenic proteins. For example, an HIV DNA vaccine is not efficient in expressing the full-length glycoenvelope protein (Env) of HIV-1, a gp160 kDa protein; however, two truncated versions of Env, the gp120 and gp140 proteins, that only express the extracellular portion of Env are capable of producing large amounts of Env antigens and eliciting high Env-specific antibody responses (Lu et al., 1998). Sometimes a signal peptide sequence different from the natural leader sequence may also improve antigen expression and immunogenicity of DNA vaccines (Wang et al., 2006a). This process of modifying the original antigen coding sequence is called "antigen engineering" (Lu et al., 1999).

Mode of Administration

The route of DNA vaccine inoculation can greatly alter the immunogenicity of DNA vaccines. Various methods to deliver DNA into the hosts have been developed, using various administration methods, with or without adjuvants. The delivery methodology for DNA vaccines started with the intramuscular injection of so-called "naked DNA" into the host allowing for the uncoated DNA to be taken up into the cells, transcribed, the antigen produced and finally, an immune response elicited. Further development of DNA vaccine technology include facilitated DNA vaccines that employ the use of carriers made of various chemical materials (e.g., lipid polymers and cationic poly(lactide-coglycolide) [PLG] microparticles) (Felgner and Ringold 1989; Wheeler et al., 1996; Stopeck et al., 1998; Herrmann et al., 1999; Klavinskis et al., 1999; O'Hagan et al., 2001; Otten et al., 2005). DNA vaccines, naked or formulated with the above carriers, can be delivered intradermally, intramuscularly, and subcutaneously by a conventional needle injection. Mucosal delivery of DNA vaccines has also been tested including intranasal route; however, in some studies, an emulsion-mediated technique was required in order to induce immunity (Kim et al., 2006).

Other physical delivery methods (such as "gene gun" and electroporation) can improve the efficiency of DNA vaccine uptake by cells and/or increase activation of the immune system. While significant immune responses have been observed in small mammals using the more traditional routes of administration (i.e., intramuscular or intradermal needle injections), these inoculation methods have proven less successful in larger animals and in human studies. On the other hand, the physical delivery approach using particle mediated epidermal delivery (PMED) device has proven to be effective in eliciting immune responses in humans against hepatitis B virus (Tacket et al., 1999; Roy et al., 2000; Rottinghaus et al., 2003), influenza (Drape et al., 2006), and malaria (McConkey et al., 2003).

Prime and Boost Approach

Since the most successful DNA vaccine inoculation method (PMED) for eliciting immune responses in nonhuman primates and in humans is not commercially available for clinical use, it has become important to utilize other techniques and methods to increase the immunogenicity of DNA vaccines that are currently in development. One such method is the prime-boost approach. The rationale underlying this strategy is that gene-based vaccines, presented by a recombinant viral vector or as DNA plasmids, elicit immune responses by producing antigens in vivo; however, these immune responses have not been strong, particularly in humans. In order to increase the levels of immune responses, in particular the cell-mediated immune responses, strategies have been developed to prime the immune system with the DNA vaccine and boost with a recombinant viral vector (Pancholi et al., 2000; Ramshaw and Ramsay, 2000; McShane et al., 2001; Schneider et al., 2001; Gonzalo et al., 2002; Mellquist-Riemenschneider et al., 2003; Woodland, 2004; Seaman et al., 2005; Wu et al., 2005; Perkins et al., 2006), or an attenuated virus (Yuan et al., 2005). This DNA–viral vector combination has proven effective in eliciting high-level cell-mediated immune

responses in nonhuman primate studies (Letvin et al., 2004; Boyer et al., 2005) and even in humans (Mwau et al., 2004; Vuola et al., 2005; Goonetilleke et al., 2006; Hanke et al., 2007).

Alternatively, recombinant protein can also be used to boost the immune system that has been primed with DNA vaccines (Barnett et al., 1997; Letvin et al., 1997; Richmond et al., 1998; Pal et al., 2005, 2006; Wang et al., 2005b, 2006b; Lu, 2006; Law et al., 2007). The DNA prime-protein boost combination has been proven effective in eliciting balanced humoral and cell-mediated immune responses even in human studies (Wang et al., 2008a). The DNA prime or protein boost components when used alone have been shown to be less effective in inducing immune responses when compared to prime plus boost approach (Wang et al., 2005b, 2006b).

REPRESENTATIVE DNA VACCINES FOR BIODEFENSE AND EMERGING INFECTIOUS DISEASES

A large number of studies, using various animal models, have been conducted over the past 15 years to examine DNA vaccine immunogenicity against a wide range of pathogens including viruses, bacteria, and parasites. Contrary to the popular belief, DNA vaccines are more complicated than simply inserting a randomly selected pathogen gene into a DNA vaccine vector. The process of developing a successful DNA vaccine is no different from any scientific discovery: trial and error. In the following sections, results from selected DNA vaccine studies are presented to illustrate various aspects of the development of DNA vaccines against many important biodefense and emerging infectious disease targets over the past decade.

DNA Vaccines against Viral Agents

Human Immunodeficiency Virus Type 1 (HIV-1)

Acquired immunodeficiency syndrome (AIDS) is the number one emerging infectious disease in the 20th century. It continues to be a worldwide pandemic in the new millennium. The development of an effective AIDS vaccine has been proven more challenging than initially anticipated. There does not appear to be natural adaptive immune protection against HIV-1 infection; hence, the correlate of protection to be induced by a vaccine is uncertain. As a retrovirus, HIV-1 integrates into the genome of host dividing cells, which in turn becomes the source of continuing infection. Its proteins go through constant mutations due to the lack of proofreading function of retroviral polymerases. The structure of envelope glycoprotein (Env), the immunodominant antigen of HIV-1, is very complicated and highly variable to escape from antibody responses.

The recombinant protein HIV-1 vaccines in the form of gp120 antigens have failed to protect a high-risk population in two phase III efficacy trials (Flynn et al., 2005; Gilbert et al., 2005; Pitisuttithum et al., 2006). While the live attenuated vaccination approach was successful in simian immunodeficiency virus (SIV) studies in nonhuman primates (Desrosiers et al., 1989; Daniel et al., 1990), due to safety concerns this approach has little hope of being tested in humans. HIV was among the first pathogens for which the DNA vaccine approach was explored (Wang et al., 1993; Lu et al., 1995) and the HIV vaccine field quickly became the major testing ground for the optimization and application of DNA vaccines. DNA vaccines have been used to express many key HIV-1 antigens including Env, Gag, Pol, Nef, Rev, and Tat for the induction of both antibody- and cell-mediated immune responses. Currently, DNA vaccines are one of the key components in almost every major HIV vaccine development program. DNA vaccines are used mainly as priming immunizations and are typically combined with either a viral vector boost (Mwau et al., 2004; Graham et al., 2006; Tavel et al., 2007) or a protein boost (Wang et al., 2008a). More human studies have been planned or are ongoing. The results from these studies will provide important guidance for the future development of DNA vaccines for other emerging infectious disease and biodefense applications.

Influenza Viruses

Influenza virus infection remains a major health threat to both humans and animals. Influenza A viruses infects both humans and other animal species, including swine, horses, and avian. The predominant human influenza virus vaccine is the trivalent inactivated influenza vaccine (TIV), which incorporates the predominant viruses that are predicted to circulate during the next influenza season. The vaccine typically includes an H1 subtype and an H3 subtype from influenza A plus an influenza B virus. The immunogenicity of these vaccines is relatively low and requires annual booster immunizations to maintain the levels of protective immune responses and to develop new protective antibodies against mutated viral antigens that occasionally emerge. A newly developed cold-adapted live influenza virus vaccine has much improved immunogenicity but it

cannot be used for young children and older populations due to a lack of safety data in these groups. This restriction greatly reduces the utility of this new vaccine because young children and older people are particularly vulnerable to influenza infection.

The emerging threat of avian influenza as a potential cause of a future pandemic has raised issues of vaccine efficacy, production, and stockpiling. The old influenza vaccine technologies may not be sufficient in facing new challenges.

Influenza DNA vaccine development was another early key area for the field. Studies demonstrated the immunogenicity of DNA vaccines using either nucleocapsid (NP) or hemagglutinin (HA) antigens (Ulmer et al., 1993; Robinson et al., 1993; Fynan et al., 1993). A landmark study in the early 1990s showed that a DNA vaccine expressing NP was effective in eliciting NP-specific CTL and protection in mice from a subsequent challenge with a heterologous strain of influenza A virus, as measured by decreased viral lung titers, inhibition of mass loss, and increased survival (Ulmer et al., 1993). Subsequent studies from this and other groups confirmed the protective immune responses induced by NP DNA vaccines (Ulmer et al., 1998; Cox et al., 2002) or by the combination of DNA prime-adenoviral vector boost vaccines (Epstein et al., 2005), but there were also reports showing that NP DNA vaccine alone was not effective in protecting pigs against challenges with homologous virus (Macklin et al., 1998). However, later studies in ferrets and non-human primates demonstrated the efficacy of a DNA vaccine encoding three proteins, NP, HA, and M1 antigens (Donnelly et al., 1995, 1997). DNA vaccine expressing other influenza viral antigens have also been reported including the co-expression of both M1 and M2 antigens (Okuda et al., 2001), the co-delivery of NP and M2 DNA vaccines plus a low dose of HA-expressing DNA vaccines (Jimenez et al., 2007), and the use of NA-expressing DNA vaccines (Chen et al., 1998, 2000). Various levels of protection with these influenza DNA vaccines were achieved in mouse models. Protection against influenza B virus infection was also achieved with DNA vaccines expressing HA or NA antigens but not with NB or NP DNA vaccines (Chen et al., 2001).

The HA-expressing DNA vaccines appear to be the most protective influenza DNA vaccine and protection elicited by HA DNA vaccines correlates with titers of neutralizing antibody (Robinson et al., 1997). However, recent studies suggested that the HA antigens from H1 and H3 serotypes of influenza A viruses require different antigen designs for the induction of optimal protective antibody responses (Wang et al., 2006c). This may further affect the selection of HA antigens from avian influenza viruses. Until now, HA DNA vaccines have successfully elicited antibody responses and protection against several avian influenza viruses including H5N1 (Kodihalli et al., 1999), H5N2 (Kodihalli et al., 1997; Jiang et al., 2007), and H9N2 (Qiu et al., 2006). The H5 HA DNA vaccine has been shown to induce immune protection against not only a homologous, lethal H5 virus but also two antigenic variants in chickens (Kodihalli et al., 1997). The level of protection may vary in different animal models. Despite the success of inducing protective immunity against heterologous viral challenge in chickens, an HA DNA vaccine encoding for heterologous viruses did not prevent infection in mice. However, this HA DNA vaccine did prevent death associated with infection (Kodihalli et al., 1999).

New DNA vaccine technologies have also been incorporated into the design of improved influenza DNA vaccine designs. Codon optimization was shown to improve the immunogenicity and protective antibody responses (both HI and microneutralization antibodies) of HA DNA vaccines (Wang et al., 2006c; Jiang et al., 2007). Consensus-based DNA vaccines against H5N1 avian influenza viruses have been produced with initial results showing the possibility of inducing cross-reactive cellular immunity (Laddy et al., 2007). However, whether such consensus antigens can induce protective immune responses against different H5N1 viruses remains unconfirmed.

One of the key contributions of influenza DNA vaccine research was the demonstration that an HA DNA vaccine could induce HA-specific antibody responses induced in humans. Using a particle-mediated epidermal delivery (PMED) device, 3 groups of 12 healthy adult subjects received a single dose of 1, 2, or 4 μg of an HA DNA vaccine. The PMED influenza DNA vaccine elicited serum hemagglutination-inhibition antibody responses at all three dose levels with the highest and most consistent responses in subjects vaccinated with the highest dose. On day 56, sera HA-specific antibody responses in both 2 and 4 μg groups reached the levels required for influenza vaccine approval established by the Committee for Proprietary Medical Products (CPMP) in the European Union (Drape et al., 2006). This result was important because it demonstrated that a DNA vaccine was capable of eliciting protective immune response levels. One notable factor in this study was the use of the "gene gun" delivery method, which has proven to be more effective than needle injection of DNA vaccines in inducing immune responses in humans. The availability of the gene gun or other epidermal delivery methods will be important in the successful development of DNA vaccines for biodefense and emerging and neglected diseases.

Smallpox

The original smallpox vaccine, based on the vaccinia virus (VACV), facilitated the worldwide eradication of smallpox with the last case of natural smallpox infection reported in Somalia in 1977 (WHO, 1980). Despite the elimination of naturally occurring smallpox infection, the threat of its use as a biological weapon is compelling enough to develop a vaccine strategy to protect the large percentage of the population that no longer has immunity against this disease. Poxviruses are large viruses with a genome that encodes about 200 proteins. The size of the virus has complicated efforts to delineate the major PAs. Furthermore, the relative importance of humoral and cellular immunity in vaccine-induced protective immunity is uncertain.

In well-designed animal studies a DNA vaccination approach has recently identified several protective pox antigens. There are two forms of infectious poxvirus: the intracellular mature virus (IMV) and the extracellular enveloped virus (EEV). Studies have shown that vaccinia virus IMV-specific antigens, A27, L1, and D8, and EEV-specific antigens, A33 and B5, are immunogenic and protective, albeit variably, against VACV infection in animal models (Galmiche et al., 1999; Hooper et al., 2000, 2004; Fogg et al., 2004; Pulford et al., 2004; Sakhatskyy et al., 2006, 2008; Xiao et al., 2007). These antigens induced high-titer serum antibodies and/or neutralizing antibodies against the vaccinia virus (Galmiche et al., 1999; Hooper et al., 2000, 2003, 2004, 2007; Heraud et al., 2006; Sakhatskyy et al., 2006, 2008). A four-gene combination DNA vaccine that encodes two IMV (A27 and L1) and two EEV (A33 and B5) antigens was protective against VACV challenge in mice and against monkeypox virus challenge in nonhuman primates (Hooper et al., 2003). In a separate study, IMV antigen D8 was shown to be a highly immunogenic antigen that induced high-level protection, alone or in combination with the other pox antigens (Sakhatskyy et al., 2006, 2008). However, these pox DNA vaccines, as well as the recombinant protein-based pox subunit vaccines, were not as protective as the live-attenuated vaccinia virus vaccine unless polyvalent formulations and/or multiple immunizations are used (Hooper et al., 2000, 2003; Fogg et al., 2004; Pulford et al., 2004; Sakhatskyy et al., 2006, 2008).

Only limited studies have measured cell-mediated immune responses following immunization with various DNA vaccines against VACV challenge (Otero et al., 2006). A recent study demonstrated that mice immunized with the DNA plasmid encoding for the B5R antigen of VACV elicited strong EEV-induced IFN-γ responses (Pulford et al., 2004). Interestingly, contrary to previous studies, this study did not observe increased antibody responses in vaccinated mice but rather found that cell-mediated responses correlated with protection. In a DNA prime-protein boost study, rhesus macaques were immunized with a four-antigen formulation (L1R, A27L, A33R, and B5R) in the form of either DNA vaccines alone, *Escherichia coli* produced recombinant protein vaccines alone, or a combination of both vaccines. Animals that received the prime-boost immunization achieved the best protection (Heraud et al., 2006).

The DNA vaccination approach also provides a unique technical advantage in developing vaccines that are more closely related to smallpox antigens. It can permit the direct cloning and expression of antigen from variola major (Sakhatskyy et al., 2008; Aldaz-Carroll et al., 2007) since the protective antigen genes can be chemically synthesized, even codon optimized, without directly working with the highly pathogenic variola major viruses, which are no longer available for research applications. In summary, DNA vaccination is particularly useful for the next generation of smallpox vaccines based on subunit antigens. It can deliver multiple protective antigens in one mixed formulation, elicit both antibody- and cell-mediated immune responses, and optimize the antigen sequences and designs for the protective antigens. Optimized genes can also be used to produce recombinant protein-based subunit vaccines.

Severe Acute Respiratory Syndrome Associated Coronavirus (SARS-CoV)

Severe acute respiratory syndrome (SARS), an acute respiratory disease cause by a newly recognized human coronavirus (SARS-CoV), was first reported in Asia in 2003. During the 2003 outbreak, approximately 8000 people worldwide became ill with 774 fatalities before the outbreak was finally contained (CDC, 2005). SARS is the first major emerging infectious disease in the 21st century. Although no final human vaccine has been developed, several candidate antigens have been discovered and some have been tested as DNA vaccines against SARS infection. Both the nucleocapsid protein (N) and the envelope spike protein (S) have been examined for their ability to induce protective immunity against SARS-CoV in mice.

DNA plasmids, encoding the N protein, have been shown effective in eliciting both humoral and cellular immunity in mice after two or three immunizations (Zhu et al., 2004; Zhao et al., 2005). Since the N antigen is not known to be a target for antibody-mediated protection, the majority of SARS-CoV DNA vaccines have incorporated the S protein as the key protective

antigen. No matter whether the entire S protein or fragments of the S protein are incorporated into the DNA vector for immunization, significant levels of S-specific immune responses were elicited including high-titer binding antibody (Yang et al., 2004; Kong et al., 2005; Zakhartchouk et al., 2005; Huang et al., 2006; Zhao et al., 2006; Hu et al., 2007; Wang et al., 2005b) or neutralizing antibody responses (Yang et al., 2004; Woo et al., 2005; Zakhartchouk et al., 2005; Wang et al., 2005b). In addition, S-specific cellular immune responses including both CD4+ and CD8+ T cell responses were detected with S DNA vaccines (Yang et al., 2004; Huang et al., 2006; Zhao et al., 2006; Hu et al., 2007). Even greater levels of immunity were observed when these S DNA vaccines were included as part of a prime-boost regimen (Kong et al., 2005; Woo et al., 2005; Zakhartchouk et al., 2005) or when a cytokine (IL-2) was included as the molecular adjuvant (Hu et al., 2007).

Although it has not been possible to determine the efficacy of most SARS DNA vaccines due to the limited availability of animal testing facilities capable of working with the SARS-CoV, it has been shown that some S DNA vaccines (i.e., deleted transmembrane domain or a truncated cytoplasmic domain) were effective in significantly reducing the viral load in the lungs of infected mice (Yang et al., 2004). However, a limitation of the SARS-CoV mouse model is its lack of clinical endpoints (e.g., disease or death) and the field is further limited by the lack of a generally accepted nonhuman primate model.

Results have been promising in the development of a DNA vaccine against SARS-CoV. However, more studies are needed, using better animal models that can assess the ability of the experimental vaccines to protect against infection and disease. It is important to note that use of the DNA vaccine platform proved to be nimble in facilitating the rapid development of highly immunogenic candidate vaccines against the sudden emergence of a new human infectious disease.

The Filoviruses: Ebola and Marburg

Infection with either Ebola or Marburg typically results in severe hemorrhagic fever in both humans and nonhuman primates. Four species of Ebola have been identified (i.e., Zaire, Sudan, Reston, and Ivory Coast) with the first known case occurring in Zaire in 1976. Marburg virus was identified in 1967 and named after the site where the infection occurred, Marburg, Germany. There is no effective prophylaxis or treatment for infection with either virus. While filoviruses are uncommon causes of human infection, the development of filovirus vaccines are warranted based on their remarkable lethality with mortality rates ranging from 23% (Marburg) to 90% (Ebola). There has been limited work on the development of live attenuated Ebola virus vaccines, but safety issues make this approach somewhat problematic.

Significant progress has been made in the development of DNA vaccines for both Ebola and Marburg viruses including the completion of a recent phase I human trial for an Ebola DNA vaccine. These vaccine strategies have targeted various viral proteins including both the secreted (sGP) and transmembrane (GP) forms of the glycoprotein and the nucleoprotein (NP). These DNA vaccines were tested in various animal models including mice, guinea pigs, and nonhuman primates, and in humans with promising immunogenicity results. In an early study, all three viral proteins were tested to determine their immunogenicity in mice and their protective efficacy in guinea pigs (Xu et al., 1998). Three 50μg injections of the NP and sGP DNA plasmids were effective, although to varying levels, in eliciting an antibody response while the GP DNA did not elicit a neutralizing response. However, the NP construct induced only minimal CTL responses, whereas the sGP and GP plasmids induced strong CTL responses. Furthermore, guinea pigs challenged approximately 2 months after the first immunization showed nearly complete protection: GP (6/6), sGP (5/6), and NP (4/4). Similar results were observed in mouse protection studies with the GP protein although as many as four immunizations were required (Vanderzanden et al., 1998; Riemenschneider et al., 2003). Likewise a GP DNA prime-recombinant baculovirus-derived GP protein boost regimen afforded guinea pigs good protection. A separate study showed that DNA immunization and subsequent boost with adenovirus vectors that encoded either GP, NP, or a combination of the two conferred 100% protection in guinea pigs (Sullivan et al., 2000). Furthermore, antibody titers were increased in mice that received the GP DNA prime plus adenovirus vector boost when compared to DNA alone. Since the Ebola virus has to be modified in order to produce disease in rodents, primate models of infection would more closely emulate infection in humans. After three injections of naked GP DNA vaccines, several months of rest, and recombinant adenovirus based vaccine boost, antibody titers were increased 10- to 20-fold when compared to DNA immunization alone and there was 9- to 20-fold increase in cellular immune responses that appear to be driven by CD4+ T cells. This vaccination regimen was able to confer protection in four out of four monkeys and sterilizing immunity was observed in three out of four.

Recently, a phase I clinical trial was conducted to determine the safety and immunogenicity of a DNA vaccine for the Ebola virus in healthy volunteers

(Martin et al., 2006). The DNA vaccine contained three plasmids in equal concentrations for the NP (Zaire strain), and two GP (one from the Zaire strain and the other from the Sudan/Gulu strain). This vaccine formulation was safe and well tolerated. DNA vaccine formulation elicited antigen-specific antibody responses to at least one of the three antigens in 100% of vaccinees and 19 out of 20 vaccines showed an antibody response to either GP antigen at one or more time points during the vaccination schedule. Similar to what was observed for monkey (Sullivan et al., 2000), CD4+ T cell responses were more robust than CD8+ responses with the GP antigens producing the greatest response when compared to NP.

The DNA vaccine platform has also been used to develop a vaccine against the Marburg virus although few studies have been conducted to date. Marburg virus GP-expressing DNA vaccine was administered to guinea pigs and serum antibodies were detected after three immunizations. This vaccine prevented death in 8 out of 10 animals that exhibited a 10-fold or higher increase in anti-Marburg virus antibodies 1 month after infection. However, a combination DNA prime plus baculovirus-expressed recombinant GP boost in adjuvant (one DNA prime and two protein boosts) conferred complete protection whereas neither vaccine modality did so when administered alone (Hevey et al., 2001). A second study observed complete protection in guinea pigs and protection in two of three monkeys vaccinated with a Marburg virus GP DNA plasmid (Riemenschneider et al., 2003). The antibody responses observed in the two monkeys that survived challenge were not significantly different from those in the monkey that did not survive, indicating that antibody levels alone do not necessarily predict protection against Marburg infection.

Results from the filovirus vaccine studies are promising in that they all indicate that vaccination with related DNA vaccines which encode for various Ebola or Marburg antigens can induce both cellular and humoral immune responses and that these vaccines can confer some level of protection from infection. More human trials will determine the efficacy of these vaccines.

Flaviviruses: West Nile Virus, Japanese and Tick-Borne Encephalitis Viruses, Dengue Virus

West Nile Virus At the end of the summer of 1999, there was an outbreak of viral encephalitis in the New York City and surrounding areas, which was later determined to be caused by West Nile virus (WNV). This outbreak continued in the subsequent years in the United States in humans and in horses. No human or veterinary vaccines existed for WNV at the time of the initial outbreak. Different versions of DNA vaccines were developed and they all showed good immunogenicity. One version expresses the WNV capsid protein, and in vivo study in mice showed Th1 type immune responses in immunized animals (Yang et al., 2001). Another used a novel approach to express a full-length infectious Kunjin virus RNA. Kunjin virus is a genetically stable Australian flavivirus originally shown to be genetically and antigenically very closely related to several WNV strains, which later was reclassified as a WNV (Heinz et al., 2000). Sequence analysis revealed 98–99% amino acid homology between Kunjin and NY99, the WNV causing the initial 1999 New York outbreak. By using a further modified molecular clone with mutated *NS1* gene, an attenuated Kunjin strain was produced and used as a vaccine. The use of DNA vaccine directing in vivo transcription of the full-length attenuated but infectious KUN viral RNA in mice led to full protection against the WNV NY strain (Hall et al., 2003).

Scientists at US CDC and Fort Dodge Laboratories, Inc., a division of Wyeth, developed the pCBWN DNA vaccine that expresses the WNV prM and E proteins (Davis et al., 2001). A single intramuscular injection of pCBWN DNA vaccine induced protective immunity, preventing WNV infection in both mice and horses (Davis et al., 2001). This vaccine was licensed by the US Department of Agriculture on July 18, 2005, becoming the first DNA vaccine approved by a regulatory agency. In granting full licensure, USDA's Center for Veterinary Biologics determined that the vaccine's safety and efficacy have been satisfactorily demonstrated.

In April of 2006, a DNA vaccine targeting WNV, developed by scientists at the NIH's Vaccine Research Center (VRC) in collaboration with Vical, Inc., entered into a phase I clinical trial with a targeted completion date of October of 2007 (NIH, 2007). This experimental vaccine encodes two key WNV surface proteins, the precursor transmembrane (prM) protein and the envelope (E) protein. The vaccine was administered via a Biojector 2000 device. Participants received three injections (i.m., 1 ml of vaccine per immunization for a total of 3 ml) at study days 0, 28, and 56. The primary study endpoint is vaccine safety, and secondary immunogenicity endpoints include ELISA and neutralizing antibody responses and ELISPOT and ICS staining assays for WNV-specific T cell responses. Results of the phase I clinical trial are not yet available (Martin et al., in press).

Japanese and Tick-Borne Encephalitis The viral encephalitides, in particular, Japanese encephalitis (JE)

and Tick-borne encephalitis (TBE), are transmitted to humans and animals by infected mosquitoes or ticks. Infection with these viruses results in various symptoms ranging from fever to encephalitis. While there are inactivated vaccines against these infections, the immunization regimens require multiple doses without producing long-term immunity. Repeated immunizations increase the cost of vaccination campaigns in the developing countries. Some of these inactivated vaccines are not licensed in the United States. Efforts have been made to utilize DNA vaccine technology in order to produce a vaccine against these encephalitides with improved efficacy, greater ease, and lower cost of production and administration.

JE, a virus widely distributed throughout Asia, causes disease in the human central nervous system. Three viral proteins have been reported to provide protective immunity: prM, E, and NS1. DNA vaccines encoding for these viral proteins have been successful in inducing antibodies and protection against JE in mouse models. In one report an NS1 DNA vaccine was shown to afford greater protection from JE challenge and to induce a higher level of antibodies compared to a DNA vaccine encoding the E and prM proteins (Lin et al., 1998). Another study found that a construct encoding prM and E produced neutralizing antibodies and protected mice against JE challenge while constructs encoding capsid (C) or non-structural proteins, NS1, NS2A, NS2B, NS3, or NS5 induced cytotoxic T lymphocyte responses but afforded only partial protection against JE challenge (Konishi et al., 2003a). These results were interpreted to indicate the relative importance of antibody vis-à-vis T cells in vaccine-induced protection. Other investigators reported that a DNA vaccine encoding both the E and prM proteins was as effective or elicited better responses when compared to the commercially available JE vaccine, JEVAX (Chang et al., 2000). Additional studies have shown that needle-free injector administration of DNA vaccines encoding E and prM proteins elicited increased neutralizing antibodies earlier when compared to intramuscular administration in monkey (Tanabayashi et al., 2003) and mouse (Konishi et al., 2003b, 2003c).

Prime-boost regimens have proven to be superior to other methods of maximizing vaccine immunogenicity. Two studies showed that boosting an E/prM DNA vaccine formulation with either sub-viral extracellular particles (Imoto and Konishi, 2005) or inactivated commercially available JEVAX (Konishi et al., 2003b, 2003c) was superior to either vaccine modality alone in inducing neutralizing antibody. The DNA prime-JEVAX boost regimen induced long-lasting immunity, as titers were still 1:80 to 1:160, as of 21 weeks following the last immunization (Imoto and Konishi, 2005). Furthermore, DNA vaccines encoding for prM/E viral proteins afforded greater cross protection against heterologous JE viral strains when compared to inactivated virus vaccines (Wu et al., 2003a).

TBE is most frequently caused by Russian spring summer encephalitis (RSSE) and Central European encephalitis (CEE). DNA vaccines developed against TBE have been successful in animal models in eliciting protective immune responses against viral challenge. As with the other flaviviruses, the most effective vaccines have encoded the prM and E genes. DNA vaccines expressing the prM and E genes of RSSE and CEE, delivered by a gene gun, have been shown to protect both mice (Schmaljohn et al., 1997) and monkeys (Schmaljohn et al., 1999) against homologous and heterologous viral challenge while inducing long-lasting neutralizing antibody responses. Protection appears to be mediated by neutralizing antibody based on passive transfer studies in mice using high neutralizing titer antibodies generated in monkeys by RSSE or CEE DNA immunization (Schmaljohn et al., 1999).

Dengue Viruses Currently, there is no approved vaccine against dengue viruses (DEN). These viruses, spread by the *Aedes aegypti* mosquito, are endemic throughout tropical and sub-tropical regions of the world. There are approximately 100 million infections per year, resulting in both dengue fever and the more serious, dengue hemorrhagic fever (DHF). Although various vaccine approaches including live attenuated, inactivated whole virion and recombinant protein-based subunit vaccines have been tested, the presence of four serotypes of DEN and complicated immunopathologic mechanisms involved in DHF have greatly reduced the speed of developing an effective DEN vaccine. Several DNA vaccine formulations have been developed against all four serotypes (DEN-1, DEN-2, DEN-3, and DEN-4), and in some cases, a tetravalent formulation has induced memory immune responses against both homologous and heterologous viral challenges (Konishi et al., 2006). Typically, the DNA vaccines that most effectively elicit both humoral and cell-mediated immune responses contain the DEN premembrane/membrane (prM) and envelope (E) genes. Immunization with plasmids encoding these genes have been shown to engender antigen-specific antibody and neutralizing antibody responses and protection against DEN-1 in mice (Raviprakash et al., 2000a; Konishi et al., 2003b, 2003c) and nonhuman primates (Kochel et al., 2000; Raviprakash et al., 2000b) and against DEN-2 in mice (Konishi et al., 2000, 2003b, 2003c; Putnak et al., 2003) and nonhuman

primates (Putnak et al., 2003). Additional studies have examined the ability of a tetravalent DNA vaccine formulation, encoding the prM and E genes of all four dengue serotypes, to induce immune responses and found that antibodies specific for each serotype could be induced following immunization (Mota et al., 2005; Apt et al., 2006; Konishi et al., 2006; Raviprakash et al., 2006). Furthermore, immunization with such a tetravalent DNA vaccine was able to elicit neutralizing antibody responses 4 days following the viral challenge against both the homologous virus used for the challenge assay and against the heterologous viruses (i.e., not used for challenge) (Konishi et al., 2006).

The ability of the dengue virus nonstructural protein 1 (NS1) to elicit immune response has also been examined with contradictory results. In one study, a DNA vaccine encoding for the NS1 failed to induce antigen-specific antibodies after one to three immunizations; however, greater responses were observed following challenge with DEN-2 in vaccinated mice when compared to the unvaccinated group (Wu et al., 2003b). In contrast, mice vaccinated with a DNA vaccine based on the NS1 protein from DEN-2 displayed high levels of antibodies (Costa et al., 2006). While it appears as though these two DNA vaccines encoded the same antigen from the DEN-2 virus, slight differences in immunization schedule and/or dosing may have led to the different results. Despite the fact that antibodies were not detected after one to three immunizations with the NS-1 from DEN-2 (Wu et al., 2003b), the NS-1 DNA vaccine conferred protection against lethal challenge in both studies. Furthermore, newborn mice born to dams that were either infected with the DEN-2 virus (100% of litters) or immunized with the NS-1 DNA vaccine (75% of litters) were also protected against the dengue virus following challenge (Wu et al., 2003b).

Alphaviruses: The Equine Encephalitides

The equine encephalitides, including Venezuelan equine encephalitis (VEE) and western equine encephalitis (WEE), are mosquito-borne viruses that can be transmitted to birds, horses, and humans. The clinical findings of these infections range from mild flu-like symptoms to encephalitis, coma, and death. While equine vaccines against some of these viruses have been developed, no human vaccines are currently available. DNA vaccine technology has been used to develop vaccines against VEE and WEE, which is of particular importance as these viruses have the potential to be used as biological warfare agents. In a first study, DNA immunization with a plasmid encoding the major structural proteins of WEE (capsid, E3, E2, 6K, and E1) afforded protection to 50–100% of mice challenged with a lethal dose of one of three strains of WEE. Furthermore, immunized mice showed a strong T-cell proliferation response to purified E2 protein and a partial response to E1 when compared to controls (Nagata et al., 2005). A DNA vaccine has also been developed against VEE. In this study, a replication-defective adenovirus (Ad5) was used to boost the immune responses following the delivery of the DNA vaccine that expressed a region encoding for the E3, E2, and 6K structural proteins (Perkins et al., 2006). Following DNA immunization, no difference was observed in VEE virus-specific IgG response; however, following one intranasal boost with a homologous Ad-based vaccine a significant increase in VEE virus-specific IgG was observed. The prime-boost strategy also significantly enhanced protection against aerosol VEE challenge.

Rabies

Infection with the rabies virus causes acute encephalitis with an extremely high fatality rate. Both inactivated and live-attenuated human rabies vaccines exist but each has its own limitations. DNA vaccination has proven successful against rabies infection in various animal models. In a first series of studies, mice immunized with the rabies glycoprotein displayed rabies virus glycoprotein-specific cell-mediated and humoral immune responses, in addition to complete protection against viral challenge (Xiang et al., 1994, 1995). Subsequent studies showed that a DNA vaccine encoding for a rabies glycoprotein induced a 176-fold increase in geometric mean neutralizing antibody titers following a boost 190 days after the primary immunization in nonhuman primates (Lodmell et al., 1998a, 1998b). Additional studies by this group showed that gene gun administration afforded mice protection against rabies virus challenge and that protective levels of antibodies persisted for over 300 days (Lodmell et al., 1998a, 1998b). They also showed that different prime-boost regimens elicited varying levels of neutralizing antibody responses: priming with a DNA vaccine, a recombinant vaccinia virus vaccine (RVV), or the commercially available inactivated rabies vaccine followed by boosting with either the DNA or inactivated vaccines resulted in rapid and long-lasting antibody responses (Lodmell and Ewalt, 2000). This group also demonstrated that DNA vaccination could be used as an effective post-exposure vaccine (Lodmell and Ewalt, 2001; Lodmell et al., 2002).

Arenaviruses

The arenaviruses are a family of viruses that are usually transmitted from rodents to humans and

include viruses such as lymphocytic choriomeningitis (LCM), Lassa virus, Junin virus, and Machupo virus. Infection with these viruses presents as a wide range of symptoms including fever and flu-like symptoms, meningitis, encephalitis and severe, fatal hemorrhagic fever. Few studies have been conducted in the development of DNA vaccines against these viral agents. In one study, a single immunization with a DNA plasmid encoding the full-length Lassa nucleoprotein was able to induce CD8+ T cell responses in mice and afforded protection against two arenaviruses, LCMV and the Pichinde virus (Rodriguez-Carreno et al., 2005). Unfortunately, DNA immunization against LCMV in another study did not show favorable results following intracranial viral challenge. Not only were some vaccinated mice not afforded protection against viral challenge but they also displayed greater immunopathology instead as evidenced by clinical symptoms of encephalitis and eventual death (Zarozinski et al., 1995). This study represented a rare example of where a DNA vaccine may worsen the outcome of viral infection. Although it is believed that such unexpected results are part of the unique immunopathogenesis of LCMV infection, careful selection of PAs may also be important for the development of DNA vaccines.

DNA Vaccines against Bacterial Agents

Anthrax

Anthrax is one of the early model pathogens used to assess the feasibility of applying DNA vaccine technology to the development of a vaccine against bacterial infection. During the early days of DNA vaccine research, many considered DNA vaccine as a useful tool for the induction of cell-mediated immune responses but did not appreciate the potential of DNA vaccine to induce high-quality protective antibody responses. Because antibody plays a central role in the control of most of the bacterial infections, initially there were only limited DNA vaccine studies for bacterial agents, and the detailed analysis of DNA vaccine against anthrax provided an important milestone in this area.

Anthrax infection, caused by *Baccillus anthracis*, is a disease with high mortality. It attracted great attention in the United States following intentional release of the agent in 2001. Although a licensed vaccine against anthrax has been developed (Bioport Corporation, Lansing, MI), multiple immunizations are required in order to maintain protective levels of immunity, and safety of previous manufacturing process has been an issue. In a first study to establish the possibility of using a DNA vaccine to induce a protective immune response against anthrax, Gu et al. (1999) developed a DNA vaccine that contained a portion of the protective antigen (PA), the protein responsible for initial binding of the bacteria to the target cell. Antibodies against the PA have been confirmed to protect guinea pigs and rabbits against anthrax challenge (Little et al., 1997; Kobiler et al., 2002; Riemenschneider et al., 2003; Mohamed et al., 2005). After multiple inoculations with the PA-expressing DNA plasmid, anti-PA IgG antibodies were observed in all immunized mice, levels of which increased with subsequent boosting. Using an in vitro neutralization assay, this study showed that pooled serum from twice-boosted immunized mice was 100% protective against anthrax at a 1:20 dilution while 50% protection was observed at a 1:100 dilution. In an in vivo protection assay, the authors found that mice immunized with the plasmid PA DNA were completely protected against challenge while no control mice survived. Subsequent studies showed that plasmid DNA prime encoding for the PA antigen followed by a recombinant protein (rPA) boost significantly increased antibody levels and protective efficacy against anthrax challenge in both mice (Williamson et al., 2002) and rabbits (Galloway et al., 2004). However, increases in antibody titers and protective efficacy were also observed in rabbits without the recombinant protein boost (DNA alone) and these effects were long-lasting (Hermanson et al., 2004). In an examination of passive immunotherapy of anthrax infection, rabbits were immunized with a codon-optimized plasmid DNA vaccine encoding PA, with the most effective immunization strategy being the twice DNA prime + one time protein boost regimen. Immune rabbit sera, shown to contain ELISA and neutralization antibodies, were transferred to mice either 1 h prior to or 1 h after lethal anthrax challenge. All mice that received the hyperimmune rabbit sera 1 h prior to anthrax challenge survived 14 days after challenge (end of observation period), while in mice that received the sera 1 h after challenge, only one out of 5 mice died (2 days after challenge), indicating that protection against anthrax could be achieved through passive administration of antibodies that resulted from DNA immunization (Herrmann et al., 2006). Together, these studies indicate that DNA immunization was effective in producing high-titer antibody responses, which conferred protection against aerosolized anthrax challenge in both mice and rabbits.

Plague

While *Yersinia pestis* (*Y. pestis*), the causative agent of plague, is endemic in many rodent populations throughout the world, it is of great concern due to

its potential as a biological weapon. Plague can be transmitted by flea bite causing bubonic plague or through aerosolization to cause pneumonic plague. It is pneumonic plague that is the greatest concern for biodefense as this form of the disease progresses very rapidly, is highly transmissible, and requires therapy shortly after infection. Without early intervention, pneumonic plague infection is most certainly fatal. These features of pneumonic plague along with its possible use as a biological weapon present a strong argument for the development of an effective vaccine.

Currently, there is no known effective clinical vaccine against pneumonic plague. While a variety of whole-cell, killed plague vaccines were developed, their efficacy in protection against pneumonic plague is limited in small animal models (Williamson et al., 1997, 2000). DNA vaccine technology offers advantages in establishing a safe and effective platform by which protection against a variety of plague antigens can be achieved. A first study compared two DNA vaccine delivery methods (i.e., gene gun delivery of 0.6 or 4 μg plasmid DNA versus intramuscular or intradermal delivery of 50 μg plasmid DNA) for the administration of a plasmid DNA encoding for the V antigen of *Y. pestis*. Antibody responses, obtained at 21 days post vaccination, were observed in all vaccinated groups. However, the highest geometric mean titers were observed in mice that were vaccinated with 4 μg DNA via gene gun, with the least effective being intradermal administration of 50 μg DNA (Bennett et al., 1999). Very little protection was afforded in mice inoculated (i.m. or gene gun) with this "optimized" V antigen-expressing DNA vaccine (addition of a CMV promoter) as only two out of six mice (gene gun) survived a subcutaneous challenge with *Y. pestis* (Garmory et al., 2004).

Greater success was achieved when mice were administered a DNA vaccine with a modified V antigen (LcrV) using a human tissue plasminogen activator (tPA) signal sequence (Wang et al., 2004b). In this study, not only were strong V antigen-specific antibodies elicited but mice were also protected against an intranasal challenge with *Y. pestis*. This is of particular importance as this model reflects infection with the more deadly mucosal challenge of plague. The tPA-V DNA vaccine was able to induce excellent secreted V antigens in oligomeric form, which has been hypothesized to be important in eliciting protective antibody responses.

In addition to the V antigen, immunity to the F1 capsular protein has been shown to afford protection against plague and F1-expressing DNA vaccines have been reported effective in eliciting protection. Grosfeld et al. (2003) compared three F1 DNA vaccines that carried different signals for cellular localization for their ability to induce antibodies and protection against *Y. pestis*. Results showed that although the full-length form of the F1 antigen was a poor immunogen, one altered plasmid in particular (deF1, containing the coding sequence of the F1 protein but a 21-amino acid long sequence that codes for a putative bacterial signal peptide is missing) induced substantial antibody titers and protective immunity (38 out of 39 mice) against a subcutaneous *Y. pestis* challenge. It was determined that mice that received a gene gun inoculation of deF1 were protected against 4000 LD_{50} *Y. pestis* challenge and 10 out of 10 animals survived this challenge.

By using the DNA vaccine technology, a group of "2nd line" antigens from *Y. pestis* have been studied for their ability in eliciting protective antibody responses (Wang et al., 2008b). *Y. pestis* outer proteins (YopB, YopD, and YopO), plasminogen activator protease (Pla), and Yop secretion protein F (YscF) are necessary for the full virulence of *Y. pestis*. They have been proposed as potential PAs for vaccines. DNA immunization was used as a tool to study the relative protective immunity of these individual antigens with a standardized intranasal challenge system in BALB/c mice. The natural full-length gene sequences for most of these *Y. pestis* proteins did not display a good level of protein expression in vitro when delivered by a DNA vaccine vector into mammalian cells. As a result, the overall immunogenicity of these wild-type gene DNA vaccines was low in eliciting antigen-specific antibody responses. However, gene sequence modifications, including the removal of hydrophobic regions and the addition of signal peptide sequences with high secretion potential, significantly improved the level of protein expression, as well as the immunogenicity of these antigens in eliciting high-level antigen-specific antibody responses in mice. Modified YopD, YopO, and YscF antigens were able to protect immunized mice, to varying degrees, against the lethal challenge of *Y. pestis* Kim strain (5000 cfu) by intranasal inoculation while no protection was observed with either the YopB or Pla antigens (Wang et al., 2008b). Results of this study demonstrate that DNA immunization is useful in screening, optimizing, and comparing the antigen design and immunogenicity of candidate antigens for the development of a subunit-based plague vaccine. This approach will be useful to expand the search for additional protective antigens against highly virulent *Y. pestis* infection.

Results from these studies indicate that protection against both subcutaneous and intranasal plague, indicative of bubonic and pneumonic plague, respectively, can be conferred through administration of DNA vaccines encoding different *Y. pestis* antigens. The development of broadly active vaccines against plague is important to defend against any ill use of this

pathogen as a biological weapon, with or without any intentional modification of the antigens to escape from the protection elicited by the original vaccination.

Botulism

Botulism is a very rare but serious paralytic disease caused by the bacterium, *Clostridium botulinum*. Historically, three natural forms of botulism existed: food-borne, wound, and infant. However, there also exits a man-made, inhalation form of botulism that is lethal in the microgram dose range and hence represents a highly dangerous potential biothreat. Seven types of non-cross-reactive botulinum neurotoxin exist (A through G) and a licensed trivalent antitoxin, available from the CDC, contains neutralizing antibodies against types A, B, and E, for treatment against botulism toxin poisoning (CDC, 2007). An additional investigational heptavalent antitoxin has been shown to be effective against all known strains of botulism. It is this heptavalent formulation that has been contracted into the Strategic National Stockpile beginning in 2007 (HHS, 2006). However, it has been shown that some strains of botulism are capable of producing mixtures of two toxin types (Cordoba et al., 1995). It is also now known that there are subtypes under each of the serotypes, indicating that the understanding of cross protection and the development of appropriate vaccine strategies will remain a great challenge.

Few studies have examined the feasibility of using DNA vaccines to protect against botulism. In an early study, mice were immunized with a DNA vaccine expressing the carboxyl terminal 50 kDa fragment of the type A toxin, which was placed in two designs: pJT-1, a construct that leads to MHC I presentation, or pJT-2 that leads to MHC II presentation (Clayton and Middlebrook, 2000). After challenge with botulinum serotype A (or in a cross-protection study serotypes B or E), it was observed that the pJT-1 construct was ineffective in inducing protection against challenge with botulism (serotype A 25 LD_{50}). However, mice that received the pJT-2 construct (at least 10 μg DNA) were afforded some level of protection when challenged at week 11. While 50 μg of DNA increased the rate of survival (9 out of 10 challenged with serotype A 25 LD_{50}), a minimum of 11 weeks had to pass prior to challenge as no protection was afforded if challenge was presented at 4 or 7 weeks after immunization. Furthermore, these results showed that no cross protection was afforded by pJT-2 DNA immunization against serotypes B or E, as none of the 10 animals survived the challenge.

Additional studies showed that a DNA vaccine against botulinium subtype F, which is a very rare form of botulism, was found to protect mice against lethal challenge with the same serotype (Bennett et al., 2003; Jathoul et al., 2004). In the first study by this group, a minimum of three i.m. injections of the F subtype-specific DNA vaccine, pABFHc2, which contained a signal sequence after the Hc domain, given over a 4-week period, was sufficient to protect 100% of mice (10 out of 10) against 10^4 MLD of botulinium toxin subtype F, and a single dose protected 60% of mice when they were challenged no less than 28 days after vaccination (Bennett et al., 2003). Additional results from this study indicated that a relationship may exist between FHc-specific antibody levels and survival in the challenge assay, and that a DNA prime-protein boost regimen induced greater levels of serum antibodies when compared to both DNA alone and protein alone. Based on these findings, DNA vaccine appears useful for the design and optimization of a future botulinum vaccine that can protect from multiple serotype toxins.

Helicobacter pylori

Gastritis, peptic ulcers and gastric cancer have all been linked to infection with the *Helicobacter pylori* bacterium. While only two studies have examined the possibility of using DNA vaccine technology to induce antibodies and protection against *H. pylori* infection, the studies were successful (Todoroki et al., 2000; Miyashita et al., 2002). The difference between studies was the DNA vaccine encoding antigen, the enzyme catalase, or the heat shock protein A or B (HspA and HspB, respectively). Both DNA vaccine formulations induced high-titer serum antibodies when compared to the empty DNA vector control. For the DNA vaccine encoding catalase, serum antibody levels were detected beginning 4 weeks after the final immunization with peak levels by 3 months post immunization. Additional analyses included measurement of bacterial colonization in stomach after challenge with *H. pylori*, and all three DNA vaccine formulations (catalase, HspA, and HspB) afforded protection against *H. pylori* replication. The results support the potential use of a DNA vaccine to protect against *H. pylori* infection. As more antibiotic-resistant strains of this bacterium develop, there will be a greater need for the development of an *H. pylori* vaccine.

Tuberculosis

The *Mycobacterium tuberculosis* (TB) vaccine Bacille Calmette-Guerin (BCG) is widely used outside the United States in settings of high TB prevalence. Unfortunately, BCG is not completely effective in preventing TB infection, it can complicate interpretation of the tuberculin skin test, and it has not prevented

the emergence of extensively drug-resistant TB strains. Despite its shortcomings, BCG will likely continue to be used in afflicted countries as it does reduce the mortality rates against the more serious forms of childhood TB (e.g., disseminated and meningeal TB) (ACET, 1998). It is clear that more effective TB vaccines are needed and numerous studies have explored the potential of using DNA vaccination technology to facilitate the development of new and more effective vaccines.

The majority of TB DNA vaccine studies have focused on a family of three protein complexes of the Ag complex: Ag85A, Ag85B, and Ag85C. These antigens are prime targets because they are both found on the cell surface and are also secreted from the bacterium (Wiker and Harboe, 1992). An initial study examined the immunogenicity of a DNA vaccine encoding all three forms of the Ag85 complex (Ag85A, B, and C) and observed high-titer antibody responses in immunized mice (Ulmer et al., 1997). A subsequent study showed that the secreted form of Ag85A induced higher levels of serum antibodies at lower DNA doses and conferred protection against a highly virulent strain of *M. tuberculosis* when compared to the mature form of the protein (Baldwin et al., 1999). DNA vaccines encoding the Ag85A and Ag85B proteins but not Ag85C induced strong Th1-like responses (e.g., increased levels of IL-2, IFN-γ, and TNF-α) towards native Ag85 protein (Lozes et al., 1997), a broader T cell response than observed with natural *M. tuberculosis* infection and increased CD8 + -mediated cytotoxicity (Denis et al., 1998). In addition to these cellular immune responses, protection against challenge was conferred by DNA vaccines encoding the Ag85A protein in mice (Lozes et al., 1997; Denis et al., 1998) and guinea pigs by intramuscular injection (Baldwin et al., 1998) and gene gun inoculation (Sugawara et al., 2003) and for the Ag85B protein in mice (Lozes et al., 1997).

Additional studies have utilized various "prime-boost" strategies to increase both the immunogenicity and protective efficacy of Ag85-encoded DNA vaccines. One such study primed with a DNA vaccine encoding the Ag85 protein and subsequently boosted with purified Ag85 protein. This "prime-boost" strategy increased IL-2 and IFN-γ responses, increased IFN-γ producing CD4+ cells, increased IgG2a isotype antibody responses, and increased the efficacy of the DNA vaccine against *M. tuberculosis* challenge (Tanghe et al., 2001). A second study examined the effects of DNA prime and subsequent boost with the current TB vaccine, BCG, and found that the DNA + BCG regimen was more effective than BCG alone in protecting against TB challenge (Feng et al., 2001; Ferraz et al., 2004) and that CD8+ T cell depletion attenuated this protection (Feng et al., 2001).

DNA vaccines have also been developed to target other TB antigens including hsp65 (Tascon et al., 1996; Ferraz et al., 2004), hsp70 (Lowrie et al., 1999; Ferraz et al., 2004), the alanine–proline-rich antigen (Apa) (Ferraz et al., 2004), and MPT-63, MPT-64, MPT-83, ESAT-6, KatG, and other antigens, either alone or in various combinations (Morris et al., 2000; Repique et al., 2002; Cai et al., 2005a, 2005b). High levels of specific IgG antibodies were observed against Ag85A, MTP-64, and MPT-83 and mice immunized with individual DNA vaccines (Cai et al., 2005b) or a construct encoding all the antigens (Cai et al., 2005a) were protected against TB challenge. While individual DNA vaccines encoding the MPT-63 and MPT-83 antigens provided only partial protection against TB challenge, the multivalent MPT-63, MPT-83, ESAT-6, and KatG DNA vaccine produced antigen-specific cell-mediated and humoral immune responses and a stronger protective response against TB challenge when compared to the current BCG vaccine (Morris et al., 2000). Studies examining the efficacy of DNA vaccines that encode for the heat shock proteins of *M. tuberculosis* found that these proteins were able to decrease the numbers of live bacteria in both the spleen and the lungs of infected mice after only one dose of the hsp65 DNA vaccine, with lower effects observed with the hsp70 and ESAT6 DNA vaccine formulations (Lowrie et al., 1999).

DNA Vaccines against Parasites

Malaria

Malaria is transmitted through mosquitoes and remains a major global public health problem. Each year 350–500 million new cases of malaria occur throughout the world with approximately 1 million deaths occurring mostly in children in sub-Saharan Africa. Although antimalarial drugs are effective in the prevention and treatment of malaria infections, the development of vaccines continues to be the ultimate goal for malaria control.

Significant developments have been made through clinical trials that have tested various designs of DNA vaccines against malaria. In the first set of human DNA vaccine studies, a plasmid DNA vaccine encoding the *Plasmodium falciparum* circumsporozoite protein (PfCSP) produced low CMI responses in human volunteers even with the use of a PMED (Wang et al., 1998, 2001). High DNA dose (2500μg per immunization) was effective in increasing positive responses, and antigen-specific CTL responses were observed (Wang et al., 1998). Measurable antibody responses were not detected in any of the volunteers who had received this safe and well-tolerated malaria DNA

vaccine. In later studies, a DNA prime-recombinant vaccinia virus Ankara (MVA) boost approach was developed to further enhance the immunogenicity of malaria DNA vaccines [for recent review, see (Gilbert et al., 2006)]. A unique chimeric antigen, ME-TRAP, was produced to express the thrombospondin related adhesion protein (TRAP) coupled with a string of multiple epitopes (ME) (18 T-cell epitopes and 2 B-cell epitopes from various pre-erythrocytic *P. falciparum* antigens) (Moorthy et al., 2003). DNA immunization elicited low-level T-cell responses that were amplified by a boost with MVA ME-TRAP. More significantly, intramuscular DNA priming was more effective than gene gun-mediated priming when combined with a MVA boost. The combination immunization regimen produced partial protection, which manifested as delayed parasitemia after sporozoite challenge with a different strain of *P. falciparum*. Recent studies have further demonstrated that the DNA prime-MVA boost vaccine encoding TRAP produced stronger ex vivo IFN-γ ELISPOT responses than did a similar DNA prime-MVA boost vaccine encoding the circumsporozoite (CS) antigen. Importantly, the latter vaccine could not protect healthy malaria-naïve adults against *P. falciparum* sporozoite challenge as did the TRAP-expressing DNA prime-MVA boost vaccine (Dunachie et al., 2006).

A different type of malaria vaccine prime-boost approach was tested in humans. The combination of a PfCSP DNA vaccine prime with the boost of a known protective recombinant protein RTS,S, which is a fusion protein of the *P. falciparum* PfCSP protein and the hepatitis B virus surface antigen (HBsAg). This construct encodes several CD4+ and CD8+ T-cell epitopes. It was administered to volunteers who had received the DNA vaccine (prime) in an earlier trial (Le et al., 2000) or naïve volunteers. Volunteers who were primed with PfCSP DNA vaccine had protective CD4+ T-cell and antibody responses (effects of protein boost) in addition to the previously observed CD8+ CTL and IFN-γ responses (effects of DNA prime). The naïve volunteer group exhibited only antibody and CD4+ T-cell responses, and not CD8+ T-cell responses (Epstein et al., 2004; Wang et al., 2004a). This finding suggested that the PfCSP DNA vaccine was not effective for the induction of antibody responses, either alone or as a priming vaccine.

In an attempt to expand the breadth of protective immune responses, volunteers were immunized with a mixture of five malaria DNA vaccines expressing different *P. falciparum* pre-erythrocyte stage antigens in conjunction with an "adjuvant" plasmid encoding human granulocyte–macrophage colony-stimulating factor (hGM-GSF) (Wang et al., 2005a). IFN-γ responses were detected to multiple class I and/or class II restricted T-cell epitopes from all five antigens (CSP, EXP-1, LSA-1, SSP2, and LSA-3) with no statistical difference between the groups. Additional analyses revealed that in volunteers who received DNA alone (i.e. without hGM-CSF) IFN-γ responses to both class I and class II peptides were boosted after challenge with *P. falciparum* parasites while only responses to class II peptides were boosted in volunteers who were vaccinated with DNA and hGM-GSF. Volunteers who received hGM-CSF actually had a reduced frequency of IFN-γ responses to class I peptides. More importantly, none were protected against malaria challenge, further raising the issue of antigen selection, since previous studies have demonstrated that only a DNA prime-MVA boost vaccine expressing ME-TRAP antigen was able to induce partial protection (Gilbert et al., 2006).

CONCLUSIONS

Tremendous strides have been made in the last two centuries in the control of human infectious diseases through the development of continuously improved vaccination technologies. The discovery of DNA immunization in 1992–1993 fundamentally changed our view of the nature of a vaccine: genetic material that encodes for antigens, rather than the actual antigens themselves, as the effective components of DNA vaccines. This new vaccine technology could not come at a more important time in history given the increasing threat of emerging and reemerging infectious diseases and a renewed concern regarding the use of biological agents for purposes of bioterrorism. Since its inception, DNA vaccination technology has undergone significant advancements and many candidate human vaccine formulations have already been developed. Improved modes of administration, the use of codon and antigen gene optimization, and the implementation of vaccination DNA prime/boost regimens have led to the quick progression of DNA vaccines from research laboratory benches to human clinical trials. Biodefense and emerging infectious disease targets have made a significant contribution to this important process.

CHAPTER

9

Vaccine Adjuvants*

Carl R. Alving
Department of Adjuvant and Antigen Research,
Division of Retrovirology, Walter Reed Army Institute of Research,
U.S. Military HIV Research Program,
Rockville, MD, USA

OUTLINE

ABSTRACT

It is widely believed that adjuvants are important, and in some cases critical, for the success of most modern vaccines, particularly for new types of vaccines that have highly purified or synthetic antigens. Although aluminum salts are the most commonly used type of adjuvant for human vaccines, they are weak adjuvants that have complex mechanisms that favor induction of antibodies rather than cellular immunity. Aluminum salts do have a long record of relative safety, but they are also often responsible for local reactions at the site of injection, particularly for reactions that are associated with subcutaneous administration. Adjuvant selection for human vaccines still relies strongly on direct empirical testing of candidate adjuvants for safety and efficacy in humans. However, principles of innate immunity have been developed that provide some guidance for rational selection of adjuvants. New forms of vaccine adjuvants that have been proposed for various vaccines feature oil-based emulsions; bacterial products, such as lipid A, heat-labile *E. coli* enterotoxin, or CpG nucleotides; viral

products, such as virus-like particles; plant products, such as saponin derivatives; biodegradable particles, such as liposomes; molecular adjuvants; and synthetic adjuvants. Adjuvant mechanisms include depot effects, recruitment of innate immunity mechanisms, specific targeting mechanisms, and carrier functions that hold the antigen in an appropriate conformation. The safety of proposed adjuvants is a primary consideration, and for this purpose it is often necessary to devise methods to reduce or eliminate the reactogenic effects of an adjuvant while preserving the efficacy. The most effective use of adjuvants for certain types of vaccines, particularly for stimulating mucosal immunity, may be to combine the adjuvant with a particular mode of delivery, such as oral, intranasal, or transcutaneous immunization. Carriers that carry and combine both the adjuvant and the antigen in a single formulation can serve as the basis for creation of important formulations for improved vaccines.

THE REQUIREMENT FOR VACCINE ADJUVANTS

A common observation in the process of recruiting the immune system to produce specific or nonspecific immunity is that the antigen by itself may not be adequate as a stimulating agent. Many potential antigens may even have no apparent immunizing activity at all when tested alone. This is particularly true for most small peptides that serve as antigens (Alving et al., 1995), but it can also be true for virtually any antigen. Because of this, the immunologist is often forced to reach into a bag of tricks to find an adjuvant, or an adjuvant strategy, to optimize the immune response. In the context of this chapter, a vaccine adjuvant is defined as any substance or strategy that improves the adaptive immune response or that stimulates the innate immune system to induce desired effectors or mediators.

Because of the need for potent adjuvants that are required for vaccines against highly purified antigens and for vaccines to chronic diseases that are difficult to control, such as HIV, parasitic diseases, and cancer, there has been considerable recent research directed toward the discovery and development of new adjuvants that are safer and stronger. Much of this recent scientific discovery activity has been stimulated both by new understanding of molecular mechanisms underlying certain types of innate immunity (Pulendran, 2004), and by the introduction of DNA that can code both for the adjuvant (sometimes referred to as a "molecular adjuvant"), and for the antigen, as components of DNA-based vaccines (Calarota and Weiner, 2004).

The definition of the term "adjuvant" that is used in the context of this chapter is quite broad and encompasses numerous mechanisms. The heterogeneity of potential adjuvants and adjuvant mechanisms has stimulated many attempts to organize and classify groups of adjuvants, often according to perceived mechanism of action, so that rational selection of adjuvants can be made from adjuvant groups. This is a useful exercise that serves to identify huge numbers of candidate adjuvants (Edelman and Tacket, 1990; Cox and Coulter, 1997; Schijns, 2000; Kenney et al., 2002; Vogel and Alving, 2002). One example of such a listing is given in Table 9.1. However, such classifications are inherently limited because individual adjuvants often have more than one mechanism or more than one dominant characteristic, and therefore, may not lend themselves easily to overarching principles of selection. Commercial considerations, such as ease of manufacture, cost, or toxic side effects are often the deciding factors for an individual adjuvant in a given vaccine. From a practical standpoint, for vaccine development there would seem to be an obvious benefit to utilizing multiple adjuvant mechanisms to either cause additive effects, or reduce the amount of expensive antigens required, or lower the side effects and enhance the safety of individual adjuvants.

In past years, and even to the present, an adjuvant function has been accomplished with human vaccines mainly through adsorption of the antigen to an aluminum salt (Glenny et al, 1926; Aprile and Wardlaw, 1966; Gupta, 1998; Lindblad, 2004). However, it should be noted that aluminum salts generally perform only weakly as adjuvants, particularly for booster immunizations, even though they do have a relatively good record of safety (Aprile and Wardlaw, 1966; Gupta et al., 1993; Baylor et al., 2002; Lindblad, 2004). Studies in which aluminum salts have been directly compared with modern experimental adjuvants in humans have shown that the aluminum adjuvants by themselves usually have lower levels of potency than many newer adjuvants (Gordon, 1993; McElrath, 1995). It may be important for certain vaccines, particularly those that address difficult diseases, such as malaria or HIV infection, to include modern adjuvants that are much stronger than the weak adjuvant activity obtained from simple adsorption of antigen to aluminum salts.

It should not be surprising that adjuvants may be required for optimization of vaccines when one considers that most elements of the immune system rely on various amplification systems as key strategies, and a highly purified antigen may lack the

TABLE 9.1 Types of immunological adjuvants (modified from Vogel and Alving, 2002)

Type of adjuvant	General type	Specific examples
Gel-type	Aluminum salts ("alum adjuvants") Calcium salts	Aluminum hydroxide, aluminum phosphate Calcium phosphate
Microbial	Muramyl dipeptide (MDP) derivatives Bacterial endotoxin Bacterial DNA Bacterial exotoxins	Murabutide, threonyl-MDP Monophosphoryl lipid A CpG Cholera toxin (CT), *Escherichia coli* heat-labile enterotoxin (LT)
Particulate	Biodegradable polymer microspheres, immuno stimulatory complexes (ISCOMs), liposomes	Virosomes
Oil emulsions and surfactants	Freund's incomplete adjuvant Microfluidized emulsions Saponins	Montanide ISA 720 MF59, AS02A QS-21
Synthetic	Nonionic block copolymers, polyphosphazene (PCPP), synthetic polynucleotides	Poly A:U, Poly A:C
Cytokines		Interleukin (IL)-2; IL-12; granulocyte-macrophage colony-stimulating factor (GM-CSF); interferon gamma (IFN-γ)
Genetic	Cytokine genes or genes encoding costimulatory molecules delivered as plasmid DNA	IL-12, IL-2, IFN-γ

ability to activate some or all of the important or most useful amplification systems. However, the older belief that adjuvants are materials that simply increase the potency of, and serve to enhance, the specific immune characteristics embodied in the vaccine antigen itself is often probably wrong. When antigens are taken out of the complex environment in which they exist in nature, whether they are normally present on bacteria, viruses, or cancer cells, the purified antigens often have a reduced ability to stimulate the immune system in the desired manner. Foreign invaders, such as bacteria, viruses, and parasites not only have antigens against which the host immune system reacts, but they also contain built-in adjuvants that carry and present the antigen in an appropriate manner and channel the immune response in an effective direction. When purified antigens are used it is often necessary to utilize adjuvants or adjuvant strategies to achieve the most efficacious presentation and amplification mechanisms.

Examples of current vaccines containing crude antigen preparations that have built-in adjuvant properties include parenterally injected killed inactivated whole cell bacterial vaccines, such as inactivated whole cell *Bordetella pertussis*, *Salmonella typhi*, or *Vibrio cholera* vaccines, which may be contaminated with bacterial endotoxin (Gupta et al., 1993). Endotoxin is a compound that can have strong natural adjuvant activity, and all of the adjuvant activity of endotoxin is due to the lipid A moiety of the bacterial surface lipopolysaccharide (LPS) (Alving and Rao, 2008).

There are, however, some unusual examples in which purified antigens themselves also have adjuvant activity. Three examples, all involving bacterial toxins, are as follows. Cholera toxin (CT) from *V. cholera* and heat-labile enterotoxin (LT) from *Escherichia coli* are examples of antigens that can exhibit both antigenic and adjuvant activity (Elson and Ealding, 1984; Snider, 1995; Glenn et al., 1998, 1999; Lavelle et al., 2004a, 2004b), and CT directly activates dendritic cells (Kawamura et al., 2003). Recombinant protective antigen, a component of the toxin of *Bacillus anthracis*, exhibited apparent adjuvant activity for inducing antibodies to itself by transcutaneous immunization, a process that normally requires an adjuvant in order to be effective (Matyas et al., 2004).

But if amplification is required beyond that supplied by the antigen itself, then the direction of amplification may also be critical. For creation of vaccines, amplification of T regulatory lymphocytes that suppress the desired immune response presumably would be an unwanted outcome (Pulendran, 2004; Pennington et al., 2005). Certain adjuvants may have complex immunomodulatory activities (Lavelle et al., 2004a, 2004b). Likewise, enhancement of IgE production by adjuvants such as by aluminum salts (Baylor et al., 2002), or by ADP-ribosylating toxins (Freytag and Clements, 2005), could be viewed as unfavorable adjuvant effects. Furthermore, in some instances the turning on of the amplification mechanisms in the host can result in unintended attacks on the host itself, and the side effects and toxicities of adjuvants are important factors

in balancing the usefulness of an adjuvant. The engine of amplification not only has to be turned on, but it also has to be harnessed and tuned to guide it in the appropriate direction.

It is also important to remember that the initiation, quality, and magnitude of the immune response to a vaccine antigen can be influenced by numerous nonspecific factors. These factors include the type and dose of the antigen, the timing of immunization and boosting, the route of immunization, and even the age and general health of the vaccinee. In some instances, the utilization of these other factors may be considered to be types of adjuvant strategies. For example, delivery of antigens by needle-free methods, such as transcutaneous immunization (Glenn et al., 2000), or oral delivery (e.g., plant-derived vaccines), or vaccines delivered by intranasal routes (McGhee et al., 1992; González et al., 2004; Freytag and Clements, 2005; Rimoldi and Rescigno, 2005) can result in the induction of mucosal immunity, an effect that directs the course of the immune response simply by the route of vaccine delivery. However, additional adjuvants may also be required for induction of mucosal immunity (Eriksson and Holmgren, 2002).

Two Examples of How Adjuvants can Affect the Qualitative Type of Immune Response

Example 1

Differences in protection against *Mycobacterium tuberculosis* challenge in mice were induced by different adjuvant formulations (Lima et al., 2004). In this study, it was found that injection of recombinant mycobacterial 65 kDa heat shock protein (hsp65) as an antigen by itself was unable to protect mice, even with Freund's incomplete adjuvant. However, when the antigen was administered as a DNA vaccine or as a recombinant protein entrapped in cationic liposomes, protection was observed. In contrast, when hsp65 was encapsulated in polymeric microspheres for sustained release of antigen, high levels of specific antibody were observed but the mice were not protected after challenge. As the authors stated, the vaccine adjuvant "makes the difference."

Example 2

Cytokines are often cited as important adjuvants, but it has been found that mixtures of cytokines can direct the immune responses in various, perhaps even unanticipated, directions. Interleukin-12 (IL-12) together with granulocyte-macrophage colony-stimulating factor (GM-CSF) or tumor necrosis factor-alpha emulsified in Freund's adjuvant was used to steer immune responses to induction of cytotoxic T lymphocytes in BALB/c mice (i.e., toward a Th1 response) (Ahlers et al., 1997). However, GM-CSF alone gave mixed Th1 and Th2 responses, while GM-CSF plus IL-7 gave predominantly a Th2 response.

FREUND'S ADJUVANT AND ALUMINUM SALTS

Freund's Adjuvant

Starting in the 1930s, Jules Freund provided evidence that antigens emulsified in water-in-oil emulsions often had a marked enhancing effect on the immune response (Freund, 1956; Hilleman, 1966). Because of Freund's interest in tuberculosis, his vaccines are referred to as either complete (containing whole-killed mycobacteria) or incomplete (lacking mycobacteria). Although complete Freund's adjuvant is universally regarded as too toxic for use in humans, incomplete Freund's has been used as a potent adjuvant formulation for a diversity of vaccines in more than a million people (Davenport, 1968; Stuart-Harris, 1969; Alving, 2002). Research and commercial applications continue to fuel an interest in Freund's adjuvant, and it is currently being developed for certain human and veterinary vaccines (Chang et al., 1998; Miles et al., 2005; Saul et al., 2005). Although incomplete Freund's adjuvant has a widespread reputation for toxicity in humans (Davenport, 1968; Chang et al., 1998), this is probably largely undeserved because it is based mainly on faulty animal models that do not reflect or translate to expression of human toxicity (Stuart-Harris, 1969; Alving, 2002)

Aluminum Salts

The early introduction of aluminum salts as adjuvants (Glenny et al., 1926) and their endurance as components of numerous types of current human vaccines (Baylor et al., 2002) has led to a huge literature addressing the chemical, physical, and immunostimulatory characteristics and behavior of this class of compounds (Aprile and Wardlaw, 1966; Gupta et al., 1995; Gupta, 1998; Lindblad, 2004). The adjuvant activity of an aluminum salt is often relatively weak, so much so that even with certain established vaccines the presence of enhanced immunological potency provided by aluminum has sometimes been inconsistent (Aprile and Wardlaw, 1966). However, because of long experience with hundreds of millions of doses in human vaccines, and the lack of parenteral side effects, and relatively benign, albeit irritating, local side effects at

the site of injection, observed with aluminum salts, this class of adjuvants has occupied a favored place as a frequent first choice for many vaccines.

The commonly used aluminum salt adjuvants include various physical forms of aluminum phosphate ($AlPO_4$), aluminum hydroxide [$(Al(OH)_3$], and aluminum-precipitates of protein (Shirodkar et al., 1990). These compounds are currently so widely referred to informally as a group by the term "alum" that this term has become an accepted generic shorthand in the vaccine field for aluminum salt adjuvants even though the name "alum" was originally given to potassium aluminum sulfate [$KAl(SO_4)_2$], a chemical entity that apparently might be used in the formulation of certain vaccines in the United States (Baylor et al., 2002), but is not a favored entity (Gupta, 1998).

The dose of aluminum adjuvant is an important consideration. It is important to understand that there may be an optimal level of aluminum for a given vaccine antigen, with decreased immune response at higher levels of aluminum (Gupta, 1998). Although it has been stated that aluminum remains at the site of injection for a long period (Gupta, 1998), small particles of aluminum salts can be internalized by dendritic cells (Morefield et al., 2005), and are known to be removed from the body with time (Hem, 2002). The acceptable dose of aluminum in adjuvants ranges up to 1.25 mg both by US and by WHO regulations, but currently licensed US vaccines have a range of only 0.125–0.85 mg (Baylor et al., 2002). The latter reference can also be consulted for a relatively current list of all licensed US vaccines containing aluminum and the aluminum content of each.

The most common current method of using aluminum is by simple adsorption, and this is accomplished by mixing of antigen with preformed aluminum gel. As deceptively simple as this may seem, considerable difficulty in adjuvant reproducibility may be encountered because of the huge complexity of aluminum–protein interactions. For example, it has been noted that different lots or different brands of the same type of aluminum salt can be inconsistent in adsorptive capacity (Wassef et al., 1994). The physiochemical complexity of interactions of aluminum salts with antigens extends not only to the adsorption of antigen during vaccine manufacture, but also to potential exchange of protein antigen with interstitial proteins and other constituents of interstitial fluids after injection (Seeber et al., 1991b; Heimlich et al., 1999; Iyer et al., 2003).

One of the major benefits of adsorption of antigen to aluminum salts is that combination vaccines can be formulated on a particulate adjuvant. Such vaccines include diphtheria–pertussis–tetanus (DPT), DPT–hemophilis influenzae, or hepatitis B–hemophilus influenzae vaccines (Baylor et al., 2002). It has been shown that cycles of deaggregation and reaggregation of aluminum hydroxide adjuvant lead to homogeneous mixing of multiple antigens on aluminum salt particles in vaccines containing more that one antigen (Morefield et al., 2004). Adsorption to alum salt might also have the interesting benefit of stabilizing and retarding the degradation of an antigen that degrades with a pH-dependent mechanism (Wittayanukulluk et al., 2004).

The adsorptive binding of proteins to aluminum is often due to electrostatic interactions, and adsorption can be strongly affected by the age of the gel (Burrell, et al., 2000), the charge of the gel, the charge of the adsorbed protein, the physical structure of the aluminum compound, and the pH and other characteristics of the buffer that is used (Wittayanukulluk et al., 2004; Seeber et al., 1991a; Callahan et al., 1991; Feldkamp et al., 1981; reviewed by Gupta, 1998). It is possible to manipulate the electrostatic adsorption in certain cases. Aluminum hydroxide gel is positively charged at pH 7.4 and it adsorbs negatively charged proteins. However, pretreatment of aluminum hydroxide with buffer containing phosphate can lower, or even reverse, the positive charge, even allowing the electrostatic adsorption of cationic protein (Rinella et al., 1996).

Many other mechanisms also play a role in the adsorptive process, including hydrophobic interactions, van der Waals forces, and hydrogen bonding (reviewed by Gupta, 1998). Recently it was suggested that ligand exchange between the phosphate groups of phospholipids in the hepatitis B surface antigen (HBsAg) with the hydroxyl groups of aluminum hydroxide provides a mechanism of high affinity binding (Iyer et al., 2004) and that ligand exchange is a stronger force than electrostatic attraction for adsorption of antigens to aluminum hydroxide (Jiang et al., 2006). Presumably this mechanism could also account for the binding of phospholipid liposomes containing monophosphoryl lipid A to aluminum hydroxide adjuvant (Wassef et al., 1994; Alving et al., 1993).

ADJUVANT MECHANISMS

Depot Effects

This strategy encompasses numerous potential formulations including aluminum salts (see above), complex emulsions (Muderhwa et al., 1999; Podda, 2001; Matyas et al., 2003; Richards et al., 2004), various microparticles (O'Hagan et al., 2004; Peyre et al., 2004; Rydell and Sjöholm, 2005; Mossman, et al.,

2005; Westwood et al., 2005; Cai et al., 2005), and other similar materials. A strong argument has been made that one of the major mechanisms of adjuvant activity of oil-based emulsions (although by no means the only mechanism) is through the formation of a depot at the site of subcutaneous (SC) injection that gradually releases small amounts of antigen over a very long time. In one study, after injection of ovalbumin emulsified with IFA, ovalbumin was detectable in the SC IFA emulsion recovered from injected mice for up to 544 days after inoculation and the half-life of ovalbumin within the emulsion was found to be about 90 days (Herbert, 1968). Neither the oil, nor the emulsifier, nor the emulsion itself when injected at a separate site from the antigen, served as an adjuvant for inducing high antibody titers.

Emulsion science, as it relates to oil-based adjuvants, relies heavily on theoretical mechanisms that control the effects of altering the relative amounts of oil and emulsifier compounds in the formulation (Hunter et al., 1981; Woodard, 1990). Variation in the ratio of the oil and emulsifier provide a mechanism for allowing different amounts of stability of the emulsion prior to slow breakup of the emulsion and gradual release of antigen. A common experimental mistake in the formulation of emulsions, such as IFA or other types of oil-based emulsions, is to ignore the emulsifying properties of individual protein antigens that are present in the emulsion. Protein constituents that are present at certain concentrations in emulsions can sometimes cause breakdown of the emulsion. The stability of an emulsion is related to relative chemical properties of emulsifying agents that are known as the "hydrophile-lipophile balance" (HLB), and the adjuvant effects of emulsions were proposed to be related to the HLB (Hunter et al., 1981; Woodard, 1990). Figure 9.1 illustrates a complex emulsion in which different amounts of liposomes containing lipid A were used as an emulsifier for creating oil-in-water emulsions having different degrees of stability. The adjuvant goals in the depot approach can be several. There might be a need to protect the antigen from degradation until it gains access to an antigen-presenting cell (APC). Particles might be able to enter an APC and direct the antigen into an appropriate antigen presentation pathway (Rock, 1996). The material might also act either as an extracellular depot that attracts APCs to the site of the depot, or as an intracellular depot that protects the antigen until it can reach the intracellular location required to generate an immune response. In the case of aluminum salts, which can be taken up by dendritic cells (Morefield et al., 2005), but do not deliver antigen to an intracellular MHC class I pathway for promotion of Th1-type immunity, it would seem more likely that the antigen is either being held as a depot for ingestion by APCs to induce Th2-type immunity, or is being released for uptake by APCs (Jiang et al., 2006), and is promoting the proliferation of B-cell clones for secretion of antibodies.

Recent work has suggested that immunostimulatory effects of emulsions can be partly or wholly independent of both the HLB and the relative stability of the emulsion (Yang et al., 2005). There are controversies in the adjuvant field as to whether one or another

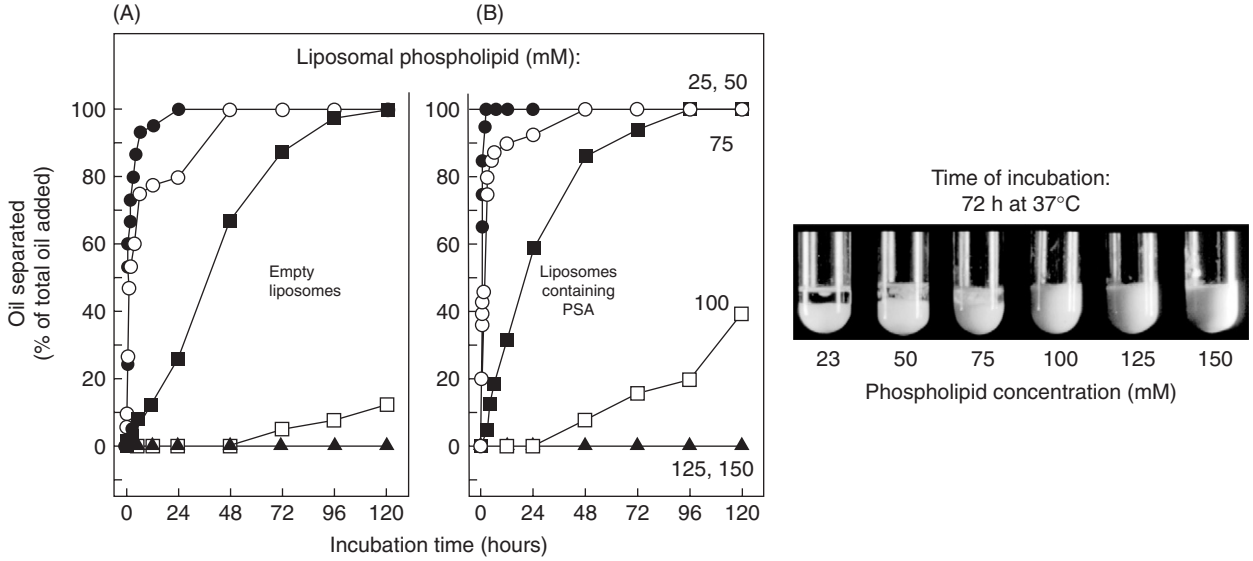

FIGURE 9.1 Time course of the degree of stability of emulsions formulated with 42.5% (v/v) of mineral oil and liposomes containing different concentrations of phospholipid and either (A) lacking or (B) containing prostate-specific antigen. Modified from Muderhwa et al. (1999) (with permission).

function of a given adjuvant represents the dominant mechanism, but it does seem unlikely that an emulsion, or a deposited particle, could simply sit as an inert material at the site of injection and still exhibit substantial adjuvant effects. As with many adjuvants, including aluminum salts (Carroll, 1998; Ulanova et al., 2001; HogenEsch, 2002), the depot may also stimulate complex innate immunity functions, such as the complement cascade, cytokines, and other factors that would recruit diverse cellular elements of the immune system to the site of antigen deposit. A depot microparticle can even exhibit complex direct stimulatory effects on dendritic cells (Westwood et al., 2005).

Innate Immunity

A major factor in the mechanism that is commonly used as the basis in the selection or creation of many different types of adjuvants involves the initiation, activation, or enhancement of innate immunity. This would include engagement of Toll-like receptors (TLRs) and other pathogen-recognition receptors (PRRs) and the co-receptors and intracellular adaptor signaling proteins with which they are associated (Pulendran, 2004; Beutler, 2004; Miller et al., 2005). The existence of such innate stimulatory materials from pathogens in the environment is consistent with the "danger theory" of immune activation (Matzinger, 1994). Adjuvant developers often seek to utilize these materials to harness the power of innate immunity to channel the immune response in a desired direction. This is a growing field that will undoubtedly lead to interesting adjuvant combinations. Scores of adjuvants utilize initiation mechanisms that involve complex interactions of intracellular signaling pathways that are the cause of, or the consequences of, initiation of the innate immune system. TLR recognition causes activation of transcription factors that drive cytokine expression, proliferation, survival, and inflammatory mediator expression. A recent summary of TLRs and PRRs and associated intracellular signaling mechanisms is illustrated in Fig. 9.2.

Gram-negative bacterial LPSs, of which the lipid A moiety is the region primarily recognized by the innate immune system, reacts mainly with TLR4 (Miller et al., 2005). Unmethylated CpG DNA dinucleotide sequences derived from bacteria reacts with TLR9 (Klinman et al., 2004). Thus, lipid A from LPS and CpG are two examples of materials from pathogens that interact with PRRs, and both of these substances are being developed

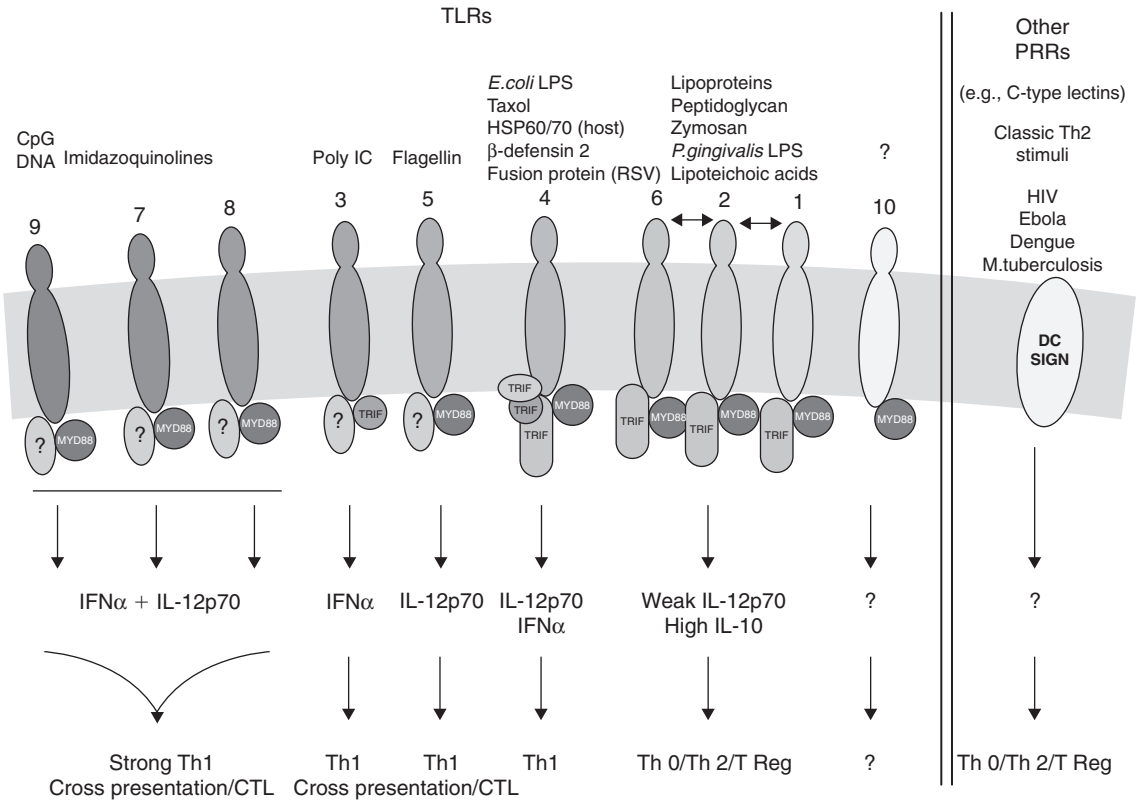

FIGURE 9.2 Regulation of adaptive immune responses by Toll-like receptors (TLRs) and adapter proteins. Reproduced from Pulendran (2004) (with permission).

as potential vaccine adjuvants. Lipid A and LPS can also cause strong complement activation (Carroll, 1998). Activation of complement, which can occur by numerous mechanisms, is a major mediator of B-cell enhancement, and activation of complement represents an important factor in the efficacy of numerous adjuvants (Carroll, 1998).

The emergence of detailed information regarding the existence and mechanisms of TLRs and PRRs has led to a new interest in the possibility of devising a rational means for selection of combinations of vaccine adjuvants that might have complementary, additive, or synergistic immunostimulatory effects (Pulendran, 2004). This is potentially a powerful and useful direction for expanding the future of adjuvant discovery, but it must also be placed in the context that there are many adjuvant mechanisms that are not necessarily related only to signaling pathways.

Secretion of cytokines is often a prominent consequence of initiation or activation of the innate immune system, and cytokines, or DNA that codes for cytokines, is also a focus of adjuvant development (Chen et al., 2001; Sasaki et al., 2003; Hoffman et al., 2003; Calarota and Weiner, 2004; Chattergoon et al., 2004; Ansari et al., 2004; Toka et al., 2004; Melchionda et al., 2005). When utilizing cytokines for enhancement of vaccine efficacy, it is important to understand which immunological parameters are important since the effects of cytokines on certain parts of the immune system can be highly focused and may not necessarily result in the desired effective immune response (Koopman et al., 2005).

Despite the possible importance of TLRs for various adjuvants, considerable caution must also be maintained in believing that adjuvant effects are driven only by recognition of TLRs. The role of TLRs as a necessary adjuvant mechanism in the generation of maximal B-cell responses to foreign proteins has been called into question (Gavin et al., 2006). Mice genetically deficient in both MYD88 and TRIF (*Myd88*$^{-/-}$; *Trif*$^{Lps2/Lps2}$ mice) have a complete lack of known TLR signaling, and because of this they were used to evaluate the role of TLRs in the mechanisms of several well-known adjuvants for enhancing the generation of induced antibodies. When T-cell dependent antigen was tested with four adjuvants: aluminum salt, Freund's complete adjuvant, Freund's incomplete adjuvant, and the "Ribi Adjuvant System" (monophosphoryl lipid A/trehalose dicorynomycolate adjuvant), robust antibody responses were observed (Gavin et al, 2006). It was thus suggested that the TLR system is not required for adjuvant effects with many classical adjuvants in the generation of adaptive immunity. If this is true, it raises the possibility that the cytokine production that is associated with TLRs may be more responsible for side effects than for adjuvant activity. The role of TLRs in the generation of adaptive immunity is an important question that has not yet been completely resolved. It should be emphasized that the exact role of TLRs as part of adjuvant mechanisms for B-cell immunology is the subject of investigations in which controversial areas still exist (Wickelgren, 2006; Nemazee et al., 2006; Pasare and Medzhitov, 2006).

An example of the complexity of adjuvant effects related to innate immunity is given by the role of apoptotic cell death induced by certain adjuvants (Dupuis et al., 2001; Yang et al., 2004). It appears that certain surfactant adjuvants, such as MF59 (an oil-in-water emulsion), or other types of emulsions, can exert their adjuvant effects at least partly by inducing apoptosis and necrosis of macrophages, dendritic cells, and perhaps other cells. It has been suggested that an emulsion can lead to apoptosis, and that phagocytosis of apoptotic bodies (e.g., from macrophages serving as first responders) can induce dendritic cells to mature and stimulate immunity (Dupuis et al., 2001). It has also been suggested that adjuvant-induced apoptosis can occur via a "nonclassical" caspase-independent pathway (Yang et al., 2004).

ADDITIONAL ADJUVANT CHARACTERISTICS AND MECHANISMS

Separation of Toxicity and Adjuvanticity

Substances that have the capacity to attach to membranes to induce nonspecific irritation, inflammation, or other types of stimulation can sometimes serve as adjuvants. However, as understanding in the adjuvant field of the underlying mechanisms of adjuvant effects has evolved, such as the realization of the potential roles of TLRs and PRRs, and dendritic cells, the importance of nonspecific irritation as a mechanism has given way to more sophisticated concepts, two examples of which are described below.

Lipid A

Native lipid A (diphosphoryl), and even monophosphoryl lipid A (Fig. 9.3), have varying degrees of toxic effect, a characteristic that is summarized by their well-known association with pyrogenicity. However, it was shown that although liposomes containing native lipid A or monophosphoryl lipid A completely lacked toxicity, both in animals (Richards et al., 1989; Alving, 1993) and humans (Fries et al., 1992), the lipid

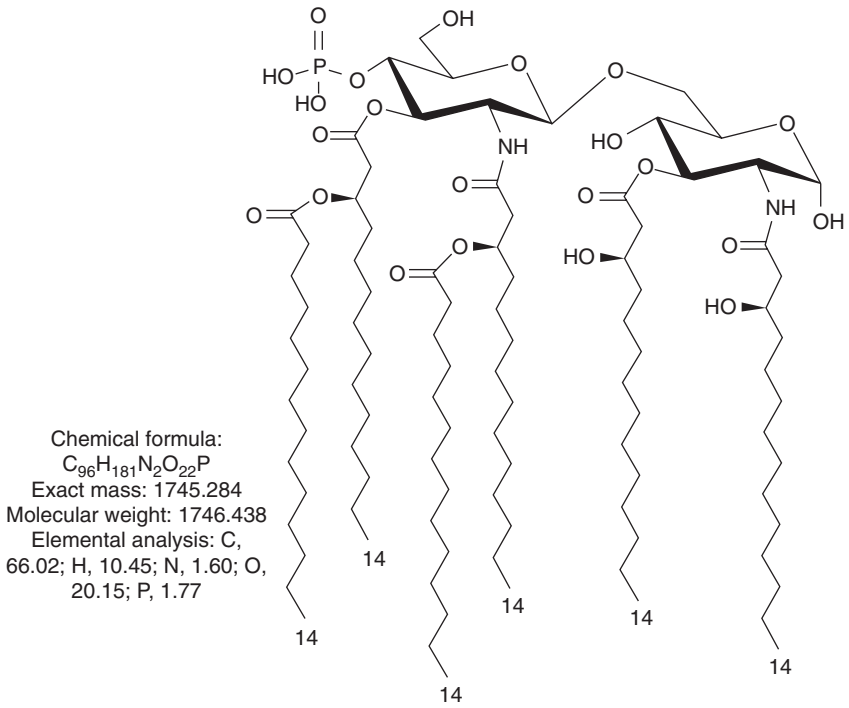

FIGURE 9.3 Synthetic monophosphoryl lipid A. Structure and chemical analysis kindly supplied by Dr. Walter Shaw, Avanti Polar Lipids, Inc., Birmingham, AL.

A in the liposomes still expressed potent adjuvant activity. Most of the toxicity of lipid A thus resides in the fatty acid portions of the molecule, and the fatty acyl groups are hidden in the hydrophobic region of the lipid bilayers of liposomes. This observation, therefore, led to the realization that toxicity could be separated from adjuvanticity. As noted earlier, it is now known that lipid A is a potent activator of TLR-4 and most, or perhaps all of the toxic effects of lipid A and monophosphoryl lipid are due to activation of TLR-4, and it is possible that the adjuvant effects has other mechanisms, such as increase of antigen presentation from inside APCs (Verma et al., 1992).

Monophosphoryl lipid A at nontoxic doses adsorbed to aluminum salt served as an effective adjuvant for inducing Th1-type immunity that led to apparent effective effectiveness of a Herpes simplex vaccine in a phase III clinical trial (Stanberry et al., 2002). It is interesting that the adjuvant appeared to be the pivotal factor in the latter study in that a previous study with a similar antigen, but with MF59 emulsion as an adjuvant, failed to exhibit significant efficacy in a phase III trial (Corey et al., 1999).

Saponins

Saponins are complex glycosides, containing a ring structure and carbohydrates, derived from tree bark and other plants that bind specifically to cholesterol and result in membrane pore formation (Bomford et al., 1992). Although the mechanisms of adjuvant activities compared to toxic effects has not been well-worked out, saponin-based materials presumably would have to balance potential toxicity (such as hemolysis of erythrocytes caused by saponin) with beneficial adjuvant effects. One material derived from saponin, termed Quil-A, is the basis for creation of so-called immunostimulating complexes (ISCOMs) (Morein, 1988; Sjölander et al., 1998). The adjuvant mechanism of Quil-A has been postulated to represent an interaction of an amphipathic antigen with the Quil-A/cholesterol complex (Sjölander et al., 1998), and it is effective for stimulating induction of cytotoxic T lymphocytes (Takahashi et al., 1990). Another prominent adjuvant in this category is QS-21, a defined structure derived from crude triterpene glycoside saponin that exhibits greatly reduced toxicity (Kensil et al., 1991). QS-21 has been very successfully used as an adjuvant in humans, particularly when given in combination with monophosphoryl lipid A in an oil-in-water emulsion known as AS02A (Stoute et al., 1997; Bojang et al., 2005). Recent research aimed at dissociating toxic effects and adjuvant effects of saponin has resulted in a new semisynthetic saponin that has reduced toxicity and enhanced adjuvant activity compared to QS-21 in humans (Slovin et al., 2005).

Specific Targeting Mechanisms

Antibodies, lectins, or toxins that carry antigens to APCs can promote adjuvant activities according to the definition of an adjuvant as used in this chapter. CT or LT from *E. coli*, and nontoxic analogues that bind to ganglioside GM1, which serve as adjuvants both for mucosal vaccines and also for transcutaneous immunization through binding to Langerhans cells in the skin (Glenn et al., 2000) would be prime examples adjuvant targeting, as would a tetanus toxin epitope that binds to ganglioside and also provides T-cell help (Boucher et al., 1994). Transcutaneous immunization using LT as an adjuvant has proven to be a promising preclinical modality in the development of new generations of vaccines to anthrax (Matyas et al., 2004; Peachman et al., 2006). An interesting twist is to attach a targeting molecule, such as a lectin, on the surface of the particle to direct an oral mucosal vaccine to intestinal M cells in the intestine (Roth-Walter et al., 2005).

Carriers that Present the Antigen in a Form that Emulates the Natural State of the Antigen

Virus-like particles (VLPs) are self-assembling particles derived from a major viral protein. They are DNA-free particles that display the antigen on their surfaces in an immunogenic form and, in keeping with the concepts in this chapter, they are therefore a type of antigen/adjuvant combination. Development of a pan-filovirus vaccine based on VLPs has been proposed (Swenson et al., 2005). A recent example of the potential of VLPs as a vaccine formulation in humans is given by the success of VLPs from human papilloma virus in a vaccine (known as Gardasil™, Merck) designed to target cervical cancer (Stanley, 2003; Stern, 2005; Villa et al, 2005). The papilloma virus VLPs, while effective by themselves, were greatly improved by adding aluminum salt as an additional adjuvant.

Certain other types of particles can be used to reconstitute an antigen in a form that exhibits the conformation that would be expected to be found in nature. Examples of this would include cells that express a surface antigen (Harshyne et al., 2001), or liposomes (such as virosomes) (Glück and Metcalfe, 2003; de Bruijn, et al., 2005) or proteosome particles (Jones et al., 2003; Treanor et al., 2006) that have antigen embedded in their surfaces. The HBsAg is an antigenic enveloped virus structure that is liposome-like in that it carries antigen in its lipid bilayer (Gavilanes et al., 1982). Recombinant HBsAg expressed in yeast has been used as the basis for creating a unique carrier in an emulsion containing two adjuvants (ASA02A) for proper conformation of unrelated recombinant antigens (Bojang et al., 2005). Although the HBsAg carrier does serve as a useful carrier/adjuvant, the adjuvant activity was greatly increased by utilizing a larger adjuvant formulation that contained MPL and QS-21 formulated in a squalene oil-in-water emulsion (Stoute et al., 1997; Bojang et al., 2005). It should be remembered that combinations of adjuvants and adjuvant strategies can often be the most effective, and the safest, method to achieve practical immunostimulation.

Phage Display as a Nanocarrier Strategy for Antigen Delivery and Presentation

Preclinical studies have suggested that T4 bacteriophage can be a useful nanocarrier for delivery and presentation of certain types antigens (Sathaliyawala et al., 2006). These particles are particularly useful for antigens that can be expressed in *E. coli*, and effectiveness has been reported in preclinical studies on anthrax and HIV vaccines (Shivachandra et al., 2006, 2007; Sathaliyawala et al., 2006). One potential benefit of a nanocarrier is that it might be used in conjunction with molecular adjuvants that are co-displayed on the T4, or with transcutaneous immunization using LT as an adjuvant.

SIDE EFFECTS OF WIDELY USED HUMAN ADJUVANTS

It is well-known that immunostimulators in general, and adjuvants in particular, can sometimes be double-edged swords. Side effects and toxicities of adjuvants can be widespread and commonplace and the toxicity and reactogenicity of a given adjuvant is often cited as having equal or greater importance than the potency as a criterion to be considered in the selection of an adjuvant (Gupta et al., 1993; Gupta and Siber, 1995). It is the fear of introduction of side effects or toxicities in otherwise healthy persons that is the most troubling aspect of potential vaccine side effects, and this is particularly true for pediatric vaccines. However, the risk of not using a vaccine, including one that contains an adjuvant, is always much higher than any possible vaccine or adjuvant-related side effect.

Some local effects, such as local ulceration induced by live Vaccinia organisms that are used for smallpox or the Bacille Calmette-Guérin (BCG) organism that is widely used around the world as a tuberculosis vaccine, and the familiar local redness and swelling at the site of injection induced by aluminum salts

(Jefferson et al., 2004), are usually tolerated as levels of toxicity that are generally not so stressful as to preclude the use of the offending materials. It is generally believed that the local inflammation associated with intramuscular injection of aluminum salts is due to the escape of adjuvant along the injection track into the SC space (Edelman, 1980). Pain after injection and the occurrence of painless nodules after multiple injections of aluminum-adjuvanted vaccines are associated with the SC route of injection (Frost et al., 1985; Pittman, 2002).

Systemic effects of various adjuvant materials sometimes can be more serious, and these can include: nausea and vomiting that are associated with a small fraction of vaccinated cohorts; pyrogenic effects due to endotoxin that are almost universally found with crude vaccines containing endotoxin; or even uveitis, a rare occurrence that may be associated with certain adjuvants (Goldenthal et al., 1993).

Sometimes the adjuvant can produce a set of symptoms that partly mimics the disease against which the vaccine is directed. Such is the case of orally administered CT or LT, each of which can induce diarrhea similar to that found in cholera or in *E. coli* diarrhea. However, a much more dramatic and dangerous example of toxicity of LT was recently discovered in a licensed Swiss vaccine that was administered intranasally (Mutsch et al., 2004; Couch, 2004). When LT was included in a liposomal (virosome) vaccine containing hemagglutinin and neuraminidase surface antigens of influenza virus, intranasal administration of the vaccine resulted in a strong association with an increased risk of facial nerve paralysis (Bell's palsy). The increased risk was highest at 31–60 days after vaccination and the toxic effect resulted in withdrawal of the vaccine from the market.

It is known that ganglioside GM1 serves as a high affinity receptor for LT and CT and, although the natural targets for CT and LT are the cells of the intestine, GM1 is widely distributed in many other tissues, including neural tissues (Eidels et al., 1983). Thus, although the mechanism of the induction of Bell's palsy was not yet completely clear, it would seem likely that the interaction of LT with GM1 on the olfactory nerve played an important role (Couch, 2004). This unfortunate neurological toxicity involving the facial nerve was probably uniquely related to the intranasal administration of enterotoxin. Fear of facial nerve toxicity should not have a negative impact on the use of native or modified enterotoxin vaccine adjuvants when given by other routes for immunomodulation and adjuvant effects. Furthermore, there is no reason to suspect that the virosome itself exhibited any toxicity independent of its role as a carrier of LT.

Although the safety of vaccine adjuvants is a primary concern because adjuvants are often applied to healthy individuals, it is important to understand that toxicity is not required in order to achieve beneficial adjuvant effects with many formulations. As noted earlier, the mediators generated by binding to TLRs do not contribute to the adjuvant effects of many commonly used adjuvants (Gavin et al., 2006). In addition, pronounced adjuvant effects have also been described in humans, without toxicity, by using liposomes containing lipid A as an adjuvant (Fries et al., 1992), or by transcutaneous immunization using LT adjuvant (Glenn et al., 2000).

OUTLINE

ABSTRACT

The recent surge in awareness of biodefense-related and emerging infectious disease agents has created a demand for development and subsequent evaluation and testing of vaccines as well as therapeutic and diagnostic products for pathogens that require high (biosafety level 3) and maximum (biosafety level 4) biocontainment. For many of these products, human clinical trials may never be practical, so significant emphasis has also been placed on the potential for their approval by the US Food and Drug Administration using new mechanisms such as the "Animal Rule" and Emergency Use Authorization. As a result, preclinical in vitro and animal testing performed in compliance with the Good Laboratory Practice (GLP) regulations may be the sole source of data to support licensure of these products. This chapter aims to provide a background to the scope, intentions, and requirements of the US GLP regulations, as defined by 21 CFR Part 58, and provide some practical considerations for establishing the necessary policies and procedures to conduct GLP-compliant studies under high and maximum biocontainment.

INTRODUCTION

The past decade has seen a considerable surge in public and political concern regarding the potential for rapid emergence or deliberate release of infectious disease agents. This has led to significant investment by governments in research focused on "biodefense and emerging infectious diseases." In the United States, the National Institute of Allergy and Infectious Diseases (NIAID) of the National Institutes of Health (NIH) developed a Priority Pathogen list as a focus for these research activities, and both the U.S. Department of Health and Human Services and the U.S. Department of Agriculture designated many of the same agents and others as "Select Agents," with significant restrictions on their use and distribution.

While the advanced stages of product development have historically been conducted by pharmaceutical companies and contract research organizations, the eminent need for the development of vaccines, therapeutics, and diagnostics to counter diseases due to emerging and potentially weaponized pathogens has necessitated that the United States Government increasingly look at the academic sector for solutions. In 2002, Dr. Elias A. Zerhouni, Director, NIH, announced the NIH Roadmap, which seeks to transform discoveries arising from basic research to clinical application in a more streamlined and timely approach. As NIH set out to "reengineer" the clinical research enterprise, it sought to leverage its prior success of funding medical research and focus on translational research as the "most challenging, but critically important" theme of the roadmap. Dr. Zerhouni noted that at the center of this vision is "the need to develop new partnerships of research with organized patient communities, community-based health care providers, and academic researchers" and "to build better integrated networks of academic centers linked to a qualified body of community-based health care providers who care for sufficiently large groups of patients interested in working with researchers to quickly develop, test, and deliver new interventions" (US DHHS NIH, 2006).

Additionally in 2002, the US Food and Drug Administration (FDA) amended the new drug and biological product regulations to allow, in certain cases, appropriate animal studies to provide substantial evidence of the effectiveness of new drug

and biological products used to reduce or prevent the toxicity of chemical, biological, radiological, or nuclear substances (FDA, DHHS 21 CFR 314 and 601: New Drug and Biological Drug Products, Evidence Needed to Demonstrate Effectiveness of New Drugs When Human Efficacy Studies are not Ethical or Feasible. Federal Register 67: 37995–37998, May 31, 2002). Whereas historically the FDA required products for use in humans to have been proven both safe and effective in clinical trials involving humans as a condition for approval by the FDA, under this amended "animal rule," the FDA can rely on data from animal studies to provide substantial evidence of product efficacy.

The US FDA also has authority to issue an Emergency Use Authorization (EUA) for the use of unapproved medical products, or for unapproved uses of approved products, in treatment of life-threatening disease or conditions caused by chemical, biological, radiological, or nuclear agents. Issuance of an EUA requires that an emergency has been declared by the Secretary of the Department of Health and Human Services, according to specific criteria. Candidate products may then be evaluated, and data supporting an EUA application should indicate that the product may be effective in diagnosing, treating, or preventing the life-threatening condition or disease. Recommended safety and efficacy data for an EUA submission includes preclinical testing data for *in vitro* and animal toxicity, *in vitro* and animal data from at least one species for effectiveness in treating the subject disease, data to support the proposed dosage, along with any clinical data demonstrating safety and efficacy in humans. Any submission for consideration for an EUA should indicate whether nonclinical laboratory studies were conducted in compliance with the US FDA Good Laboratory Practice (GLP) regulations (21 CFR Part 58 Good Laboratory Practice for Nonclinical Laboratory Studies).

These new pathways for product development are well suited for products intended for the prevention or treatment of many of the emerging infectious disease and biological threat agents, including many of the NIAID Priority Pathogens. The GLP regulations for preclinical research studies will most probably be the quality system required for much of the development and critical testing work that is to be performed in support of these products. Results from developmental and preclinical studies may be the only data available to evaluate a new product under the Animal Rule or EUA. As work with many of these Priority Pathogens and Select Agents requires high or maximum biocontainment (biosafety level [BSL] 3 or 4), critical development, and testing work of new vaccines and therapeutics must occur in those facilities and must be done with appropriate quality systems in place to ensure the quality and integrity of the data that is generated.

This chapter provides an overview of the requirements of GLP, with emphasis on the US FDA regulations, and identifies some specific considerations related to studies requiring high biocontainment (BSL3/BSL4). The information presented here is the authors' opinion and reflects both the specific requirements set out in the GLP regulations and our experiences during the planning and implementation of a GLP program to support biodefense and emerging infectious disease research activities at the University of Texas Medical Branch. At the time of writing, this program remains a work in progress.

HISTORY, INTENT, AND PENALTIES—*WHY REGULATE?*

In the mid-1970s, the FDA began investigating the conduct of preclinical research in response to allegations of impropriety. Since product licensure is granted based on the review of data submitted to the Agency, the investigation focused on the integrity of the data. FDA Officials investigated studies performed at G.D. Searle & Co. and Hazleton Laboratories; both produced data in support of Searle products. The initial investigation included review of over 20 completed and ongoing studies supporting new submissions, marketed drug products, an approved food additive, a pending new drug application, and a veterinary drug. Agency in-house reviews preceded the lengthy on-site investigation, which started in early October of 1975 and concluded in mid-December of 1975.

An employee of G.D. Searle & Co. wrote of his experience: "At times, there were more than 20 FDA employees present at Searle during this massive and unprecedented investigation. The FDA investigators were divided into five teams, with each team looking at the studies supporting different compounds. Searle, on its part, had as many as 300 individuals collecting and organizing documents on all its drug products in preparation for the FDA investigation…Over 200 interviews were conducted of Searle employees…" (Thies, 1978).

U.S. Senate subcommittees were formed to hear testimony from the FDA task force members who investigated Searle. The hearings raised serious questions about the testing of new drugs on animals.

At the center was the concern over the quality and the integrity of the data used to support applications. Based on the findings from the investigation, FDA Commissioner Alexander M. Schmidt prepared statements that included evidence of data omission, discrepancies between the protocol and reports submitted to the FDA, dosing errors, solubility problems, incomplete records, lack of animal identification, lack of established written procedures, high animal mortality rates, lack of trained personnel, improper data management, lack of management oversight, and significant quality control problems. His report included the Agency's action plan for additional inspections, the promulgation of standards for GLPs, and a method to monitor preclinical studies.

Additional investigations in the late 1970s involving the US Environmental Protection Agency (EPA) and the National Cancer Institute focused on Industrial Bio-Test Laboratories (IBT), an independent contract research organization. At the time approximately 22,000 toxicology studies in support of product licensure had been performed by this company, including studies for the Pentagon (Marshall, 1983). This number represented approximately 40% of all such studies that had been carried out (Novak, 2001). Results of the investigations revealed numerous findings of fraud and poor animal housing facilities including an improperly working automatic watering system that drenched some animals while allowing others to die of thirst; the animal facility was in such poor condition that it was referred to as "the swamp." After the investigation at IBT, millions of dollars were spent on the retesting of thousands of industrial chemicals and three IBT company officials were found guilty of mail fraud and making false statements to the government and were sentenced to jail time (Baldeshwiler, 2003).

The result of these findings was that the U.S. Congress proposed and then enacted the GLP Regulations for FDA as part of the Federal Food, Drug, and Cosmetic Act. The proposed regulations for GLP were published in the Code of Federal Regulations (21 CFR Part 58) on November 19, 1976 and the Final Rule was published on December 22, 1978. The latter includes preambles documenting the Agency's intent of the GLP regulations. Only two minor revisions have been made since the original enactment.

Subsequently, Congress proposed and eventually enacted (in 1983) the GLP Regulations for EPA. Two sets of EPA GLP regulations exist: 40 CFR Part 160 Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) and 40 CFR Part 792 Toxic Substances Control Act (TSCA). FIFRA governs pesticides, whereas TSCA governs most other toxic chemicals. Based on the U.S. FDA GLP regulations, the Organization for Economic Co-operation and Development (OECD), an international organization, published a policy series on the Principles of GLP and Compliance Monitoring. To date, there are 15 documents in the OECD series on GLP. The directives apply to safety testing of chemicals and allow for the mutual acceptance of data by member countries.

The FDA GLP regulations define a quality system that aims to ensure the quality and integrity of study data. They set the minimum standards for study personnel, facility management, animal and laboratory facilities, equipment, animal care, administration of the test agent, recording and handling of data, record retention, standard operating procedures (SOPs), reagents, quality assurance (QA), inspections, and provide a mechanism for facility disqualification. The standards outlined in the regulations are process oriented, as opposed to product oriented, and provide a mechanism of documentation that allows for reconstruction of the study. Each of these specific areas will be addressed in the remainder of this chapter.

APPLICATION AND SCOPE—*WHEN AND WHY SHOULD COMPLIANCE WITH THE GLP REGULATIONS BE IMPLEMENTED?*

There are common misconceptions that "GLP" refers to a simple principle of scientific performance and integrity that is applicable to all researchers, or perhaps represents a basic checklist of things to do above and beyond the activities of a "normal" research laboratory to improve the quality of the data generated: prepare some SOPs, buy the right GLP-compliant equipment, make sure you use carbon notebooks and ink pens, and start work.

In reality, the FDA GLP regulations define a complex quality system, with specific requirements for performance, documentation, oversight and review of preclinical research, and include penalties for noncompliance. All of the GLP regulations apply to data submitted to an official governing body that will determine if the candidate product is safe for use. The US FDA GLP regulations are also the quality system of choice for developmental and preclinical testing data that may be submitted in support of animal rule and EUA applications. While the intent of the respective regulations/principles is to assure the reliability of the data, the defined scope for the U.S. regulations mandates the type of data that must be submitted to the Agency in compliance with the law. The defined scope of the FDA, EPA (TSCA) regulations, and the OECD Principles are listed below.

U.S. FDA GLP (safety data for nonclinical laboratory studies in support of product licensure):

> (a) This part prescribes GLPs for conducting nonclinical laboratory studies that support or are intended to support applications for research or marketing permits for products regulated by the FDA, including food and color additives, animal food additives, human and animal drugs, medical devices for human use, biological products, and electronic products. Compliance with this part is intended to assure the quality and integrity of the safety data filed pursuant to *sections 406, 408, 409, 502, 503, 505, 506, 507, 510, 512–516, 518–520, 706, and 801* of the Federal Food, Drug, and Cosmetic Act and *sections 351 and 354–360F* of the Public Health Service Act (US DHHS FDA, 1987).

U.S. EPA-TSCA (toxic chemicals):

> (a) This part prescribes GLPs for conducting studies relating to health effects, environmental effects, and chemical fate testing. This part is intended to ensure the quality and integrity of data submitted pursuant to testing consent agreements and test rules issued under *section 4* of the TSCA.
> (b) This part applies to any study described by paragraph "a" of this section which any person conducts, initiates, or supports on or after September 18, 1989.
> (c) It is EPA's policy that all data developed under section 5 of TSCA is in accordance with provisions of this part. If data are not developed in accordance with provisions of this part, EPA will consider such data insufficient to evaluate the health and environmental effects of the chemical substances unless the submitter provides additional information demonstrating that the data are reliable and adequate (US EPA, 1989).

OECD (safety testing of chemicals):

> These Principles of GLP should be applied to the nonclinical safety testing of test items contained in pharmaceutical products, pesticide products, cosmetic products, veterinary drugs as well as food additives, feed additives, and industrial chemicals. These test items are frequently synthetic chemicals, but may be of natural or biological origin and, in some circumstances, may be living organisms. The purpose of testing these test items is to obtain data on their properties and/or their safety with respect to human health and/or the environment.
>
> Nonclinical health and environmental safety studies covered by the Principles of GLP include work conducted in the laboratory, in greenhouses, and in the field.
>
> Unless specifically exempted by national legislation, these Principles of GLP apply to all nonclinical health and environmental safety studies required by regulations for the purpose of registering or licensing pharmaceuticals, pesticides, food and feed additives, cosmetic products, veterinary drug products and similar products, and for the regulation of industrial chemicals (OECD, 1997).

However, many areas that are identified in the regulations as requiring compliance do not include specific benchmarks but rather employ terms such as "appropriate," "adequate," or "suitable." This lack of specific definition means that there is no one-size-fits-all answer to GLP compliance. The specific policies and procedures must be defined by facility management and study staff to ensure they are appropriate to and compatible with the requirements of the study and the limitations of the facility. This becomes particularly apparent when considering performance of GLP-compliant research under high biocontainment conditions. Furthermore, unlike some other quality systems, such as certification of clinical laboratories or ISO certification of manufacturing and testing facilities, there is no GLP certification process. In many cases, the first test of compliance will be an FDA audit following submission of a completed study. At the simplest level, the GLP regulations represent a standard for performance and documentation of research studies to ensure the quality and integrity of the data generated, and to capture all information and key reagents that would be necessary to allow the study to be reproduced. The mantra of many GLP consultants is, "If it wasn't documented, it didn't happen."

Clearly there are a number of additional activities required to conduct GLP-compliant studies in a biocontainment environment and these should be given careful consideration from the moment a study is conceptualized. From a biological safety perspective, one must take into account the increased time and effort necessary to obtain security clearances, health status verifications, and vaccinations as well as training that may be necessary to allow individuals to work in BSL3/BSL4 laboratories. From a regulatory perspective, standardizing all routine procedures, validating and maintaining equipment, training study personnel, maintaining proper documentation, participating in and responding to QA inspections/audits, and compiling reports also add substantial time to the length of the study. Study schedules should, therefore, be scrutinized to assure that sufficient time is allowed for completing these tasks. One should also consider the possible need for additional personnel to assist with the increased workload associated with performing regulated studies.

While the U.S. GLP regulations mandate that the study sponsor must notify contracted laboratories of their intent to submit data to the Agency, the contract laboratory must not be negligent of the scope of the regulations/principles. If a facility is performing any type of testing that generates data for submission to the FDA in support of product licensure, the work must be done in compliance with the applicable regulations. In addition to regulatory mandates, there may be contractual obligations that apply the GLP regulations to what would otherwise be nonregulated studies. In order to promote the quality and integrity of data derived from studies that would not normally require compliance with the GLP regulations,

a sponsor may contractually require a testing facility to comply with the regulations. The sponsor may argue that this compliance will expedite market approval reviews by the governing agency and decrease the possibility of repeat studies.

Inspections by Regulatory Authorities

Testing facilities that perform studies meeting the scope of the GLP regulations/principles are subject to inspection by the Agency or the appropriate country's compliance monitoring program. Inspection of a testing facility is performed by FDA, EPA, or by National Monitoring Program officials, each of which has published procedures for conducting inspections. The OECD published procedures are mutually accepted by its membership countries in order to assure harmonization and promote the mutual acceptance of data. Testing facilities that perform regulated work must accommodate inspections by Agency officials. Failure to comply with an Agency inspection will disallow the review of an application for a research or marketing permit that relies on data generated as part of the regulated work.

During inspections, Agency officials can request or make copies of documents; therefore, the testing facility should have a standardized operating procedure for the copy and release of restricted or regulated documents associated with select agents and select agent facilities to ensure appropriate compliance with Select Agent regulations. Furthermore, access to high containment areas by Agency officials may be impossible due to security restrictions, facility training requirements, vaccination requirements, etc. This potential inability to access an area by an Agency inspector may result in a request to inspect similar space at a lower containment level. In response to the limitation of inspecting the facility directly, the inspector may scrutinize the study protocol, procedures, and data in greater detail in order to reconstruct the processes that occur in these areas.

Definitions and Terms—*The Same Words Don't Always Mean the Same to Different Regulatory Authorities and Study Sponsors*

In the study planning phases, it is essential to align the country of the intended marketing permit submission with the appropriate set of GLP regulations/principles. The subsequent development of study documents should include common language and terminology. Before creating any documents, the definition of terms that are included in the applicable set of the GLP regulations/principles must be reviewed. Each document begins with these definitions, and they are crucial for effective communication between the governing agencies, the sponsor, and the testing sites or contracted laboratories. The terms should be used appropriately and consistently in all written documentation such as the protocol/study plan, SOPs, and the final report.

Some definitions are unique to a particular set of the GLP regulations/principles. For example, one difference is in the terminology used to define the compound or product being tested during the preclinical phase. This test compound is referred to as the test article (FDA GLP), test substance (EPA GLP), or the test item (OECD). Another definition difference is that the OECD Principles of GLP include a definition of principal investigator (PI)—an individual who acts on behalf of the study director in a multisite study. Neither the FDA nor EPA regulations include a definition that equates to a PI. Another variance applies to the definition of study start dates. While all the GLP regulations/principles define the study initiation date as the date the Study Director signs the Protocol/Study Plan, the EPA GLP regulations, and the OECD Principles of GLP include definitions for the experimental start and stop dates. The EPA GLP regulations define the experimental start date as the first date that the test substance is applied to the test system, whereas the OECD Principles of GLP define the experimental start date as the date on which the first study-specific data are collected.

Standardized terminology will facilitate communication between the Agency, the sponsor, and the testing facility. Utilize the respective definitions sections when negotiating contracts, during study planning, and in all study documentation for the duration of the study.

ORGANIZATION AND PERSONNEL—*WHO DOES WHAT AND HOW DO WE KNOW THEY CAN DO THAT JOB?*

Reducing variables that may affect study data is critical and consideration must be given to the human element in this regard. Proper training, education, and/or experience of study personnel combined with SOPs can reduce risks while streamlining efficiency and improving staff proficiency. Standardization and identification of personnel roles and responsibilities, along with proper personnel organization and

appropriate training of study personnel, are key components of the GLP regulations/principles.

Defined roles and responsibilities for study personnel must be recorded and the completion of training necessary to perform these roles and responsibilities must be documented. This information should be organized in such a manner that an auditor can match training records to the assigned tasks for any given GLP study. Suggestions for organizing this documentation include the establishment of standardized training files for all GLP personnel and the creation of an organization chart that identifies the roles and illustrates the interactive relationships. GLP study personnel include any individuals who have impact on the study data such as GLP management, study directors, PIs, laboratory managers, research technicians, graduate students, veterinarians, animal handlers, statisticians (data handlers), and QA auditors. Training of study personnel should include any necessary technical training, biocontainment training, SOP training, and GLP training relevant to the job responsibilities.

For studies in high biocontainment facilities, the issues of appropriate training are significant. Not only must all laboratory and biocontainment engineering staff be appropriately trained to work safely in that environment, they must also be trained to meet the requirements of the GLP regulations. Likewise, GLP management and QA staff may require specialized training for access to those laboratory facilities to ensure appropriate oversight and review of the research activities. Consideration must also be given to the requirements placed on all individuals by other relevant regulations, such as those governing the use of Select Agents. Training of new staff for a GLP study in a high biocontainment laboratory is a process that requires significant investment of time, effort, and resources.

For any GLP study, there must be a defined testing facility management, a study director, and an independent quality assurance unit (QAU)/program. Further, the GLP regulations/principles specifically define the minimum responsibilities for study personnel, including GLP management, the study director, the QAU/program, and the PI (OECD only). SOPs should define how each role functions within the overall business structure of the testing facility along with the mechanisms followed to perform their responsibilities. These procedures should also address sanitation and health precautions that personnel must follow in order to decrease the potential of contaminating the test and control articles and test systems, including the reporting of any illness that may adversely affect the data. For many biocontainment laboratories, these issues overlap with precautions and reporting required from an employee health and safety perspective. Procedures governing these issues may also be addressed in facility policies that are not specific to the GLP program, as employee health records are subject to other regulatory requirements that maintain the privacy of medical records.

GLP Management

It is crucial for a facility to define their management structure prior to performance of GLP-compliant studies. Testing facilities that function primarily as contract research organizations may have a business hierarchy that directly aligns with the GLP management structure, whereas academic and other large institutions may need to have a separately defined infrastructure in place to support GLP studies. Effective GLP management structures in large institutions should possess the capacity to bridge multiple departments as studies may require cooperation from animal resource facilities, environmental monitoring and facilities maintenance departments, information technology groups, statisticians, and veterinary pathology laboratories. While appropriate allocation of management roles is a business decision, it is imperative to identify GLP management and equally important for GLP management to understand their roles and responsibilities. Failure to identify a functioning GLP management structure and failure of proper training of GLP management is a violation of the GLP regulations.

GLP management is responsible for providing the appropriate resources (facilities, equipment, procedures, and personnel) necessary to perform a regulated study and must be capable of appointing and/or replacing the study director. The latter may not necessarily transpire from poor performance, but may be necessary if the study director has insufficient time to devote to a GLP study, or may be unavailable for a significant portion of the study. Management must also assure that a sufficient number of personnel are available to conduct the study in accordance with the protocol. Furthermore, management is tasked with assuring that the QAU/program is completely independent of the study conduct and that QA inspection/audit findings are communicated to the study director.

The Study Director

The study director serves as the central point of contact for a GLP study and is responsible for the

technical conduct of the study, including assuring that the GLP regulations are followed. Since the study director serves as the central point of contact for a GLP study, only one study director is allowed for each study; however, the OECD Principles of GLP allow for PIs to serve, under the direction of the study director, as points of contact for multisite studies. It is important to note that the OECD defined role and responsibility of the PI does not necessarily align with the U.S. terminology used to annotate the PI for grants and contracts. Care should be taken to identify which GLP regulations/principles are applicable to the study when defining the responsibilities of an individual serving in the role as a PI.

Since study directors serve as the central point of contact for the study, they must be knowledgeable in the GLP regulations, familiar with the science of the project, and possess skills in project management. However, it is acceptable to delegate tasks during a study and often the appointment of a laboratory manager or supervisor can assist in study organization. Care should be taken to clearly delineate these task assignments and, while delegating tasks can streamline efficiency, it must be remembered that the ultimate responsibility of the study conduct lies with the individual designated as the study director.

The study director is also responsible for all experimental data including any deviations from procedures or unforeseen circumstances that occur during the study. As documentation should allow for the reconstruction of the study, it is imperative that the study director assess all study circumstances for possible effects on the data. Facility or study-specific SOPs should describe how the study director reviews study documentation and how deviations from SOPs and/or the study protocol are managed. Furthermore, the study director determines the study initiation and closing dates by signing and dating the protocol and final report respectively, and is responsible for assuring that all records and specimens are transferred to archives during or at the close of the study.

Quality Assurance

The GLP regulations/principles also delineate a QA requirement. While individual studies may plan for appropriate quality control of procedures and data management, the QAU assesses the overall conduct of a GLP study and adherence to the regulations, study protocol/plan, and approved SOPs. This function involves facility and study-specific inspections and/or audits performed by an independent unit or program. Members of the QAU or QA program are referred to as QA auditors and, in order to remain unbiased, the QA auditor(s) for a specific study may not be involved in the conduct of that study. The frequency and type of inspections depend on the length of the study and the critical phases of the study; communication between the study director and the QA auditor facilitates the process. Inspections and data audit findings are compiled in a QA report that is distributed to the GLP testing facility management and the study director. The content of these reports is not subject to inspection by a government agency representative during a routine Agency audit; however, QA must keep a log of these inspections/audits as documentation of their occurrence. In order to properly manage the performance of inspections and audits, the QAU maintains copies of study protocols and a copy of the master schedule. The latter is a log of all GLP studies performed at the facility and is used by the Agency representatives to organize their facility inspections and to assess study director workload.

QA of GLP studies differs from the QA requirements included in the Good Manufacturing Practice (GMP) regulations. Significant findings during a GMP QA inspection/audit can halt production. The intent of the GLP regulations is to have an internal QA process that allows for correction during the study, thereby decreasing the possibility of repeat testing or validation, or study rejection. The QA auditor reports any gaps and/or deviations from the regulations, protocol, and approved SOPs to the study director and management. It is then the responsibility of management and the study director to correct any applicable issues as stated in the QA findings. In a high biocontainment laboratory environment, where physical access to study areas for audits by sponsors or regulatory agencies is likely to be limited, it is reasonable to expect that QAU personnel should be trained for access to the laboratories to ensure that they can adequately fulfill their oversight responsibilities.

Archivist

Another important role in a GLP program is that of the archivist since study records will be transferred from the supervision of the study director to an archive facility. The latest document from OECD actually includes a definition of an archivist, stating that an archivist is “an individual designated by test facility or test site management to be responsible for the management of the archive, i.e., for the operations and procedures for archiving” (OECD, 2007). Although the archive facility is discussed in the “records and reports” section of this chapter, study planning should

include the identification of the individual who will be responsible for the archive.

FACILITIES—*WHAT MAKES A LABORATORY SUITABLE FOR GLP?*

Unlike other regulations governing laboratory or manufacturing facilities, the GLP regulations place relatively few specific requirements on the physical infrastructure of the laboratory. Testing facilities should be of "suitable size and construction" and designed to prevent any "adverse effect" on the study (21 CFR Subpart 58.41). In general, the intent is to separate various components of the study to reduce or eliminate risks of contamination.

Facilities for animal care, laboratory procedures, supply storage, and specimen and data storage must operate under standardized procedures and must be properly managed and maintained in order to decrease the risk of contamination of the study data. In high biocontainment laboratories, where available space and laboratory design may not permit physical separation of study components of different research activities, study design should consider methods to decrease contamination risks when establishing the workflow. Methods can include the use of separate rooms, biosafety cabinets, ventilated cage rack systems, procedures for decontamination, and appropriate personal protective equipment for study staff. Additionally, supplies such as feed, bedding, and animal enrichments should be stored separately from the animal housing rooms. Workflow should address all aspects of the study including animal quarantine prior to study placement, requirements and location of animal isolation, disposal of waste, and operation of shared areas in order to prevent study mix-ups and cross contamination. A facility floor plan can be used as a diagram to illustrate the workflow; however, floor plans for areas used for Select Agent studies should have SOPs established for their secured distribution since they may be considered sensitive documents under Select Agent regulations.

Facility design should also address isolation of areas used to prepare test/control articles in order to prevent mistakes and cross contamination. Care should be taken to separate areas for the receipt, handling, mixing, and storage of the test article. The storage areas must be separate from the test system and must meet the environmental specifications needed in order to maintain the integrity of the compound.

Biocontainment laboratories are complex facilities, often having sophisticated building automation systems (BAS) for control and monitoring of the biocontainment environment and facility security. Careful consideration must be given to the operation of these systems and their potential use in primary monitoring of laboratory spaces used for GLP-compliant studies. This will be discussed further in the following section.

In addition to laboratory and animal facilities necessary to perform GLP studies, space needs to be identified for specimen and data retention. Specimen and data retention during a study can be in proximity to the study location or can be in a central location; however, an archiving facility (or facilities) is required for long-term retention of study data and specimens. Archive facilities can be located at the sponsor facility, at an external facility, or internally at the testing site, but must be under the control of an archivist in order to expedite retrieval of the records. During the study, the data and specimen integrity is the responsibility of the study director; however, once transferred to the archive, the archivist is tasked with maintaining the integrity by assuring that the data and/or specimens are secure and stored in the appropriate environmental conditions necessary to prevent degradation. The indexing and operation of the archive should be defined in SOPs and retrieval of items should occur in a timely manner during the course of an inspection. If an off-site facility is utilized as a GLP archive, it is recommended that a QA inspection be performed in order for management and the study director to determine if the archive facility is adequate.

EQUIPMENT

Despite the common perception that performance of GLP-compliant studies requires certain specialized equipment, the US FDA regulations specify only that equipment used in the "generation, measurement, or assessment of data" and equipment for facility environmental control be of "appropriate design and adequate capacity to function according to the protocol" (21 CFR Part 58). As with planning for many other areas of GLP compliance, selection, and operation of equipment should be driven by the requirements of the study, within the limitations of the particular laboratory environment.

In order to increase data integrity, equipment should be designed to meet the needs of the study, and should be calibrated and maintained throughout the study. Equipment documentation is generally maintained from the point of acquisition until the point of retirement—i.e., throughout the equipment life cycle. Acquisition can be procurement of a new piece of equipment or the assessment of an existing

piece of equipment. The process of documenting that a piece of equipment meets the needs of the study, and is operating and performing correctly, is generally referred to as equipment validation or equipment qualification. For purposes of discussion, this chapter will discuss the validation of equipment using a four-step process utilizing the terms design, installation, operational, and performance qualification (PQ).

Generally, a facility should develop high level policies governing the approach for equipment acquisition, validation, and operation for GLP-compliant studies. Before purchasing or using a piece of equipment during a GLP study, the system should be assessed to see if it meets the needs of the study. Documentation should align the manufacturer's specifications with the study needs. This process is referred to as design qualification (DQ). Next, the equipment must be installed and shown to be correctly functioning in its environment; this is called installation qualification (IQ). Once working, the equipment should be tested to see if it is operating according to the manufacturer's specifications (operational qualification, or OQ). If there are any special performance requirements specific to the needs of the study, these must also be tested and documented (performance qualification, or PQ). For simple pieces of equipment that do not collect data, a simplified validation/qualification process that combines these processes may be employed. This is sometimes referred to as equipment verification. As mentioned above, the requirements of and processes to be used for equipment validation or verification should ideally be defined at a facility or institutional level.

Planning for the equipment validation process should also include the preparation of specific SOPs for calibrating and maintaining equipment in a validated state. The type and frequency of the calibration, preventive maintenance, and general cleaning will be determined based on the use of the equipment, the requirements of the study, and the specific limitations of the operating environment. In a high biocontainment environment, equipment maintenance, and calibration schedules and procedures may be largely dictated by broader facility operational requirements and the limited access to laboratory spaces. The specific maintenance and calibration that is performed on the same piece of equipment will likely differ between BSL2, BSL3, and BSL4 laboratories within the same facility due to the unique nature of each laboratory environment. In any case, documentation of the performance of these functions should be retained with the study data. Finally, procedures should be in place addressing the retirement of equipment. Before retiring, assess the impact of the retirement on current studies, and determine if electronic data was generated. Plans for data storage and future data migration should be developed prior to the retirement of computerized equipment.

Validation of complicated systems can be a lengthy process. When procuring new pieces of equipment, requests can be made for validation documents and support from the manufacturer. Often the IQ and OQ portions may be completed by a vendor representative, but the supporting documentation may need to be evaluated to assure that sufficient documentation is obtained according to the facility's validation policies. Complicated systems that are critical to the study data collection may need to be validated under the direction of an experienced validation team or outside consultant. The length of time necessary to validate equipment should be considered in study planning and contract negotiations with the sponsor. Furthermore, retrospective evaluation of existing equipment for DQ prior to the start of the study may indicate that the equipment is not suitable for the needs of the study and a new piece of equipment may need to be purchased and validated before the study can begin.

Selection and validation of systems or equipment used for environmental monitoring will also depend upon the specific requirements of the facility and the studies that require GLP compliance. In a large biocontainment facility where only a subset of laboratories or rooms may be set aside for GLP-compliant research, validation of the BAS used for control and monitoring of the entire building may be impractical or deemed to be cost ineffective. In those cases, local monitoring using stand-alone devices or networked supervisory control and data acquisition (SCADA) systems may be a more practical solution for appropriate monitoring of laboratories used in performance of GLP-compliant studies.

If an area also contains equipment not used for GLP studies, which is likely to be the case in many BSL3 and BSL4 laboratories, it is recommended that some type of labeling process be established and documented to differentiate the equipment. This will clearly define to an Agency inspection official what supportive documentation should (and should not) be audited. In areas of high containment, it is recommended that annual or semiannual schedules for equipment calibration and preventive maintenance are coordinated with area/unit decontamination and shutdown times. This will increase efficiency of space utilization and allow for more accurate study timelines.

Another consideration for equipment in high biocontainment laboratories is the collection and storage of raw data. In many cases, a solely paper-based data collection system will be impractical due to the

difficulty in transferring materials out of the laboratory. Capturing raw data in an electronic format may simplify the transfer and storage of that data, but requires that all components of the network and electronic systems be appropriately validated and function in compliance with 21 CFR Part 11 Electronic Records; Electronic Signatures. Suitable systems and processes for storage and backup of raw data must also be established to eliminate or otherwise minimize the risk of data loss.

TESTING FACILITIES OPERATION—*HOW DO WE DO WHAT WE DO?*

All routine methods and processes for GLP studies and critical supporting activities must follow standardized procedures that are approved by GLP management. Decisions on the extent of documentation required for supporting activities should be based on risk assessments that determine which functions may directly impact the performance and outcome of a study. SOPs govern day-to-day practices, whereas the protocol/study plan (discussed later) serves as the overall blueprint for the study. Each set of GLP regulations/principles list the minimum required SOPs to support a GLP study, but the list is not all-inclusive. Standard business policies should exist for facility operation and are subject to inspection; however, they should be reviewed prior to the start of a GLP study to assure that they are compliant with the regulations and appropriate to the requirements of the study. The QAU/program audit schedule should include a general facility inspection in addition to one or several study-specific inspections and/or audits. SOPs must ultimately be approved by management and implementation of subsequent changes made to an SOP should follow a standardized procedure that also includes management approval. Historical files of all SOPs and their respective versions should be retained and are subject to Agency inspections. Business definitions should identify if there is a difference between an SOP approval date and the actual effective date of the SOP. The latter date should be established after consideration of the length of time necessary to train appropriate personnel on the SOP or the new version of the SOP.

Current versions of the SOPs must be available in the area where the procedure is performed. While it is appropriate for a study director to maintain copies of all approved SOPs for his/her study, copies of applicable SOPs need only be present where the procedure occurs. Care should be taken in high containment areas and SOPs should be in place to handle contaminated paper documentation, including raw data or SOPs. An SOP may be available in a printed form with an expiration date or an SOP may be viewable from a computer screen. The handling and distribution of the SOPs should be addressed in an approved administrative or document-handling SOP. No expired or outdated versions of SOPs should be located in areas where procedures are performed. A paper-based system for preparation and distribution of SOPs may be impractical for high biocontainment laboratories, and even for GLP programs that support multiple concurrent studies. Suitable electronic document management systems are available that can be configured and validated for compliance with 21 CFR Part 11 and that will coordinate and control the processes for preparation, approval, distribution, and archiving of SOPs, as well as documenting SOP training.

Facility SOPs should include the operation of the animal care facility as well as the specific animal husbandry and handling that occurs within the biocontainment laboratory environment. It should be clear how a facility handles cage cleaning and change-outs, animal feeding and handling, animal isolation, animal treatment, finding of moribund animals, storage of feed and bedding, and use of any pest controls. Documentation of activities is necessary for study reconstruction and calibration, maintenance and quality control procedures need to be established not only for equipment that will generate study data, but also for other key equipment that supports an animal study (e.g., cage washing and sterilizing equipment). For instance, scales that are used to determine animal weights should be validated, cleaned, maintained, and calibrated if the data they generate will be used to calculate dosing concentrations.

Study planning should also include the type of feed, water, and bedding to be used. The study director, along with the sponsor, should evaluate these items for the presence of any interfering substances that should not be present in the feed, water, or bedding and should maintain documentation that demonstrates the absence of these interfering substances. Vendors may be able to provide documentation of testing for certified feed and bedding. Animal facility SOPs should state the frequency and types of testing performed on potable water. If additional testing is required to support a regulated study, communication with animal care facility management is critical and these issues should also be addressed in the budgeting and planning phases of project development.

Reagents used during a GLP study must be labeled with the identity, titer or concentration, storage requirements, and expiration date. Use of expired

reagents is a violation of the regulations/principles; however, SOPs can be in place that allow for extension of the expiration date based on scientific evaluation or analysis. The OECD Principles of GLP also require that the source, preparation date, and stability information be accessible. Reagent preparations that include dilutions or mixing with other reagents must also be appropriately labeled. Generally, the expiration date of mixed reagents is the earliest expiration date of any one of the combined chemicals. Documentation of reagent lot numbers, reagent volumes, and identification of personnel preparing reagents may be critical pieces of information depending on the nature of the study and use of the reagent.

TEST AND CONTROL ARTICLES—*WHAT ARE WE TESTING AND HOW DO WE HANDLE IT?*

Since data obtained during the study will be used to support the product licensure of the test article, characterization and handling of the compound is critical. SOPs should describe the labeling and handling of the test and control articles from receipt to final discard or retention. Documentation should include the condition upon receipt as well as the storage location, and the storage location should align with the storage requirements and provide appropriate environmental conditions in order to retain the compound integrity. Storage of the test and control articles must be in a secured location and procedures should be established that allow complete accountability of handling and volume depletions and/or distributions.

Analysis of the test and control articles prior to study initiation includes identification of the compound along with its strength, purity, and composition. This analysis must be conducted for each batch that is manufactured. Sample derivation is also required; such documentation can be provided by the sponsor or, in the case of a marketed compound, be identified by the label (FDA only). The above characteristics must be identified prior to the initiation of the study; however, compound stability can be determined either prior to or concomitantly with the study. The responsibility for characterization of test and control articles (i.e., provided by the sponsor, or carried out by the testing laboratory) should be clearly established during contract negotiations and study planning. SOPs should exist to describe how compounds are mixed with carriers, and the mixtures must be tested in order to determine the uniformity and subsequent concentration. Care should be taken when handling or mixing the compounds with carriers to ensure that no contamination is introduced during the process. Preparation of test and control articles should occur in separate areas as appropriate to decrease the introduction of contaminants during the process, and to prevent any inadvertent mixing or substitution of test and control articles. Standard decontamination practices performed prior to compound preparation should be documented in order to demonstrate that the SOPs are being followed. For high biocontainment facilities, storage and even preparation of test and control articles should generally occur at BSL2. However, the specific requirements of the study and the characteristics of the test and control articles may require that final reagent preparation occur in the BSL3/BSL4 laboratory.

In addition to proper receipt, handling, and mixing of test and control articles, the storage containers must be labeled by name, chemical abstract number or code number, batch number, expiration date (if known), and storage conditions. Test and control article storage containers should be kept for the duration of the study (FDA, EPA) and an aliquot of the test/control compounds must be retained for long-term studies (defined as longer than 4 weeks by FDA, EPA). The Agency has the authority to transport a test compound and the SOPs in order to reproduce the study in their laboratories if that is deemed necessary and if appropriate facilities are available.

STUDY CONDUCT—*THE EXPERIMENTAL PLAN*

The document that states the overall plan for the study is called the protocol (FDA, EPA) or the study plan (OECD). All of the GLP regulations/principles state the minimum requirements for the information that must be included in the protocol/study plan. In general, the protocol/study plan should include the identification of the sponsor and the testing facility, key personnel involved in the study, the test system, the test and control articles, the study methods, the data collection methods, and the statistical manipulations. This document often serves as a contract between the sponsor and the testing facility and should serve as a communication tool stating the agreed parameters of the study to the sponsor, study director, testing facility management, QAU, and study personnel. Study director signature (FDA, EPA, and OECD) is required on the document as is the signature of the sponsor (FDA, EPA). For OECD studies, the signature of the sponsor and testing facility management is a requirement that varies by national

regulation or legislation. Failure to perform the study in accordance with the protocol is a violation of the GLP regulations/principles.

As outlined earlier in this Chapter, under the FDA GLP regulations the date that the study director signs the protocol/study plan is the study initiation date. Any changes made to the protocol/study plan after this time must be made in the form of an amendment that also requires the dated signature of the study director. In general, the protocol/study plan along with any amendments outline the study objectives, the SOPs describe in greater detail the methods used to accomplish the study objectives, and the final report summarizes the study data and findings. During the study, any contradicting statements between the protocol/study plan and an SOP are decided by the protocol/study plan as the statements contained within a protocol/study plan supersede the SOPs. Writing effective protocols/study plans, SOPs, and final reports can lengthen the time needed to complete contract negotiations and study timelines. Training on SOP writing can be beneficial for individuals who possess minimal experience writing these types of documents.

Failure to perform the study in compliance with the protocol is a regulatory violation. While deviations from protocols/study plans or SOPs can happen, these deviations must be properly documented. SOP deviations must also be documented and the study director should assess whether or not the deviation impacted the study. The study director should also review the deviations for trends. If the same deviation is occurring frequently, it is possible that an SOP needs to be revised or the personnel are not properly trained to adequately perform their job duties. If SOP deviations are properly handled and the documentation is included in the study records, then they do not need to be listed individually in the final report; however, all protocol deviations must be identified in the final report. If SOP deviations are not appropriately handled or if the deviation had a direct impact on the quality and integrity of the data, then the circumstances must be disclosed in the final study report.

Recording data properly during the study is a critical aspect since the data generated will be used to reconstruct the study and subsequently used to support the application for product licensure. Unless the initial data is captured via electronic systems, collection of all study data must be documented promptly and in ink. All data must be accompanied by the signature or initials of the person entering the data and the date the data was recorded. The first capture of information is considered the raw data so care must be taken when observations are recorded. Trained study personnel should be aware of the appropriate places to record study data. The creation of standardized forms can assist in the capturing of raw data promptly. All original data must be retained. If changes need to be made to recorded data, the original data must not be obscured or deleted. The change must also be accompanied by a reason for the change, the signature/initials of the person making the change, and the date the change was made. These rules are applicable to manually recorded data as well as electronically captured data. As discussed earlier in this Chapter, paper-based data collection may not be practical for some studies, particularly in high biocontainment laboratories. However, the use of electronic data collection and handling raises compliance issues related to 21 CFR Part 11, and may also be subject to restrictions related to select agent or other regulations.

Proper study conduct also includes the correct labeling of specimens collected during the study. Specimens collected for studies following the FDA or EPA GLP regulations must be identified by test system, study nature, and date of collection. This information can be recorded on the specimen container directly or identified and linked in a manner that allows for traceability to the information. Specimens collected for studies following the OECD Principles on GLP must be labeled with a unique study identifier as well as the specimen origin.

RECORDS AND REPORTS—*WHAT DID WE DO AND WHAT DID WE FIND?*

Once the experimental data has been collected, a final report is written to summarize the study findings. While the minimum requirements for the report content are listed in the regulations/principles, any contributing scientific reports should be included in their entirety and not changed by the study director or sponsor. After the final report is written, the regulations require a review of the final report and experimental data by the QAU/program in order to determine if the data presented in the final report are an accurate reflection of the raw data collected during the study. The QAU will also provide a statement that specifies the dates study inspections were made and the dates the findings were reported to management and to the study director.

All study records must be retained and archived prior to or at the close of the study. The study director is responsible for identifying all data, specimens, and study records that must be transferred to the archives.

Once the records and specimens are moved to the archives it is no longer the study director's responsibility, as the archivist is tasked with the organization, storage location, and security of the archives. All study records must be easily retrievable during an audit. Several archive locations can be identified, but the organization of materials for expedited retrieval must be under the direction of one archivist. Off-site archives are appropriate for use, but due diligence by management must occur. It is recommended that off-site archive facilities be inspected by the QAU/program prior to initial record transfers and periodically, as decided by GLP management. Required duration periods are specified in each regulation/principle; however, business procedures should be developed for facility record retention policies. It is also appropriate for some or all of the study records or specimens to be transferred to the sponsor. In this regard, the final disposition of archival materials should ideally be established during initial contract negotiations with the sponsor, particularly in situations where on-site storage is limited or the timetable for product submission (and hence the timeframe for data retention) is not clear. Documentation of this transfer agreement should be retained with the study data as location of all records and specimens must be included.

DISQUALIFICATION OF TESTING FACILITIES—*WHAT HAPPENS IF WE GET IT WRONG?*

During data review, product marketing applications can be rejected or approving Agencies can request further validation of studies if there are concerns about the performance of the study or the quality and integrity of the data. However, disqualification of a testing facility is a unique part of the FDA GLP regulations. When a facility is disqualified, the FDA can refuse to accept any data submitted by the facility in support of an application for a research or marketing permit. In addition, any study data historically submitted to the Agency by the disqualified testing facility can be rereviewed. Disqualification proceedings occur only after a facility has failed to comply with the regulations, the noncompliance directly affected study data, and regulatory warnings have been inadequately addressed or ignored. The FDA GLP regulations also address the issue of the sponsor initiating the termination of studies at a testing facility. If a sponsor terminates or suspends a testing facility during a GLP study, the sponsor must notify the FDA in writing within 15 working days of the termination.

As an example, in 1999, FDA performed an inspection at the Coulston Foundation, a testing facility in the state of New Mexico, U.S. The inspection revealed significant findings that were detailed in a subsequent Warning Letter to the company Chief Executive Officer. The Coulston Foundation did not provide sufficient proof to the FDA that the findings had been addressed and a subsequent site visit in 2000 was conducted. During the review process, FDA instructed Coulston not to initiate any new studies and required Coulston to request reinspection after the deficiencies had been corrected. Coulston did not request such a reinspection and received another Warning Letter in 2001 stating that if they did not address the violations and correct the deficiencies, action may be taken to initiate disqualification. By 2003, FDA proceeded with disqualification and sent notice to Coulston of their opportunity to request a regulatory hearing; but by late 2002, the New Mexico Business Weekly was already reporting that the Coulston Foundation was shutting down and the animals were being relocated (Anonymous, 2002).

Once disqualified, the regulations provide a mechanism for facility reinstatement. The request for reinstatement must be made in writing to the FDA Commissioner and must contain proof that the deficiencies have been addressed in order to prevent violation of the regulations.

CONCLUSIONS

The intent of the GLP regulations/principles is to assure the quality and integrity of the data. They are standards that describe the minimum requirements necessary to assure integrity of the data and allow for the reconstruction of a study. The current emphasis of governments on developing products to protect the public from emerging infectious disease pathogens or deliberate release of a biological agent has led to an increased role in this process for the academic sector and those institutions with the appropriate facilities to house these agents.

The implementation of compliant studies in a university setting, where the organization of personnel may not immediately align with the requirements of the regulations, may require definition of new organizational structures, and the prospect of carrying out GLP-compliant studies in BSL3 and/or BSL4 laboratories adds additional hurdles. Among these are the limited amounts of space available in these laboratories for records retention, the difficulty or impossibility of transferring certain types of data and specimens out

of the laboratories, the increased level of scrutiny on personnel who may access these facilities, and other regulations governing the conduct of work in these laboratories (e.g., Select Agent regulations).

All of these factors should be carefully considered from the moment a GLP study is contemplated and negotiations with potential study sponsors should take into account the increased time and resources required to complete regulated studies in these environments. In addition, it is imperative that investigators who consider studies that require compliance with the GLP regulations fully understand the additional effort that will be required of them and of their staff.

While the intent of this chapter is to introduce the reader to the GLP regulations and guidelines and the potential impact that regulated study planning will have on vaccine development, particularly in studies requiring high biocontainment, it is also important to understand that the field of compliance in the 21st century is changing. Currently, the US FDA is using enforcement discretion with regards to 21 CFR Part 11, the OECD continues to publish additional directorates, modernization of the US FDA regulations is under discussion, and global harmonization is increasing communication between regulating bodies. In the meantime, research and testing organizations should make compliance policy decisions utilizing a risk-based approach, keeping in mind that ignorance of the regulations is not accepted by the US FDA or other regulating agencies as an excuse for noncompliance.

OUTLINE

ABSTRACT

The world was struck by surprise when a Severe Acute Respiratory Syndrome (SARS) epidemic started in 2003 in China. This disease had never been observed in man before; the SARS-Coronavirus causing the disease was unknown. With the uncertainty about the future impact of this epidemic, an important international collaboration started spontaneously sharing scientific knowledge and reagents. Resources became quickly available, and public and private efforts were undertaken to develop rapidly a vaccine. We will discuss here the importance of the international collaboration and the availability of funding. Moreover, we will review the most important and challenging steps during the industrial development of the SARS vaccine highlighting the difficulties in terms of safety working

with such a highly pathogenic, unknown virus. We will emphasize the industrial perspectives on inactivation and decontamination experiments, the selection of the most promising vaccine candidate, the production process and the choice and use of animal models in such a pressing and difficult situation. Finally, we will briefly review the unique regulatory environment created during this period for the development of a SARS vaccine.

INTRODUCTION

In late 2002, several hundred cases of a severe atypical pneumonia were reported in the Guangdong Province of the People's Republic of China. By the first quarter of 2003, similar cases were reported in Hong Kong and sporadically throughout South-East Asia and Canada. This severe disease, with a mortality of 5–10%, spread rapidly around the world and in April 2003, 25 countries on 5 different continents had reported cases [World Health Organization (WHO), accumulative SARS cases]. As a result, the WHO issued on March 2003 a global alert for the illness that would be known as "Severe Acute Respiratory Syndrome" (SARS) (WHO SARS alert). Within the same time frame, secondary cases of SARS were being identified in health care workers and family members who had close contact with patients suffering from this severe respiratory illness.

By the second week of June, using the WHO case definition (WHO case description), approximately 8000 SARS cases and 774 SARS-related deaths had been reported to the WHO. While the first wave of the SARS epidemic seemed to have reached its conclusion, it was completely unclear how the spread of the virus would evolve. There was no clear understanding of the animal reservoir and the impact of virus mutation and unapparent infections. Different situations could be envisaged; one scenario was that virulent SARS-coronavirus (SARS-CoV) would persist and become endemic. Another possibility was that other epidemic waves would occur or, finally, that the virus would disappear. Taking into account all the uncertainties and anticipating the worst-case scenario, many laboratories and vaccine manufacturers started working on a vaccine approach against SARS infection, largely based on what was known from animal CoVs.

In this chapter, we will discuss the necessity for international cooperation and the importance of discretionary funding for rapidly developing a prototype vaccine candidate. We will review the decision-making process, the strategic choices made in terms of vaccine candidate, adjuvants, working conditions, and the safety precautions implemented at the beginning and throughout the entire production process of the SARS vaccine. In addition, we will discuss the unique challenges associated with moving a vaccine such as SARS through the regulatory process.

ROLE OF INTERNATIONAL COLLABORATION AND U.S. NATIONAL INSTITUTE OF ALLERGY AND INFECTIOUS DISEASES (NIAID)—LESSONS LEARNED

With the uncertainty about the possible extent of the spread of the SARS outbreak in early 2003, there was substantial international collaboration first in the isolation and identification of the CoV, sharing of sequence data, and eventually the sharing of seed virus that would be suitable for vaccine development. In the case of the sanofi pasteur vaccine, the prototype virus was supplied by the Centers for Disease Control and Prevention (CDC) (Utah Virus P2/Vero cell P143). Furthermore, in this spirit of collaboration, sanofi pasteur provided stocks of the Vero cells for the virus isolation to better ensure that any vaccine made from these cells would be acceptable from a regulatory perspective. These were the same Vero cells as are routinely used in the commercial production of inactivated polio vaccine. In addition, there was rapid sharing of immunological reagents to ensure that the plaque-purified prototype seed virus accurately reflected the circulating epidemic SARS-CoV.

One particular difficulty with rapidly emerging infections such as SARS, of course, is that they may occur anytime of the year and are unlikely to be aligned with the annual process for assigning financial and human resources and project prioritization. In order to circumvent these problems, once it became clear that the SARS-CoV could grow in Vero cells, the National Institute for Allergy and Infectious Diseases (NIAID) in the United States focused their request on several companies that had experience in large-scale Vero cell culture and had the experience to work with viruses at biosafety level 3 (BSL3) containment. Our first contact with NIAID on the possibility of developing an inactivated vaccine occurred in the first quarter of 2003. Sanofi pasteur was one of only two companies that satisfied the NIAID's eligibility criteria. The solicitation and funding mechanism that NIAID employed was a directed Request for Proposals (RFP). This is sometimes called a Letter Contract by virtue of the fact that NIAID initiated contact with the companies first by letter outlining the project objectives, infrastructure requirements, and deliverables. The advantage of this mechanism, for diseases such as SARS, is that

the absolute eligibility criteria, vaccine characteristics, and project objectives are clearly defined; the proposal review cycle is very short; and the necessary financial resources are immediately available. In this particular case, the RFP was received by us on May 23, and we submitted our project plan and budget by June 16. Preliminary work began in July and August, and by the third week of September 2003, we had a fully executed contract. By October 2004, our inactivated prototype SARS vaccine was filled and available for clinical assessment. Another positive aspect of this mechanism is that involvement of such a large research organization provides the potential to access the expertise of many different investigators, as technical problems may arise. Unlike traditional research grants, these types of contracts have very short duration and, consistent with the sense of urgency, progress against objectives is monitored on a weekly basis, perhaps, contributing to the fact that our project finished almost a month ahead of schedule. Importantly, this type of mechanism does not compete with academic researchers for funding but allows these researchers to develop more basic science proposals of longer duration that can be reviewed and funded by other established mechanisms.

Perhaps, among others, there are three important lessons about responding to emerging threats that can be learned from the SARS experience. First, information must be shared quickly and transparently. The somewhat surprising observation that the SARS-CoV grew well in Vero cells was important in prioritizing the development of an inactivated, Vero cell–derived virus. Second, there should be an ongoing dialogue between the national research organizations and their potential industrial partners to understand what capacity and experience could be urgently brought to bear in a crisis situation. Although there are potential issues with competitive intelligence, it remains important that information about industrial capability should be shared. Third, funding organizations should have in place a mechanism for rapid proposal solicitation, review and monitoring, and also adequate discretionary funding that could support new vaccine projects in an urgent manner.

PRIOR TO THE START OF THE LABORATORY WORK

As early as April 25, 2003, the WHO and the CDC in the United States (WHO guidelines, CDC) recommended laboratories and vaccine manufacturers to handle SARS-CoV specimens using Standard BSL3 work practices. It is not exceptional for vaccine manufacturers to work in BSL3 facilities for the production of certain vaccines, e.g., rabies, Japanese encephalitits, or polio viruses. Some of these commercial vaccines have been made for decades. For these vaccines, robust production processes and standard operating procedures have been put in place. The experience gained on the decontamination and inactivation of viral vaccines during the production process and the quality control (QC) are all important. Moreover, the personnel working at the different stages of such a vaccine production are typically vaccinated, and revaccination procedures are in place in case of major accidents (i.e., boost after potential rabies contamination).

In case of an emerging virus such as SARS, the situation is completely different. Although the BSL3 experience will be fully exploited, all processes and procedures need to be discussed, evaluated, validated, and implemented. For each emerging virus, this exercise needs to be repeated and specific conditions must to be adopted according to the unique characteristics of the new virus.

Consistent with the WHO and CDC recommendations, at sanofi pasteur live SARS-CoV was handled in a BSL3 facility. Since no treatment or vaccine was available against SARS, we decided to work in "BSL3 plus" laboratory conditions. Essentially our basic level of containment was BSL3 incorporating several BSL4 working practices: clothing change before entering the facilities, shower on exit, and all material decontaminated before exit from the facilities. Also, all steps, where the product was handled in open phase, were performed within Class III Biological Safety Cabinets (CSB). To prevent accidental contamination, the laboratory workers wore a positive pressure personal mask. These precautions were considered necessary taking into consideration the large amount of live virus handled (20–50 l) and finally turned out to be valid as the risk for contamination existed as was shown in the laboratory accidents in Singapore, Taiwan, and Beijing in China (Senior, 2003; Normile, 2004; Orellana, 2004). Furthermore, as described below, the decontamination experiments demonstrated that the SARS-CoV is an extremely resistant virus.

For the medical follow-up of the BSL3-trained personal involved in the SARS vaccine development, it was of critical importance to be able to distinguish the symptoms of respiratory distress caused by SARS or other respiratory agents. It was therefore decided that the BSL3 laboratory workers should be selected in accordance with their immune status and would be immunized with *Streptococcus pneumoniae* and influenza vaccines, if appropriate. In case a worker would present symptoms, a procedure had been put in place to isolate the worker using a high-efficiency particulate air (HEPA) filter mask before being transported to

a nearby hospital where a special, dedicated negative pressure hospital room had been prepared.

STARTING THE LABORATORY WORK: FIRST STEPS

Definition of the Vaccine Profile

The very first decision concerned the choice of vaccine immunization strategy. In the intense early days of the epidemic a variety of approaches were considered. These included inactivated vaccines, subunit products, DNA (either alone or in combination as part of a prime-boost strategy), vectored vaccines, and live attenuated candidates. Similarly, alternative routes of vaccine administration (inoculation, aerosol, etc.) and formulation (adjuvants, etc.) were considered. In fact, several live attenuated and killed vaccines for veterinary CoVs are already marketed: e.g., a live attenuated and killed vaccine against the chicken infectious bronchitis virus (Ladman et al., 2002), a live modified virus against canine CoV (Pratelli et al., 2004). Ultimately, however, the crucial factor in the decision-making process was likely development timelines. At the time of this decision, the epidemic was prevalent and there was a sense of urgency that a prototype vaccine had to be developed as soon as possible. Embedded in this decision-making process was the realization that we were seeking a vaccine candidate that largely used existing, conventional technology and that could be made in significant quantities, if necessary.

In the context of the likelihood for rapid development and the possibility for large-scale production, the decision was taken to produce a monovalent, whole, inactivated, aluminum-adjuvanted SARS vaccine for intramuscular injection. From our perspective, a whole, inactivated vaccine was a logical first choice taking into consideration our extensive experience with inactivated vaccines such as inactivated poliovirus, rabies, and hepatitis A vaccines. We were also encouraged by the fact that SARS-CoV grew very well in Vero cells. Sanofi pasteur has a long industrial experience with these particular cells and developed cell banks that are validated and registered around the world. Even for such a direct experience-based approach, we realized that it would take 12 months to make a good manufacturing practice (GMP) clinical lot for Phase 1 and 2 clinical studies.

Killed vaccines need, in many cases, adjuvantation. In our case, the adjuvant of choice was aluminum hydroxide. Again, in the situation where a new virus is emerging, there is no time to evaluate new adjuvants. Our preference was to use aluminum hydroxide since it is well known, used in many vaccines, and well accepted by regulatory authorities.

SARS Inactivation and Testing Reagents

When the laboratory work on the SARS-CoV vaccine development started, no data were available on the inactivation characteristics of the virus. One of the priorities was to identify the conditions to fully inactivate the virus for vaccine development, but also for decontamination of equipment, facilities, and waste decontamination. The results, as described in more detail below, were unexpected. The SARS-CoV is an extremely resistant virus and several of the routine decontamination working practices cannot be applied for this virus. These results demonstrate how important it is to immediately perform decontamination testing and adapt decontamination practices and strategies for each specific (emerging) virus.

At the time the development of a vaccine against an emerging virus is initiated, it is very unlikely that routine tests and reagents are available. This was indeed the case for SARS. Therefore, our first experiments were dedicated to develop routine tests that are required for vaccine development and the analysis of the host response after immunization. These include neutralization tests, enzyme-linked immunosorbent assays (ELISA), polymerase chain reactions (PCRs), and others. Well-validated reagents are needed as reference standards for essential laboratory tests as polyclonal and monoclonal antibodies, recombinant proteins, and PCR primer pairs. One of the most sensitive issues was how to select an appropriate animal model to evaluate the candidate vaccines. For example, we observed that NMRI mice gave a very heterogeneous response whereas Balb-C or C57BL/6J mice responded uniformly to immunization with the vaccine candidate. Also, guinea pigs appeared to be a good model for the evaluation of immune responses. Beyond immunogenicity, it is important to work with an animal model that is appropriate for challenge studies, as an assessment of vaccine efficacy. This is especially important for emerging infections since efficacy studies in humans may not be possible. In case of the SARS, the *Macaca fascicularis* was identified very early on (Fouchier et al., 2003) as a likely predictive, challenge model.

All of the work was done in constant communication with the regulatory authorities. Our experience with SARS reinforces the idea that manufacturers should be encouraged to open and maintain an active dialogue with regulatory officials, very early in the development process.

Results of the Decontamination Experiments

Viruses can be inactivated by several methods, based on either physical or chemical mechanisms. We investigated five decontamination methods that are currently used for equipment, facilities, and waste decontamination: heat, alkaline treatment, sodium hypochlorite treatment, gaseous formol fumigation, and drying.

It should be stressed that the data presented here have been obtained under our specific experimental conditions. Indeed, the virus sensitivity to inactivation depends on the virus environment and concentration. Thus, the methods presented here were validated with our specific suspensions and experimental conditions, and appropriate precautions should be taken when manipulating SARS-CoV under other laboratory conditions.

Inactivation experiments using different pH values gave rise to unexpected results. When the pH was adjusted to pH13 or pH13.5, a strong decrease in the viral infectivity titer can be observed. However, the virus is not totally inactivated and even after 6 h of alkaline treatment, infectious particles can still be observed. Total inactivation is observed only after 24 h of treatment. These data are surprising as enveloped viruses are usually sensitive to such drastic alkaline conditions.

The results from the experiments performed to evaluate the viral loss of the SARS-CoV due to drying on glass surface were also surprising: 35–42 days were necessary to inactivate the virus to the detection limit of the technique. Other viruses, such as polio or rabies, can be inactivated by drying durations of approximately 72 and 144 h, respectively. In our experience, the SARS-CoV is the most resistant virus ever described in an industrial setting.

The gaseous formaldehyde fumigation is a viral decontamination technique widely used throughout the world. We found that formol fumigation is totally inefficient on dried virus. However, virus in solution is efficiently inactivated. The two decontamination techniques tested here, drying and formaldehyde fumigation, reinforce the necessity to decontaminate the working areas in the laboratory, as well as the equipment, very frequently in order to avoid any drying of viral suspension onto glass or any other surface.

Finally, sodium hypochlorite (2°Cl) and heat treatment were evaluated. The effect of sodium hypochlorite on dried virus is very rapid and efficient, as no infectious viral particles were recovered after washing the surface with sodium hypochlorite. Thermal decontamination was shown to be efficient at both 58 and 68°C. To achieve total inactivation of the SARS-CoV, 1 h heating at 68°C and 2 h heating at 58°C are necessary.

Considering the decontamination data, the following strategy was put in place. All solid waste, as well as the equipment that could resist such a drastic treatment, was autoclaved. For liquid waste, the solutions were subjected to alkaline pH treatment for at least 2 h and then transferred into a tank for thermal decontamination at 105°C for 30 min. The laboratory facilities, and the equipment that could not be autoclaved, were decontaminated with 2°Cl sodium hypochlorite solutions, before being fumigated with gaseous formol.

The data on decontamination of the SARS-CoV presented here show that existing decontamination strategies cannot be directly extrapolated to emerging viruses and that these inactivation conditions should be determined empirically for each virus.

THE PRODUCTION PROCESS

Viral Source and Raw Material

The SARS-CoV seed virus isolate was provided on August 25, 2003, by the CDC. This isolate (the so-called UTAH strain) was made from the sputum from an acutely ill U.S. traveler who had apparently been exposed in Hong Kong. This isolate was fully sequenced by the CDC and shown to be virtually identical to the Urbani strain of SARS-CoV.

To obtain an original seed virus, in full accordance with Food and Drug Administration (FDA) requirements, sanofi pasteur provided certified Vero cells to the CDC, who performed the isolation of the virus and made two passages before sending the virus to sanofi pasteur. Upon receipt, the virus underwent two additional passages, and was plaque purified. This plaque purification step is of importance to limit the risk of adventitious agents during the subsequent expansion of the virus. In contrast, there is also a risk that in selecting a plaque, it may differ significantly from the uncloned vaccine. To evaluate the latter, it was decided to compare cloned *vs.* uncloned virus in terms of virus sequence and immunogenicity in guinea pigs. It was demonstrated that the two candidate vaccines were totally similar.

Following this verification, the selected clone (VVNFL11) was passaged eight additional times for adaptation. From our experience with viruses to be used to prepare an inactivated viral vaccine at industrial scale, there is a need to reach a titer of virus >7.0 log/ml. Indeed, with the SARS-CoV, we obtained a consistent titer of around 7.3 $\log_{10}$ $TCID_{50}$/ml. In Vero cells, distinct cytopathic effect (CPE) is always observed at day 2 or 3 post-infection. These first

experiments encouraged us that the prototype vaccine could be produced in Vero cells using a single harvest totally compatible with our experience with inactivated poliovirus.

Raw materials used to develop the candidate vaccine (serum and trypsin) were selected in accordance with current regulation. Calf serum was imported from Australia, and gamma irradiated prior to use. The trypsin was from porcine origin and also gamma irradiated. Extensive evaluation for adventitious agents was performed on the raw material, which included the search for cytopathogenic agents, hemadsorbing agents, and specific viral contaminants as bluetongue, reovirus, rabies, parainfluenza type 3, specific bovine viruses [adenovirus, parvovirus, respiratory syncytial virus (RSV)], bovine viral diarrhea, rhinotracheitis virus), and porcine viruses (parvovirus, adenovirus; transmissible gastroenteritis virus; hepatitis E virus, rabies virus, and porcine pestis virus).

Manufacturing of the Viral Seed Lots

The viral seed lots were produced in Vero cells. QC testing is a major step in the qualification of such a seed. Of all the different tests performed (identification of the Vero cells, sterility, mycoplasma, titer, and contaminating viruses), the research of contaminating virus(es), also called adventitious agents, represents the most crucial step. To detect adventitious agents, sensitive cell culture monolayers of CV-1 cells, human diploid MRC-5 cells, and chick embryo fibroblasts (CEFs) were inoculated with the crude viral suspension and are observed for induced CPE and/or hemadsorption. CV-1 cells are used in these tests, as they are of the same species and the same origin as the cells used for vaccine manufacturing. MRC-5 cells are human diploid cells and can potentially reveal other viruses able to infect human cells. And finally, taking into consideration the origin of the specimen (pulmonary syndrome) we added CEF, which are known to be sensitive to the infection of several respiratory viruses such as influenza virus and RSV. At the same time, adventitious agent testing was performed on control cells (search for hemagglutining or hemadsorbant viruses) and on the supernatant of the control cells (search for adventitious agents) by inoculation of the three cell lines: Vero, MRC-5, and CEF. Adventitious agent testing was also done in vivo by inoculation in suckling mice, mice, and guinea pigs, as well as the allantoïc cavity and yolk sac of embryonated chicken eggs.

Complementary to the conventional methods to qualify viral seed, as described above, extensive characterization was performed using PCR testing. The PCR tests are listed in Table 11.1.

TABLE 11.1 List of viruses for which the crude SARS-CoV viral suspension was monitored by PCR

Detection of viruses by PCR
Adenovirus
Bovine and porcine circovirus
Bovine herpesvirus—I, IV
Bovine polyoma virus
Cytomegalovirus
Epstein-Barr virus
Hepatitis A virus
Hepatitis B virus
Hepatitis C virus
Human herpes virus (HHV)-6 and HHV-7
HHV-8
Human immunodeficiency virus (HIV)-1 and HIV-2
Human respiratory syncytial virus
Herpes simplex virus
Human T-cell leukemia virus type-1 (HTLV-1)
Human T-cell leukemia virus type-2 (HTLV-2)
Human papilloma virus
Human parainfluenza virus—1, 2, 3
Human polyoma virus
Metapneumovirus
Parvovirus B19
Simian spumavirus
Simian immunodeficiency virus
Simian retrovirus—1, 2, 3/SMRV
Simian T-cell lymphotropic virus
Simian virus 40

All tests were performed in accordance with international requirements, showing that no adventitious agents were detected.

Results of the Inactivation Experiments

The difficulty with inactivating viruses remains the balance between fully validated inactivation and preservation of immunogenicity or epitopes associated with protection. It is well known that reagents used to inactivate viruses [betapropiolactone (BPL), formaldehyde] can change the outer membrane antigens with the risk of a reduced immunogenicity of the vaccine. For the inactivation of SARS-CoV, we chose to test BPL. Assays were performed to determine the best BPL concentration for inactivation while maintaining a good immune response in mice. Virus

inactivation was performed using three different BPL concentrations: 1/2000, 1/3000, and 1/4000 (v/v). In our experience, a 1/4000 dilution of BPL was the optimal concentration for the inactivation of SARS-CoV based on a balance between total inactivation and maintenance of antigenic properties. The 1/4000 BPL dilution is similar to what is used for rabies vaccine inactivation.

The usual way to measure viral inactivation is by kinetic studies, i.e., reduction in virus infectivity. This technique has a detection limit of 1.5 $\log_{10}$ $TCID_{50}$/ml. The kinetics of inactivation was performed at 0, 5, 30 min, and 1, 2, 3, 4, 6, 8, and 24 h, and it was shown that inactivation below the limit of detection was obtained after 6 h. In order to increase the detection sensitivity, an amplification test was also performed. For this amplification, Vero cells are incubated with a portion of the viral solution following inactivation for different periods of time. After 7 days of incubation, the cells are trypsinized and cultivated for additional 14 days. At the different stages of amplification, the cells were microscopically observed for CPE and at the end of the incubation (day 21) an immunocolorimetric assay test was performed. Our data demonstrated that the virus is fully inactivated by 12 h, not 6 h of BPL treatment, demonstrating that the amplification test is much more sensitive.

To complete the validation of the amplification test, the minimum limit of detectable infectious viral particles was determined. This was done by spiking the inactivated vaccine with different concentrations of live virus and incubating with Vero cells. Using this approach, it was possible to establish the minimum virus detection as 1 pfu.

Based on these data, it was concluded that inactivation with 1/4000 BPL dilution for 12 h fully inactivates the SARS-CoV batches. To ensure a very large safety margin, we adopted an inactivation period of 24 h for the SARS-CoV vaccine production process.

ANIMAL MODELS

Since a direct efficacy trial in humans will be impossible, because of a lack of naturally circulating SARS-CoV, the licensure of a SARS-CoV vaccine will depend on surrogate markers. Recently (as described below) the FDA adopted the Animal Efficacy Rule that envisions that under such circumstances, demonstration of efficacy can be performed in two animal models. For SARS-CoV vaccine development, monkeys and ferrets can be used to evaluate candidate vaccine. Both animal models show pathology in the lungs upon autopsy.

The immunogenicity of the SARS vaccine was evaluated in nonhuman primates, *M. fascicularis*, and ferrets. Both animal models are susceptible to infection, do show some signs of disease (lethargy), and show signs of pulmonary lesions upon histological examination (Fouchier et al., 2003; Martina et al., 2003; ter Meulen et al., 2004; Rowe et al., 2004; McAuliffe et al., 2004). Different doses of the SARS vaccine (6 or 7 $\log_{10}$ $TCID_{50}$/ml) were injected in the presence or absence of aluminum hydroxide. Two intramuscular injections were performed at a one month interval.

Regarding the humoral response, sustained levels of ELISA and serum-neutralizing virus-specific antibodies were elicited in vaccinated monkeys and ferrets. A significant dose–effect relationship could be demonstrated. Moreover, a strong adjuvant effect of aluminum hydroxide was evidenced for each vaccine dose and proved in most cases to be highly significant.

In order to evaluate the efficacy of the SARS vaccine, immunized monkeys and ferrets were challenged intratracheally with a heterologous Hong Kong SARS-CoV strain (Coronovative, Rotterdam, The Netherlands). Monkeys immunized with 6 or 7 $\log_{10}$ of inactivated virus were protected as measured by RT-PCR and viral titration on lung samples five days post-challenge. The ferrets were protected at the lower immunization dose of 5 or 6 $\log_{10}$.

Based on our experience to date, the inactivated, adjuvanted SARS-CoV prototype vaccine seems to be a good candidate for further evaluation in Phase 1 studies.

REGULATORY APPROVAL PROCESS—SOME UNIQUE ASPECTS OF SARS AND OTHER EMERGING DISEASES

As with other vaccines, vaccines for SARS and other emerging threats need to follow a structured pattern of regulatory development. The initial stages would be very similar to those followed for vaccines under development for conventional infectious diseases. In the United States, the earliest stages would include the development of sufficient preclinical information about the vaccine to allow the preparation of an investigational new drug (IND) application for submission to the FDA (see Chapter 13). The IND may have information unique to the vaccine candidate but should include information about the rationale for the vaccine design, the source of the virus and other components, the manufacture of the active vaccine component, formulation, preliminary characterization of the vaccine

including purity and potential contaminants, immunological testing, and animal testing, including toxicology. Even at this early stage, the vaccine should be made under GMP conditions and other laboratory work conducted under good laboratory practice (GLP) conditions, as appropriate. The IND application should also include important information about the Phase 1 clinical design, focusing on how the safety will be monitored and a discussion of any potential adverse reactions based on the experience with vaccines that have similar components or methods of preparation. There should be an opportunity to outline the vaccine concept and Phase 1 clinical study at a pre-IND meeting that often provides the opportunity to receive the input and concerns of the regulatory agency.

Following approval of the IND, vaccines such as SARS can progress to a conventionally designed Phase 1 study. Typically, this Phase 1 clinical study is descriptive and would include a small number of healthy young adults with the emphasis on monitoring the safety of the vaccine (local and systemic reactions). Often, the first immunologic assessment is part of this study. Following successful completion of the Phase 1, as with other vaccines, a SARS vaccine candidate could move forward to Phase 2. During this phase, in addition to safety monitoring, dose-ranging studies are conducted in much larger groups of individuals and the vaccine should meet predefined primary and secondary endpoints. If the Phase 2 is successful, following a pre-Phase 3 meeting, clinical studies are conducted in a greater number of subjects during which less frequent reactions can be detected and the efficacy or effectiveness of the vaccine determined. As part of this Phase 3 evaluation, the consistency of sequential lots of the vaccine are typically compared in order to ensure that the vaccine can be reproducibly manufactured.

Obviously, as the vaccine progresses clinically from Phase 1 to Phase 3, the size of the lots of vaccine often increases and the manufacturing and in-process and release testing specifications become increasingly well defined, so as to guarantee that the vaccine can consistently be made at a commercially useful scale. If all three phases of clinical development are successful, the manufacturer may then submit a Biologics License Application (BLA), which is a very extensive compilation of all of the information relating to the development and manufacture of the vaccine.

As suggested in the Animal Models section above, the unique challenge for SARS and other emerging threats, whether anthrax or Ebola viruses, is that it may not be possible to conduct Phase 3 clinical studies to determine the effectiveness of the vaccine. For these agents, it would be too dangerous to conduct challenge studies in humans and the prevalence of the disease is either nonexistent, sporadic, or too small to allow the development of a reasonable clinical protocol. In anticipation of this problem, largely in the face of potential bioterrorist agents, in 2002, the FDA adapted the so-called Animal Rule [see Federal Register, May 31, 2002 (Volume 67, Number 105)]. Under this guidance, new drugs or biological products that are intended to prevent serious or life-threatening conditions may be approved on evidence of effectiveness derived from appropriate studies in animals and any additional supporting data, if controlled clinical studies cannot be conducted in human volunteers and field trials are not possible. In order to satisfy this alternative mechanism, however, several criteria must be met. First, there is a reasonably well-understood pathophysiological mechanism that can be ameliorated or prevented by the product. Second, the effect is demonstrated in more than one animal species, unless it is demonstrated in a single species that represents a sufficiently well-characterized animal model. Third, the animal study endpoint is clearly related to the desired benefit in humans. And finally, the data are sufficiently well understood to allow selection of an effective dose in humans. It is therefore reasonable to expect that the effectiveness of the product in animal model(s) is a reliable indicator of its effectiveness in humans.

Obviously, it is too early to know whether the SARS vaccine candidate as described in this chapter will move forward and be able to meet all of the criteria of the Animal Rule. In particular, SARS vaccine development is hindered by relatively little information about human CoVs in general. Until the rapid emergence of SARS, most of the basic research was focused on animal CoVs and our inactivated SARS vaccine candidate described in this chapter is exclusively based on experience with vaccines to animal CoVs. Certainly, it is too early to conclude whether the ferret and/or *M. fascicularis* is/are the most appropriate model(s) for human SARS infections. As a result, except for clinical cases documented during the outbreak, there is relatively little information about SARS pathogenesis and correlates of immunity. Another difficult aspect is that a feline infectious peritonitis (FIP) vaccine was actually harmful to the health of the immunized cats upon challenge with wild-type FIP virus (Weiss and Scott, 1981). Before moving forward with approval, therefore, it will be very important to determine whether these adverse outcomes can be prompted or mimicked by any of the SARS vaccine candidates.

CONCLUSIONS

What Were the Parameters for the Rapid Development of the SARS Vaccine?

The production of a GMP clinical lot of a monovalent, whole, inactivated, aluminum hydroxide-adjuvanted SARS-CoV vaccine took 12 months. In terms of vaccine development, this is extremely rapid. Several factors contributed to these short timelines.

The grants made available by the NIAID for the development of a SARS vaccine completely changed the classical environment, allowing vaccine industries to start almost immediately the development of a new vaccine. Indeed, the development of a new vaccine can only be done to the detriment of other vaccine developments, mobilizing teams and facilities.

From a technical point of view, the choice of a classical vaccine development strategy using conventional procedures, such as Vero cell culture for viral propagation and BPL inactivation, was a decisive factor to success. Importantly, we were able to quickly recruit a volunteer workforce that was both familiar with the technology and trained to work in a BSL3-plus environment.

A close collaboration with the reference laboratory, the CDC's Influenza Branch, where the SARS-CoV was isolated, was essential. We provided certified Vero cells to the CDC, which allowed us, upon receipt of the purified strain from the CDC, to re-isolate the SARS-CoV under conditions making the prompt start of a vaccine development possible.

When initiating vaccine development against a new emerging infectious agent, the problem of availability of reagents and routine tests to perform biological and molecular studies must be addressed. It is obvious, that at the beginning of such development, there are no such reagents or commercial kits available. As a consequence, the first step in the SARS-CoV project was to prepare the different reagents (antisera and monoclonal antibodies) and the appropriate tests (viral titration, PCR, ELISA, immunofluorescence assay, etc.). Finally, a series of preliminary experiments on monkeys (three months after the start of the project) had given guidance whether it was appropriate to use an inactivated vaccine, as well as to the choice of the adjuvant.

Constant communication with regulatory authorities has allowed the validation of this strategy from the beginning of the project. This communication was also very important for the qualification of the viral seed lots. The qualification of the Vero cells was not an issue as several vaccines are already produced in Vero cells, but this was obviously not the case for the viral seeds. Two major obstacles had to be overcome: (1) the realization that the animal testing had to be done in BSL3 facilities by BSL3-trained personnel, and (2) the search for adventitious agents using general classical tests (search for adventitious viruses on cells and in animals) and specific tests (PCR). For the latter, there was no list available and the final testing to be performed was under the responsibility of health authorities. This resulted in a rather exhaustive list of PCR testing.

Can We Shorten the Timelines Even More When Facing an Emerging Pathogen?

It is likely that epidemics will emerge in the future from unrecognized sources and some of these will be highly pathogenic for humans. These pathogens will be categorized as BSL3 or BSL4 pathogens needing high security level laboratories as well as specialized personnel. How to manipulate these pathogens that are highly pathogenic, in large quantities? To face the emergence of new pathogens, dedicated structures are needed with the right equipment and trained personnel. From an industrial perspective, this seems not compatible with the need and use of trained personnel and facilities that do have a constant activity to assure the production of existing vaccines and the development of new vaccines. Such emergency structures could be set up and maintained by national reference centers respecting the BSL requirements as well as the GMP conditions. It would be very beneficial for industries to collaborate with such reference centers that provide purified pathogens and reagents allowing a prompt start of a vaccine development.

CHAPTER

12

Clinical Trials of Vaccines for Biodefense and Emerging and Neglected Diseases

Wendy A. Keitel
Baylor College of Medicine, Houston, TX, USA

OUTLINE

ABSTRACT

The development of safe and effective vaccines for the prevention and control of emerging and neglected infectious diseases is an international priority, as is the development of similar control measures for bioterrorist threats. International standards have been established to ensure the protection of human subjects and the scientific integrity of clinical trial study design and data collection. A general overview of the history of the regulatory guidelines and ethical principles underpinning the vaccine development process is provided, with an emphasis on clinical trials conducted in the United States.

The contemporary vaccine development process involves sequential assessment of safety, immunogenicity, and efficacy in phase1, 2, and 3 clinical trials. The process is not always linear or straightforward, and adaptive flexible clinical trial designs can increase the likelihood of a successful outcome. Because the efficacy of vaccines for a number of the diseases discussed in this volume cannot be tested directly in humans, alternative approaches have been developed to address this challenge. The major elements of typical clinical trial protocol are discussed, and a checklist of essential documents supporting the trial is provided. As novel vaccine approaches and technologies emerge, the regulatory and ethical considerations will need to be revisited and adapted to respond to the ever-changing landscape.

INTRODUCTION

Vaccines are considered among the most valuable and cost-effective tools for the control of infectious diseases; indeed, universal immunization of infants and children against a variety of pathogens was considered one of the top ten achievements of the 20th century (CDC, 1999). Major scientific, technical, ethical, and regulatory principles and/or processes underpinning the vaccine development and evaluation process have been defined; however, challenges posed by the threats of bioterrorism and emerging infectious diseases, as well as technological advances in the composition, formulation, and delivery of vaccines, expose gaps in policy and practice that require ongoing consideration and refinement of approaches to the evaluation of new vaccines. The purpose of this chapter is to provide a brief overview of the approach to the evaluation of candidate vaccines in humans, with a particular attention to issues related to vaccines for biodefense and emerging and neglected diseases. The major focus will be on clinical trials and protocol development in the US, although many of the principles, regulations, and practices have been harmonized across the globe. A brief overview of related regulatory issues and preclinical vaccine development is provided; however, detailed discussions of these topics can be found elsewhere in this volume.

HISTORICAL CONSIDERATIONS

In the US, vaccines are regulated as biologicals, although vaccines are legally defined as drugs under the Food, Drug and Cosmetic Act (FDCA). The ethical principles, and the regulatory agencies and requirements that guide product development and clinical research in the 21st century evolved progressively over the 20th century. In many cases, the development of codified guidelines and the establishment of a regulatory authority were spurred by a tragic accident or a clear ethical breech (for reviews of Historical Considerations, see Baylor and Midthun, 2004; Borchers et al., 2007).

Regulatory Issues

In 1901, a number of children became ill and died after treatment with diphtheria antitoxin contaminated with tetanus toxin. This episode resulted in the first legislation designed to regulate the purity and potency of biologicals—the Biologics Control Act (BCA) of 1902. In 1938, over 100 people died after ingesting an elixir of sulfanilamide containing diethylene glycol (antifreeze), leading to the enactment of the FDCA (Ballentine, 1981). Provisions of the FDCA required manufacturers to submit safety data to the Food and Drug Administration (FDA) prior to registration. The 1962 Kefauver–Harris Amendments to the FDCA required that efficacy data also be submitted. The1944 Public Health Service Act incorporated the BCA into section 351 of the US Code of Federal Regulations (CFR), which gave the federal government the authority to license biologicals and manufacturing facilities. In 1955, incomplete inactivation of a poliovirus vaccine resulted in the development of polio in a number of children (the "Cutter Incident"); this led to the establishment of the Division of Biologics Standards (DBS) within the NIH (Offit, 2005). The authority vested in the DBS was transferred to the FDA in 1972. The organization that is currently responsible for regulating biologics is the Center for Biologics Evaluation and Research (CBER) at the FDA. Title 21 of the CFR contains regulations pertaining to biologicals, including product standards, manufacturing, labeling, licensing, advertising, investigational use, and protection of human subjects (informed consent, nonclinical laboratory studies, and Institutional Review Boards, or IRBs). Part 312 of Title 21 CFR contains regulations related to the Investigational New Drug Application (IND). The CFR is updated each year to reflect changes in policies and procedures. Additional guidance documents related to vaccines are published by the FDA, as appropriate.

During the 1990s, an international group comprised of scientists, regulators, ethicists, and pharmaceutical representatives convened to discuss standards for designing, implementing, documenting and reporting clinical trials. The International Conference on

Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) established guidelines for the conduct of clinical research (Good Clinical Practice, or GCP), many of which have been adopted by the US FDA (FDA, 1996). The ICH GCP provides a unified standard to ensure the quality of clinical trial data and the protection of human subjects for the European Union, Japan, and the US for clinical trials that will support licensure of new vaccines and drugs. For research related to the evaluation of vaccines for emerging and neglected diseases, implementation of GCP in developing countries may pose unique challenges. Acosta et al. (2007) conducted a multinational clinical trial of Vi polysaccharide typhoid fever vaccine in Asia among 200,000 individuals, during which implementation of GCP required adaptations in order to comply with the goals of the guidelines.

Ethical Issues

The revelation that Nazi physicians tortured and experimented on prisoners during World War II culminated in the publication of the Nuremberg Code in 1947 (Macrae, 2007). The Code is recognized as the first set of ethical guidelines for human research to be recognized by the international community. In 1965, the Declaration of Helsinki articulated additional responsibilities of investigators to research subjects, and paved the way for the development of IRBs.

Continued violations of informed consent were summarized in a *New England Journal of Medicine* article written by Dr. Henry Beecher (1966). This article and the subsequent expose of the ethical violations perpetrated during the Tuskeege Syphilis Study led to the 1974 National Research Act, which established IRBs and the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research. After considering the principles and practices of human research in the US, the commission published the Belmont Report in 1979. This report defined the three major ethical principles (and their related clinical trial applications) pertaining to human research: respect for persons (informed consent); beneficence (risk-benefit assessment); and justice (equitable subject selection). Recommendations of the National Bioethics Commission from 1981 related to research involving human subjects were adopted into federal law in 1991. The so-called Common Rule (45 CFR 46 Subpart A) articulated the federal policy for protection of human subjects who are participating in clinical trials. Additional protections for pregnant women and fetuses, prisoners, and children are outlined in Subparts B, C, and D of 45 CFR 46. The Council for International Organizations and Medical Sciences, formed in 1949, recently published updated international ethical guidelines for research involving human subjects (CIOMS, 2002).

It is abundantly clear that the ethical considerations and regulatory guidelines for the conduct of clinical research are inextricably intertwined: ethical considerations drive the need to regulate the conduct of clinical trials to ensure the protection of human subjects and the quality and integrity of the data generated. Seven ethical requirements that should be fulfilled in the conduct of clinical research have been proposed by Emanuel et al. (2000): the research should provide information that will advance science and knowledge (value); scientific validity; fair subject selection; favorable risk-benefit ratio; independent review; informed consent; and respect for enrolled subjects. The increasing complexity and redundancy of the oversight of contemporary clinical trials reflects the commitment to accomplish these goals. A simplified prototypical organizational structure for a vaccine research clinical trial is shown in Fig. 12.1. Further details regarding the roles and responsibilities of the participants in the clinical trials process are provided below.

STAGES OF VACCINE DEVELOPMENT

Overview

The major stages of vaccine development are outlined in Fig. 12.2. The initial stage is referred to as the pre-IND (investigational new drug) stage. Activities conducted in this stage culminate in the production of a vaccine that can be evaluated in humans—the IND stage. Vaccines that are shown to be safe, pure, and effective in humans may then be licensed for use (licensing and postmarketing stage).

Pre-IND Stage

Once a public health need for control of a disease by means of vaccination has been identified, detailed studies designed to understand the pathogenesis of infection and to identify immune responses associated with protection are conducted. Studies may involve assessment of infection and immunity in humans if the disease occurs naturally at a frequency high enough to permit their evaluation (interpandemic influenza, malaria, tuberculosis, and others); however, detailed evaluations of other rare and lethal diseases—particularly those included in the Centers for Disease Control and Prevention (CDC) Category A biothreat list—must

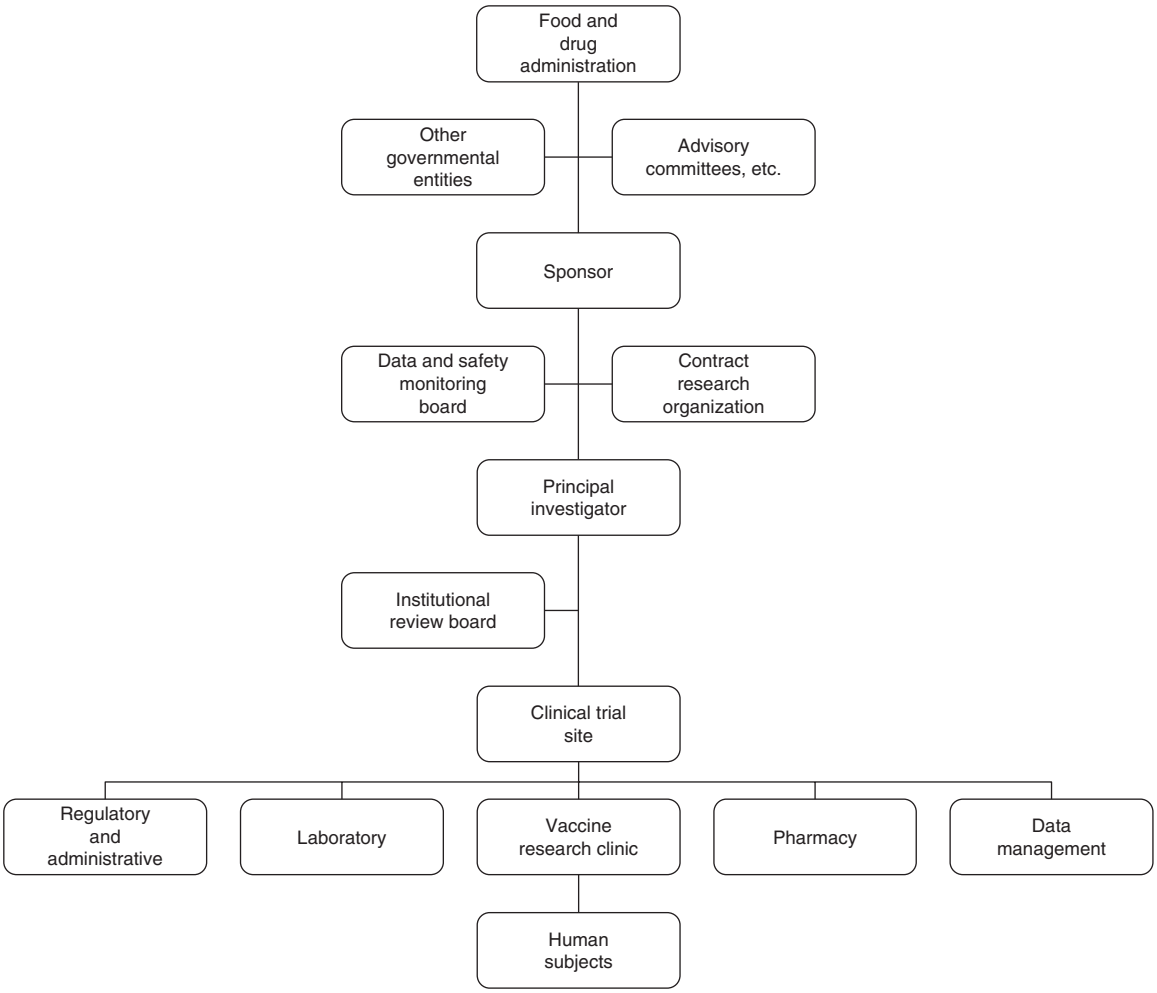

FIGURE 12.1 Organizational structure of a typical single-center vaccine clinical trial.

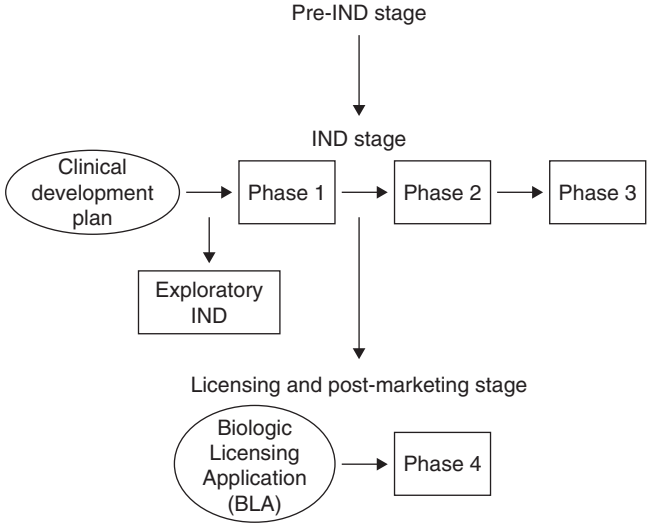

FIGURE 12.2 Overview of the major stages of vaccine development; IND, investigational new drug.

be studied in animal models that might predict the pathology and immune responses that occur in humans (smallpox, tularemia, inhalational anthrax, hemorrhagic fever viruses, etc.). Candidate vaccine formulations containing or expressing epitopes that can elicit immune responses associated with protection are then designed and evaluated in vitro and in animals, where their safety and immunogenicity profiles are established. A critical part of the pre-IND stage is the development and validation of a manufacturing process.

IND Stage

Candidate vaccines typically undergo a sequential series of evaluations in humans. Three major phases are identified, as summarized in Table 12.1. In practice, the scheme is not so straightforward: phase 1 and phase 2 clinical trials may overlap or be combined,

TABLE 12.1 Phases of clinical vaccine development

Clinical trial phase	Major objectives	Typical number of subjects	Type of subjects	Comments
I	Safety and tolerability; preliminary immunogenicity	20–80	Healthy adults	First introduction of a candidate vaccine into humans
II	Immunogenicity; safety	Hundreds	Healthy adults, followed by target populations	Immunization regimen defined (dosage levels, number of doses)
III	Efficacy; safety	Hundreds to thousands	At-risk population(s)	May be limited to immune response determinations[a]
IV	Safety; duration of protection; efficacy in other groups or for other indications	Thousands to millions	Vaccine recipients	Postmarketing studies

[a] If efficacy cannot be assessed in humans because disease does not occur naturally or at a high enough frequency (smallpox, inhalational anthrax, etc.), then efficacy may be established in animal models (see text) and correlates of protection identified in humans.

and multiple phase 1 and/or phase 2 evaluations may be necessary for adjustment of dosage, change in regimen, and evaluation in other age and/or risk groups, even after pivotal phase 3 studies have demonstrated efficacy. Close and ongoing communication between the sponsor, regulatory agencies, investigators, and IRBs is critical throughout the IND stage, including pre-IND meetings, end-of-phase 2 meeting, pre-Biologic Licensing Application (BLA), and BLA meetings to facilitate the timely progression through the clinical trials process.

Phase 1 Clinical Trials

The first evaluation of a candidate vaccine in humans is referred to as a phase 1 clinical trial. Typically less than 100 healthy young adult subjects are enrolled in phase 1 trials. In fact, the number may be considerably smaller for novel products, in which case investigators may elect to inoculate only a handful of subjects to exclude the possibility of unexpected reactogenicity or toxicity (Keitel et al., 1993a). The major goal of the phase 1 trial is to assess safety and tolerability; however, preliminary immunogenicity assessments and dose-ranging information can provide valuable information regarding dosage selection for subsequent evaluations. Although the design of phase 1 clinical trials of drugs often is open-label, many contemporary phase 1 clinical trials of candidate vaccines are randomized, double-blind, placebo-controlled trials. The phase 1 trial may be performed in stages, where a small cohort of subjects is vaccinated and observed for a period of 1–4 or more weeks before the remainder of the study cohort is vaccinated in stage 2. This approach reduces the exposure of subjects to the occurrence of unexpected toxicity. For vaccines that are produced in the US whose ultimate use will be in other countries (such as malaria vaccines), the initial evaluation occurs in the US (phase 1a), followed by phase 1b testing in a healthy population in the target country. Inclusion of placebos in this and other phases of development reduces bias in the assessment of adverse events (AEs) and serious AEs (SAEs), and provides internal controls for laboratory assessments of immune responses following immunization.

Because the number of subjects enrolled in a phase 1 trial is small, these studies lack statistical power to detect AEs that occur at a low rate. Nevertheless, small, carefully monitored phase 1 trials can identify unexpected and/or unacceptable toxicities that require reformulation or reevaluation of a potential candidate (Keitel et al., 1999; Edelman et al., 2002). In some circumstances, specific monitoring of subjects in phase 1 or phase 2 trials for evidence of infection after immunization is relevant, particularly if there are concerns that the vaccine might elicit immunopathologic responses when the vaccinated subject is naturally infected. Immunopatholgy resulting in severe atypical infection and/or death occurred among persons immunized with an inactivated measles vaccine and in infants given an inactivated vaccine to prevent respiratory syncytial virus (RSV) vaccine (Polack, 2007). Similar concerns exist regarding the potential for dengue virus and SARS coronavirus vaccines to elicit immunopathologic responses (Edelman et al., 2003; Deming et al., 2006).

Although not specifically relevant for this chapter, an exploratory IND study may precede a typical

phase 1 evaluation for the assessment of drugs and therapeutic biologicals (FDA, 2006). The exploratory IND study option is characterized as a small early phase 1 trial that has no therapeutic or diagnostic intent; rather, the goal is to assess feasibility for further development of a drug or biological. Goals of this type of study may include determination of the mechanism of action of a drug in humans; evaluation of the pharmacokinetic profile of the agent; selection of one from a group of promising candidates; and exploring biodistribution characteristics using imaging techniques. Because these studies pose lower potential risk to subjects, exploratory IND studies require less or different preclinical support than typical phase 1 studies.

Phase 2 Clinical Trials

Vaccine candidates that have favorable safety and immunogenicity profiles in phase 1 trials may progress to expanded phase 2 trials. Several hundred healthy subjects may be enrolled into phase 2 trials. The major goals of phase 2 trials are to assess safety and to develop optimal regimens for immunization. Typically several dosage levels are evaluated; different immunization regimens (number of doses and interval between doses) also may be explored. Most phase 2 trials are randomized, double-blind, placebo-controlled trials. Although larger numbers of subjects are evaluated, phase 2 trials still lack statistical power to detect events that occur in a low proportion of subjects. Initial phase 2 trials are usually conducted among persons who are at low risk for acquiring the target disease; therefore, additional phase 1 and phase 2 trials may be necessary to assess safety and immunogenicity among populations who are at high risk for the disease, in which pivotal efficacy trials will be conducted. For several emerging and neglected diseases, the preliminary efficacy of a vaccine can be assessed in a human challenge model, including malaria, influenza, and cholera (Couch et al., 1971; Epstein et al., 2007; Tacket et al., 1999). These carefully controlled experimental inoculations of subjects with the target pathogen can provide proof of concept that immunization with a vaccine candidate confers protection prior to large phase 3 clinical trials. In the pediatric population, rechallenge of vaccinated subjects with homologous or related live attenuated influenza virus vaccines (LAIV) provided supportive evidence that intranasal immunization with LAIV would confer protection against subsequent infection with wild-type influenza viruses (Belshe et al., 2000). Phase 2 trials may also incorporate plans to assess the concomitant administration of other vaccines, biologicals, or medications. For example, administration of a new vaccine to infants in the context of the increasingly complicated childhood immunization schedule poses complex problems; evidence that simultaneous administration of licensed and experimental vaccines does not interfere with protective responses to components in either product is necessary (Rennels et al., 2000).

Phase 3 Clinical Trials

Once a vaccine candidate has been shown to be safe and to possess acceptable reactogenicity and immunogenicity profiles, assessment of the efficacy can be undertaken in phase 3 clinical trials. The type and size of the population to be studied will depend on epidemiology of the target disease (population at risk for disease and the disease attack rate) and the level of protection conferred via immunization. A phase 3 clinical trial for prevention of disease that occurs at a low incidence may require hundreds of thousands of subjects, such as the US field trial of inactivated poliovirus vaccine in the 1950s (Francis, 1955); whereas phase 3 trials of vaccines for prevention of high-incidence infections (such as RSV in infants) theoretically would require no more than hundreds of subjects, particularly if the vaccine was expected to be highly efficacious.

The assessment of efficacy of vaccines against agents of bioterrorism, as well as vaccines for candidate pandemic influenza, may be problematic. For example, smallpox, inhalational anthrax, hemorrhagic fever viruses, tularemia, plague, and influenza A/H5N1 do not occur naturally at a frequency high enough to permit controlled evaluation of clinical vaccine efficacy prior to licensure of vaccines. The FDA final rule entitled "New Drug and Biological Drug Products: Evidence Needed to Demonstrate Effectiveness of New Drugs When Human Efficacy Studies Are Not Ethical or Feasible" (otherwise referred to as the "Animal Rule") was published to address this circumstance (FDA, 2002). The rule permits use of animal efficacy data when collection of human efficacy data is not feasible. Safety and immunogenicity data in humans and animal efficacy data can be used to support licensure when several conditions are met, as follows: (1) the pathophysiology of the infection is reasonably well understood; (2) the pathogenesis and immune responses in one or two animal species are expected to predict these responses in humans; (3) the immunogenicity endpoint(s) correlated with protection in the animal(s) are related to human immune responses; and (4) immunogenicity

endpoints in animals and humans are sufficiently well understood to permit selection of a regimen that would be expected to predict protection in humans. For other diseases where correlates of protection are reasonably well defined (for example, serum HAI antibody level against influenza viruses), surrogate markers can be used to support licensure (FDA, 2007a). Finally, in order to facilitate the approval of vaccines for such severe, life-threatening illnesses, additional mechanisms for expedited review and accelerated approval have been developed by the FDA.

Phase 4 Clinical Trials

Regulatory authorities are increasingly requiring additional studies to be conducted after market approval. Phase 4 studies may also be initiated by the sponsor for a variety of reasons. While a vaccine appears safe after it has been studied in thousands of individuals, rare adverse events may only be observed after hundreds of thousands or even millions of people have been vaccinated, as occurred with the first-generation live attenuated rotavirus vaccine (Murphy et al., 2001). The long-term safety or continued efficacy of a vaccine may be unknown at the time of licensure, and the benefit of immunization of special populations that may have been underrepresented or not studied in the IND stage may be of interest. Unfortunately, phase 4 clinical trials typically are not randomized, and they may be uncontrolled. Nevertheless, several safety surveillance systems have been established to facilitate the early detection of potential rare, serious reactions to vaccines, including the Vaccine Adverse Event Reporting System (VAERS), the Vaccine Safety Datalink (VSD), and the American Academy of Pediatrics Practice Research Office Settings (PROS) (Ellenberg et al., 2005). Design options for phase 4 studies include case-control studies and cohort studies.

CLINICAL TRIAL PROTOCOL DEVELOPMENT

The design of protocols for the evaluation of candidate vaccines requires consideration of the pathogen, the disease pathogenesis and immune response profile, and the characteristics of the vaccine candidate itself. The success of a clinical trial will depend on implementation of a well-designed protocol, followed by careful monitoring and retention of subjects, close adherence to the protocol, and accurate reporting and documentation of observations made during the trial (for Comprehensive discussions, see Chow and Liu, 2004; Meinert, 1986; Wang and Bakhai, 2006).

A brief outline of essential elements for inclusion in clinical trial protocols is shown in Table 12.2. A detailed template for protocol development has been prepared by the National Institute of Allergy and Infectious Diseases that can be used to guide protocol development (NIAID, 2006). Novel constructs such as live, attenuated vaccines may require additional discussion of risks and special facilities for isolation, such as the evaluation of live attenuated vaccines based on potential pandemic influenza viruses. Note that the basic protocol elements are mirrored in the Informed Consent document.

Background and Rationale

The background and rationale should provide information regarding the current understanding of the disease epidemiology, pathogenesis, and immune responses relevant for protection against infection; and need for development of control measures. The

scientific rationale for selection of the vaccine candidate should be discussed. A concise description of the study agent should be provided, including summaries of preclinical studies and relevant clinical studies. Finally, potential risks and benefits of immunization with the investigational agent should be delineated.

Objectives and Purpose

The objectives and purpose of the trial should be clearly and explicitly stated. For phase 1 trials, the primary objectives will be to assess the safety, tolerability, and reactogenicity of a vaccine, whereas assessment of immunogenicity is a secondary objective. For combined phase 1/2 and phase 2 clinical trials, safety and immunogenicity may be coprimary endpoints. Exploratory endpoints may also be included, such as the effect of age, race, or gender on immune responses (Keitel et al., 2006). Combined phase 1/2 trials may be proposed when the vaccine candidate represents a variant of a previously licensed construct, such as a subvirion influenza vaccine for prevention of avian influenza (Treanor et al., 2006). Efficacy and safety typically are the primary endpoints for phase 3 trial.

Study Design

The study design then should be described. For clinical trials of candidate vaccines, the study design typically is a randomized, double-blind, controlled clinical trial—one example of a parallel group design. Phase 1 safety and tolerability studies often utilize a titration design, where ascending dosages of the experimental agent are sequentially administered to new cohorts of subjects (Gorse et al., 2006). Cluster-randomized clinical trial design is occasionally employed to assess vaccine efficacy. In this circumstance, larger groups of individuals (such as nursing homes or schools) are randomized to an intervention, rather than individual subjects, and the clinical endpoints are ascertained for vaccinated subjects (Rodrigues et al., 2005), or for a subset of the cluster, such as the contacts of healthcare workers in a closed setting (Hayward et al., 2006). Phase 1 clinical trials historically were open-label; however, in recent years most phase 1 clinical trials of vaccines have been randomized and blinded. The value of a placebo control in clinical trials has been described; however, a licensed control vaccine may be used rather than a placebo, particularly for phase 3 clinical trials in children. In a recent phase 3 clinical trial of pneumococcal conjugate vaccine in infants, a meningococcal type C vaccine served as the control vaccine (Black et al., 2000). In this case, the meningococcal control vaccine provided potential benefits to the study participants. Flexible adaptive design methods frequently are employed in the development of vaccines; these incorporate plans for modifications of the clinical trial design that are made before or during the conduct of the research (Chow and Chang, 2007). Adaptations to ongoing trials may include prospective adaptations, such as interim analysis, stopping rules for early termination due to futility/safety concerns/efficacy, or sample size re-estimation; ad hoc adaptations such as changes in inclusion and exclusion criteria, dosage or regimen alteration, and trial duration; or retrospective adaptations at the end of the study but before unblinding, including changing the study endpoint or altering the statistical hypothesis (superiority to noninferiority). The goal of this approach is to permit modification based on accumulated evidence to alter trial design to increase the probability of success without undermining the validity of the trial (Gallo et al., 2006). Such adaptations may require modifications of the study hypotheses, protocol amendments, and sample size recalculations.

Clinical trials are also classified as single-center or multicenter studies. Phase 1 studies often are single-center studies; however, multicenter trial design may be used for any phase of clinical vaccine development. Multicenter study design provides several advantages: enrollment of subjects is expedited, and the results of the trial are likely to be more generalizable.

Study endpoints need to be clearly identified. For phase 1 trials, safety, tolerability, and reactogenicity primary endpoints may include the frequencies and severities of injection site reactions (pain, tenderness, redness, and swelling) and systemic reactions (fever, chills, headache, myalgia, arthralgia, etc.), as well a laboratory evidence of adverse reactions (hematologic, biochemical, and other). For phase 2 clinical trials, specific immune responses at defined time points after immunization typically characterize the primary endpoints; safety and reactogenicity may be primary or secondary endpoints. For phase 3 clinical trials, protection against laboratory-confirmed infection and/or disease is the primary endpoint, and the major safety assessment may be the frequency of SAEs associated with administration of the investigational agent.

Study Population

A detailed description of the proposed study population and the number of subjects to be studied must be provided; specifically, characteristics (age range,

health status, ability to provide informed consent, etc.) of potentially eligible persons (Inclusion Criteria) and factors that would render an individual ineligible (Exclusion Criteria) should be explicitly enumerated. For some phase 1 trials, screening for eligibility may include medical history, physical examination, and laboratory screening for evidence of good health (normal hematologic and biochemical parameters, and no evidence of active hepatitis B, hepatitis C, or HIV infection). Information regarding serosusceptibility to the candidate pathogen may be necessary. For example, a phase 1 clinical trial of a dengue virus vaccine may require evidence of no prior infections caused by these viruses (Edelman et al., 2003), and a phase 1 or 2 clinical trial assessing the immunogenicity of LAIV may focus on persons with low or absent levels of preexisting immunity to the candidate vaccine (Keitel et al., 1993b). For phase 3 clinical trials, it is necessary to identify a population in which the infection or disease occurs at a high enough frequency to assess the ability of a vaccine to protect. For example, pivotal phase 3 trials of an inactivated hepatitis A vaccine were conducted in specific US communities where the rate of hepatitis A infections in children was high (Werzberger et al., 1992).

Human subjects considerations may include a description of certain behaviors and/or concomitant medications that would exclude a subject. For most clinical trials of vaccines, women who are capable of bearing children must consent to certain birth control measures. The US Department of Health and Human Services (DHHS) has published a guidance regarding research in pregnant women: for research conducted in this population, there must be direct benefit to the woman or her fetus or there must be only minimal risk to the fetus, and information cannot be obtained any other way. For many phase 1 clinical trials, use of prescription medications is not permitted. Clinical trials of vaccines that potentially could be transmitted to others in the community raise special concerns. Recent reevaluations of smallpox vaccines posed concerns with regard to transmission of the vaccine virus from subjects to their contacts (Frey et al., 2002). In this case, persons who had household or other significant contacts with young infants, people with eczema, pregnant women, and immunocompromised individuals were excluded from participation.

The methods for test article allocation should also be described. For most phase 1 and phase 2 clinical trials of vaccines, the subjects are randomized to receive one of several dosage levels of vaccine or placebo. Ideally, randomization should not occur until the subjects have been qualified for participation. Typically the randomization occurs in blocks of a prespecified number that represents a multiple of the number of test articles. For example, if there were four dosage levels of vaccine and a placebo, then the block size might be 5, 10, or 15. If the block size chosen were 5, then the subjects would be randomized 1:1:1:1:1. Block randomization can reduce the risk of unequal group sizes. In some circumstances the probability of receiving one product differs from the probability of receiving another. For example, in an efficacy study to be conducted in children, an investigator may wish to reduce the number of subjects randomized to receive the placebo, and the randomization scheme selected may be 2:1 (vaccine:placebo). The vaccine group assignments for subjects should be concealed from the subjects and from investigators to reduce bias in the assessments performed after vaccination (so-called double blinding). Additional measures can be taken to reduce the potential for imbalances in baseline characteristics of enrolled subjects, such as stratification of subjects according to age, prior receipt of a related vaccine, etc., prior to randomization.

Study Agent/Interventions

The clinical trial protocol should contain basic information regarding the characterization of the vaccine formulations—including dosage(s), packaging, labeling, storage; preparation, administration, dosing, and accountability methods for each study product, including placebo and/or control preparations. More complete descriptions of study vaccines, including manufacturing information, preclinical and clinical safety, immunogenicity, and efficacy should be provided separately in the Investigators' Brochure (IB). Information regarding the use of concomitant medications, including prohibited medications, should be detailed. For example, during phase 1 clinical trials concomitant use of prescription medications may be prohibited. During phase 2 clinical trials, concomitant use of certain medications may be allowed, such as antihypertensive medications or antidepressants. In general, concomitant use of immunosuppressive, immunomodulatory, or cytotoxic drugs would be prohibited in any clinical trials of live attenuated vaccines.

Study Procedures and Evaluations

A description of the proposed clinical evaluations then follows. In phase 1 or 2 clinical trials, detailed and frequent physical assessments of the injection site and systemic responses may be indicated, as well as review of subject records of clinical responses following

immunization. The intensity of study assessments will vary according to the nature of the study product: more frequent and detailed assessments would be indicated for novel products whose safety profile is undefined. Periodic collection of blood, nasal, fecal, or other samples to assess for the occurrence of toxicity, or to determine the frequency, magnitude, and/or duration of shedding of a live vaccine candidate may also be indicated (Piedra et al., 1993; Taylor et al., 1997). These laboratory assessments should be tailored to the particular needs of the protocol, and should be based on the pathogenesis of the disease, the vaccine under evaluation, and information collected in the pre-IND stage. Brief descriptions of the type(s) of specimens to be collected, methods for specimen collection, preparation, handling, storing, and shipping (if applicable) should be outlined; detailed procedures should be provided in a separate Manual of Procedures (MOP) for each study. For phase 3 trials, clinical follow-up is specifically targeted at ascertaining whether the vaccine prevents infection or disease and capturing the occurrence of SAEs; however, limited prospective safety assessments may be included (perhaps only in a subset of subjects) to expand the safety database (Oxman et al., 2005).

Study Schedule

Once the specific clinical and laboratory procedures for assessing safety, immunogenicity, and/or efficacy have been described, a detailed study schedule indicating the timing of various assessments/procedures/interventions should be outlined, including those that will be conducted at screening, enrollment, and each follow-up visit. Clinical assessments and laboratory procedures that should be completed in the event the subject's participation in the trial is terminated early should be described, as should those for women who become pregnant during the study. Finally, a description of clinical and laboratory assessments to be performed in the event the subject returns for an unscheduled visit (for example, for a severe vaccine reaction) may be appropriate. A summary table or figure outlining study procedures is particularly useful.

Assessment of Safety

As described above, the clinical trial protocol should detail the specific safety parameters that will be monitored during the course of the trial, along with the methods and timing for their assessment and reporting. Standardized definitions for AEs and SAEs have been formulated (FDA, 1996): an AE is defined as any untoward medical event that occurs in a subject who has received a study agent. SAEs include death, life-threatening events, hospitalization or prolongation of hospitalization, congenital anomalies, and events that result in permanent disability. Each AE and SAE that is recorded should be assessed for its severity and relationship to vaccination. The grading of AEs is usually based on the interference with activity, where 1 = mild, does not interfere with usual activities; 2 = moderate, interferes somewhat with usual activities; and 3 = severe, incapacitating. The severity grading system of laboratory abnormalities should be established before the initiation of the trial. The FDA has suggested guidelines for toxicity grading scale for healthy adults and adolescents enrolled in vaccine clinical trials (FDA, 2007b).

Contemporary standards for assessing the relationship of the AE to immunization have narrowed the choices to "associated" and "not associated." All AEs that are temporally related to administration of the investigational agent and have no alternative etiologies to explain the event are considered associated. SAEs should be reported promptly to the sponsor; in turn, the Sponsor must notify the FDA in a timely fashion.

Prospective guidelines for discontinuation of individuals from further vaccinations, as well as halting rules for the clinical trial should be outlined. Typical circumstances for discontinuation of an individual include severe and/or hypersensitivity reactions following immunization, development of an Exclusion Criterion during the trial, and failure or inability of the subject to comply with study procedures. Note that every attempt should be made to continue to follow these subjects for safety assessments. Rules for halting a phase 1 clinical trial may include the occurrence of one or two hypersensitivity reactions or SAEs associated with the investigational agent or the occurrence of moderate or severe reactogenicity among a predefined proportion of subjects.

Finally, the safety oversight plan should be described. For single-center trials or other small clinical trials, a Safety Monitoring Committee (SMC) consisting an Independent Safety Monitor (ISM) from each site and an independent member with expertize relevant to the protocol has the responsibility to review trial results periodically and on an ad hoc basis, and to make recommendations to the Sponsor regarding the conduct of the clinical trial. For larger, multicenter trials, a Data and Safety Monitoring Board (DSMB) consisting of site ISMs and individuals with clinical and statistical expertize relevant to the protocol is constituted to review study progress and advise

the Sponsor. The SMC or DSMB may recommend terminating a trial because of unexpected or severe toxicity; continuation of a trial after review of AEs that triggered halting rules; alteration of sample size based on interim analyses; or any other protocol modifications that are deemed necessary to complete the trial successfully.

Clinical Monitoring

A clear plan for monitoring the conduct of the clinical trial site(s) should be outlined in the study protocol. Specific objectives of site-monitoring visits are to review all study documentation to ensure protection of human subjects; compliance with GCP, clinical and laboratory procedures, test article administration and accountability guidelines; and accurate and complete data collection and documentation. The Sponsor may conduct monitoring visits, and may also designate an independent Contract Research Organization (CRO) to conduct monitoring visits on a regular basis throughout the trial. Early monitoring visits can be particularly valuable in order to identify systematic, unintentional deviations from the protocol.

Statistical Considerations

A detailed Statistical Analysis Plan (SAP) should be prepared that restates the study hypotheses, objective and endpoints, describes the statistical basis for the sample size selected, and outlines the methods that will be used to analyze safety and efficacy. If interim analyses are planned, then the statistical issues related to this should be discussed.

Quality Management

The clinical trial site is responsible for protocol compliance and accurate and complete data collection and recording. In a separate document, site-specific Standard Operating Procedures (SOPs) should outline the methods that will be used to ensure that these activities are accomplished, as well as methods to ensure appropriate training of the study staff. The overall quality management plan should be described in the protocol.

Ethics/Protection of Human Subjects

A description of the ethical standards that will be followed to ensure protection of human subjects should be described: in the US, compliance with 45 CFR Part 46 and ICH E6 GCP is expected. The protocol should indicate that no research (including screening) will begin until the protocol and the consent form have been IRB-approved. The consent process should be described, as should the provisions for subject confidentiality. The Health Insurance Portability and Accountability Act of 1996 (HIPAA) was enacted to improve portability and continuity of health insurance coverage; nevertheless, it contains regulations that have direct relevance for clinical research (DHHS, 2007). For example, informed consent documents are required to include extensive information on how the participant's protected health information (PHI) will be kept private. Administrative, physical, and technical safeguards must be adopted to ensure the security of electronic PHI. Finally, special issues related to exclusion of special populations (women, minorities, and children) should be addressed.

Data Management and Record Keeping

The goals of data management are to ensure the accuracy, completeness, and timeliness of clinical trial data collection. While the primary responsibilities for data collection rest with the clinical trial site, additional oversight and data management responsibilities (quality review, analysis, and reporting) may be shared with the sponsor and a data coordinating center (DCC). The organizational structure of data management should be described in this part of the protocol. Data capture methods and internal quality checks, types of data, timing of reports, study records retention, and identification of protocol deviations and corrective actions should be addressed here, as well as in greater detail in the MOP.

Other Considerations

In addition to the major protocol elements described above, a full protocol should include a title page, a statement of compliance with GCP, and other regulatory guidelines, a signature page, a table of contents, a list of abbreviations; a protocol summary; a list of key personnel and their roles, a description of unique facilities, if applicable, a list of references, publication policy; and appropriate appendices. A list of essential documents that should be on file before the trial starts is shown in Table 12.3; additional documents should be added to the trial documentation as new information becomes available (protocol amendments, updates, IRB approvals, training certificates, CVs, screening and enrollment logs, test article accountability and shipment logs, monitoring reports, consent forms, source documents, CRFs, communications with the sponsor, etc.).

TABLE 12.3 Checklist of essential documents on file at the clinical trial site before the clinical trial begins

Signed full clinical trial protocol, and amendments, if applicable
Sample case report forms (CRFs)
IRB-approved informed consent document
Investigators' brochure
Manual of procedures (MOP)
Information that will be given to subjects
Recruiting materials (text of advertisements, flyers, etc.)
IRB approval letter
Copy of IRB/IEC Federal Wide Assurance
Composition of IRB
FDA Form 1572 (Principal Investigator Responsibilities)
Curriculum vitae of participating investigators
Financial disclosures; other clinical trial agreements
Copy of the principal investigator's medical license
Laboratory credentials/certifications
Laboratory reference ranges
Sample labels for investigational product
Instructions for handling investigational product and other trial materials
Shipping records for trial-related materials
Clinical trial site initiation monitoring report

CONCLUSIONS

The success of any clinical trial hinges on the development of a carefully designed protocol. Although discussion of clinical trial implementation is beyond the scope of this chapter, it is clear that the protection of human subjects and scientific integrity of the trial design and documentation are the overarching goals of any clinical research protocol. The clinical trial protocol must document the processes that will be used to ensure that these goals are attained. Conscientious supervision of clinical trial activities is a shared responsibility of the investigators, the IRB, the sponsor, the CRO, the DCC, the safety oversight committee, and all other partners who are participating in the trial. While meticulous attention to detail and strict protocol compliance are essential, the entire study team must be flexible and prepared to respond in a timely fashion to unexpected findings. Novel approaches to the development of vaccines for biodefense and emerging and neglected diseases will continue to evolve and will require ongoing reconsideration of the ethical and regulatory principles and practices that guide the conduct of clinical trials.

ACKNOWLEDGMENTS

I gratefully acknowledge Dr. Robert Atmar and Connie Rangel, R.N., for their thoughtful reading of the manuscript, and Yvette Rugeley and Michelle Thomas-Sturm for assistance with manuscript preparation.

OUTLINE

ABSTRACT

Vaccines provide the most effective means of preventing potentially serious infectious diseases and play a critical role in public health management. Vaccines are regulated in the United States by the Office of Vaccines Research and Review in the Center for Biologics Evaluation and Research of the Food and Drug Administration (FDA). To conduct a human clinical trial of a new vaccine, the sponsor of the trial must submit an original Investigational New Drug Application (IND) to the FDA. The required content of an original IND is described in the Code of Federal Regulations. The IND provides the Agency with detailed information pertaining to the manufacture and testing of the vaccine to demonstrate its identity, safety, purity, potency and other quality attributes, the preclinical studies conducted in animals to establish the safety of the product, and the protocol for the proposed clinical study. The FDA will assemble a team of experts to review the information in the IND and determine whether the new vaccine is sufficiently safe for administration to human subjects. Sponsors can increase the likelihood of receiving a positive review decision from the Agency by ensuring that the original IND is detailed and complete, and addresses any potential safety concerns associated with the investigational product. Many resources are available to assist sponsors in the preparation of a successful IND. Numerous guidance documents have been issued by the FDA and other regulatory authorities that summarize FDA and worldwide expectations for the manufacture, testing, and clinical evaluation of specific product types. Most importantly, sponsors have the opportunity to meet with members of the FDA review staff via a formal "pre-IND" telephone conference (meeting) to seek specific guidance from the Agency regarding their product development plans. Optimally, the pre-IND meeting establishes a working relationship between the sponsor and the FDA that facilitates ongoing dialogue leading up to the IND submission and throughout the product development life cycle. After the submission of the original IND and initiation of clinical studies, communication with the FDA is primarily maintained through the submission of IND amendments, such as new clinical protocols, safety reports, or updated manufacturing information. Regulations also provide for additional meetings between the sponsor and FDA at prescribed points in product development, and at other times if issues arise that require detailed discussion. Ongoing communication with the FDA is an essential element of product and clinical development, and provides the most efficient mechanism to meet all regulatory requirements for product approval in the shortest possible time frame.

INTRODUCTION

The submission of an original Investigational New Drug Application (IND) to the US Food and Drug Administration (FDA) represents the first step under the US regulatory process toward evaluation of a new drug, biologic product, or vaccine in a human clinical trial. The original IND application provides all of the data and other information necessary for the FDA to assess the safety of an investigational product for administration to human volunteers. As product development progresses to more advanced clinical studies, the FDA will maintain regulatory oversight "to assure the safety and rights of [clinical trial] subjects" and "to help assure that the quality of the scientific evaluation of drugs is adequate to permit an evaluation of the drug's effectiveness and safety" (Code of Federal Regulations, Title 21, Part 312.22).

Deliberate and clear communication with FDA will result in the most streamlined and cost-effective development program with the greatest assurance of a successful outcome. The purpose of this chapter is to provide an overview of the IND process for sponsors of investigational vaccines, as well as to provide helpful hints to facilitate effective communication with the FDA.

REGULATORY OVERVIEW

FDA Regulations

An IND application must be submitted to the FDA for review and approval before the initiation of the first clinical study of a novel investigational drug or vaccine. The content of an original IND application and the sponsor's obligations throughout the IND process are described in the US Code of Federal Regulations, Title 21, Part 312 (21 CFR 312). In legal terms, the IND is a request for an exemption from the federal statute that prohibits an unapproved drug product from being shipped in interstate commerce. Practically, the IND provides the Agency with a complete description of the investigational product, including the results of any proof of concept studies justifying its evaluation in human subjects, the methods for product manufacture and analytical testing, the results of nonclinical safety studies in animals, and

proposals for the clinical investigations planned in the first year of product development.

The majority of investigational products are developed through the submission of a routine or "commercial" IND. Typically, the entities that submit, or "sponsor," a commercial IND are pharmaceutical or biotechnology companies, or individuals or organizations with the intent that the investigational product will be commercialized. In addition to pharmaceutical or biotechnology firms, individual clinical investigators can sponsor an IND. The sponsor-investigator IND is subject to the same regulations as a commercially sponsored IND, but differs in that the investigator assumes the responsibilities of both the sponsor and the investigator, as defined in 21 CFR 312.3.

The sponsor of an IND need not have the intention to commercialize the investigational product in the United States. In fact, FDA has recently issued guidance to clarify its position that, for vaccines intended to treat global infectious diseases, submission of an IND application is encouraged regardless of the intended target population for the licensed vaccine. Specifically, "FDA encourages submission of an IND so that it can provide input on manufacturing, quality testing, assay validation, non-clinical and clinical trial design issues, statistical analysis plans, endpoints, and other important aspects of vaccine development. The IND process will allow sponsors to obtain important scientific and regulatory advice on products that are critical to the advancement of world health" (FDA Guidance for Industry, September 2008).

One exception to the regulatory IND requirements outlined above is provided by the Project Bioshield Act of 2004. The Act amended the Food Drug and Cosmetic Act to permit the introduction into interstate commerce of an unapproved drug, device, or biological product for use in an actual or potential emergency (Emergency Use Authorization, or EUA). In the event that there is a government determination of an emergency, or the potential for an emergency, due to exposure to a specific biologic, chemical, radiological, or nuclear agent with the potential to cause a serious or life-threatening disease or condition, the FDA may issue an EUA for a specific product or products. A product may be eligible for EUA if it is reasonable to believe, based on the scientific evidence available, that the product may be effective in treating the disease or condition, the known and potential benefits outweigh the known and potential risks, and there is no adequate, approved, and available alternative to the product for treating the disease or condition. FDA's guidance on "Emergency Use Authorization of Medical Products" was issued in September 2007.

FDA regulations include multiple elements to facilitate the development and licensure of high priority products intended to treat or prevent serious or life-threatening diseases or conditions. For example, a sponsor may seek, and FDA may grant, "fast track" designation for a specific product development program (FDA, 2006). Fast track designation entitles the sponsor to early and frequent communication with the FDA throughout product development, in order to optimize the design of Phase 2 and Phase 3 clinical studies, and expedite the resolution of any product development issues that may arise. Such products may receive "priority review" status at the time of Biologics License Application (BLA) submission which provides for a shorter, 6-month review of the license application, rather than the standard 10-month review clock. In addition, the license application may utilize a "rolling submission" process, in which sections of the application may be submitted sequentially rather than all at once.

The regulations governing licensure of biologic products (21 CFR 601) provide for approval of certain products intended to treat serious or life-threatening illnesses for which clinical efficacy data cannot readily be obtained (e.g., a vaccine for a potentially pandemic influenza virus strain). At its discretion, FDA may approve such a product based upon a surrogate endpoint (such as immunogenicity) that is reasonably likely, based on existing evidence, to predict clinical benefit. Accelerated approval may include a stipulation that the applicant "study the biological product further [in post-approval studies] to verify and describe its clinical benefit" (21 CFR 601.41). In addition, certain products intended to treat or prevent "serious or life-threatening conditions caused by exposure to lethal or permanently disabling toxic biological, chemical, radiological, or nuclear substances" (21 CFR 601.90) for which human clinical efficacy studies are not ethical or feasible, may be approved under the "animal rule." In this case, reasonable evidence of clinical benefit may be provided by the results from animal studies, where the animal species can be justified to provide an adequate model of the human response to both the toxic substance and the investigational biologic product. FDA has recently issued a concept paper to identify the critical characteristics of an animal model necessary for efficacy evaluation under the Animal Rule (FDA Concept Paper, September 2008).

FDA Organization and Review Responsibility

The FDA includes two centers of expertise with responsibility for review of IND applications. The

Center for Biologics Evaluation and Research (CBER) reviews applications pertaining to therapeutic and prophylactic vaccines, blood and blood products, and tissue, cellular and gene therapy products, while the Center for Drug Evaluation and Research (CDER) has primary responsibility for review of therapeutic drug and biologics applications.

CBER is organized into the following offices: the Office of Vaccines Research and Review (OVRR), the Office of Blood Research and Review, and the Office of Cellular, Tissue and Gene Therapies. Within the Office of Vaccines Research and Review, there is a discreet applications division, the Division of Vaccines and Related Products Applications (DVRPA) that is responsible for receiving IND submissions, routing the submissions for review and corresponding with the IND sponsor. An original IND submission will be routed to a specific project manager within DVRPA who will serve as the primary point of contact for the sponsor during the IND review and throughout the subsequent period of product development.

Guidance Documents

A variety of guidance materials are available to assist sponsors with the submission of an original IND. CBER makes available an "IND packet" that provides applicable regulations, forms, and articles helpful in the preparation of original INDs. These and other guidance materials may be obtained from CBER's Office of Communication, Training and Manufacturers Assistance (OCTMA), which is an office dedicated to providing general guidance and information to individuals and organizations interested in the regulatory process. FDA guidance is also available on the internet and may be accessed by visiting the FDA (http://www.fda.gov/) or CBER (http://www.fda.gov/cber/index.html) home pages and following the links for guidance documents. IND guidance from the OCTMA is available at http://www.fda.gov/cber/ind/ind.htm.

In addition to guidance materials for the IND submission process, the FDA has issued a wide variety of guidance documents pertaining to product manufacture, analytical testing, preclinical evaluation, and clinical trial design for vaccine products. The International Conference on Harmonization or ICH (an organization dedicated to the harmonization of regulatory requirements between the United States, Europe, and Japan) has also developed guidance documents in these areas, many of which have been adopted as official guidance of the US FDA. Links to FDA guidance documents pertaining to vaccine development can be found on the CBER website (http://www.fda.gov/cber/vaccine/vacpubs.htm), while current ICH guidelines may be downloaded from the ICH website (http://www.ich.org/cache/compo/276-254-1.html).

COMMUNICATIONS WITH THE FDA

Meetings and Teleconferences

To facilitate effective and timely communications regarding the development of investigational products, FDA will participate in certain meetings and telephone calls with IND sponsors. There are three basic types of meetings that can be requested by an IND sponsor. The Type A meeting is requested when a sponsor feels the development of their product or clinical program has been "stalled," and they require urgent input from the Agency in order to proceed. The Type A meeting must be scheduled by FDA within 30 days after the receipt of the formal written request for such meeting. Type B meetings are routine meetings that may be requested at critical milestones during the clinical development of an investigational product (21 CFR 312.47). The pre-IND, the End of Phase 2, and the pre-BLA meetings are all classified as Type B meetings. Type B meetings must be scheduled within 60 days after FDA receives the request for a meeting. The Type C meeting is reserved for less time-critical issues and must be scheduled within 75 days after FDA receives the request for a meeting. The FDA Guidance for Industry document entitled, "Formal Meetings with Sponsors and Applicants for PDUFA Products" (February 2000) provides detailed instructions for requesting, scheduling, conducting, and documenting these meetings.

Pre-IND Meeting or Teleconference

To facilitate submission of a successful IND, the FDA will conduct formal meetings with sponsors referred to as "pre-IND meetings." As mentioned previously, the pre-IND meeting is a Type B meeting and is discussed in more detail below. It should be noted that in recent years the OVRR will grant pre-IND telephone conferences, but will rarely grant face-to-face meetings due to limited time and resources. However, sponsors are encouraged to request a face-to-face meeting with the Agency if they feel the scientific, clinical, or regulatory issues surrounding their new vaccine warrant this type of interaction.

The pre-IND teleconference should be used by sponsors to discuss any product, nonclinical, clinical,

or regulatory issues that the investigational vaccine may present. If a sponsor would like to request a pre-IND teleconference, they should follow the FDA meeting request guidance document mentioned above (February 2000) and refer to the SOPP 8101.1 issued by CBER. These documents describe exactly what is required for a written request for a meeting or teleconference with the Agency and outline the format for the request. Note that the Agency can deny a request for a meeting if the sponsor's written request is incomplete.

Most importantly, the meeting or teleconference request should include a statement of purpose of the meeting and a draft of a list of questions that the sponsor wishes to discuss with the Agency. This means that, before making a pre-IND meeting request, the sponsor should be able to identify the key issues for which guidance or concurrence from the Agency are necessary before submission of the IND.

The sponsor should prepare and submit a briefing document at least 4 weeks in advance of the scheduled teleconference date. Depending on the issues to be discussed, the briefing document may include background information on the product, its method of manufacture and analytical testing, preclinical testing completed and/or planned, and a brief outline of the proposed clinical trial (discussed below). A list of questions critical to further product development and the initial clinical trial(s) should be included in the briefing document for Agency review and consideration. The allotted time for the meeting or teleconference may be from 1 to 2 h. Due to time constraints, sponsors are not usually permitted to make formal presentations at a meeting or have lengthy introductory remarks on a telephone conference. Therefore, emphasis should be placed on ensuring that the briefing document is clear, complete, succinct, and easy to navigate.

The FDA review team will make every effort at the pre-IND teleconference to provide responses to the questions submitted by the sponsor and will frequently advise the sponsor of information needed in the original IND submission. Typically, FDA representatives will include scientists with product, pharmacology/toxicology, and clinical expertise. Most importantly, the emphasis of the telephone conference should be on the questions and issues that the sponsor would like to address rather than on information already provided in the meeting materials.

It is now the norm that written responses to the questions posed in the briefing document will be supplied by FDA one or more days in advance of the scheduled telephone conference. It is recommended that the sponsor communicate to the FDA project manager their interest in receiving such written responses before the teleconference, if possible, as this will enable both the sponsor and the Agency to focus the meeting on those issues requiring further discussion. Upon forwarding their written responses to questions, the FDA will offer to cancel the teleconference if the responses are deemed satisfactory by the sponsor; however, it is recommended that the sponsor proceed with the call in order to discuss any issues requiring clarification. In addition, the pre-IND call provides an opportunity for the sponsor to "meet" the FDA reviewers and to potentially obtain additional useful advice. Sponsors are encouraged to submit a meeting summary describing their understanding of the FDA's comments and recommendations to the pre-IND file. The FDA will issue an official record of the meeting in the form of meeting minutes within 30 days after the meeting date.

End of Phase 2 Meeting and Special Protocol Assessment

For investigational products with the potential to treat or prevent a serious or life-threatening disease, the sponsor may request an "End of Phase 1" meeting (see section Other Meetings with FDA1 below). More typically, however, the next Type B meeting occurs after the completion of Phase 2 studies when the pivotal Phase 3 studies are being planned. This "End of Phase 2" meeting is held to: (1) determine the safety of proceeding to Phase 3 efficacy studies; (2) evaluate the Phase 3 plan and protocol(s) (a well-written draft protocol is sufficient); (3) identify any additional information necessary to support a license application, such as additional nonclinical safety studies; and (4) discuss relevant product issues, such as plans for manufacturing scale-up to produce product for commercial sale and the need for comparability testing relative to the product used in earlier Phase 1 and Phase 2 clinical studies. It may be necessary to schedule a separate meeting to address all of the product-related issues for Phase 3 and future commercial manufacture (FDA Guidance for Industry, May 2001).

Another important issue to be discussed at the End of Phase 2 meeting is whether a Special Protocol Assessment (SPA) agreement is appropriate for the Phase 3 pivotal study program. SPA, implemented in 1997, allows for a "binding agreement" between the sponsor and FDA that the design, endpoints, conduct, statistical analysis plan, and other details of the Phase 3 protocol(s) will be adequate to support efficacy claims for the vaccine being tested. The formal process for requesting and obtaining a SPA is described in the FDA Guidance for Industry entitled, "Special Protocol Assessment," issued in May 2002.

Pre-BLA Meeting

The pre-BLA meeting is held after the completion of Phase 3 efficacy studies and prior to the submission of a license application. This is a very important meeting for sponsors as it affords the opportunity to present the FDA with a complete overview of the proposed contents of the planned license application and to obtain guidance from the Agency regarding the information that will be sufficient to support filing of the BLA and Agency review of the license application. The meeting should be used to discuss all safety and efficacy data from clinical trials, potential post-approval obligations of the sponsor, product release specifications, stability data to support expiration dating, and the claims and indication statement in the vaccine product label.

Although the required contents of a BLA are stipulated by regulation in 21 CFR 601.2, the organization and format of a BLA most often follows the outline of the "Common Technical Document," or "CTD." The CTD was developed by the ICH to provide a common format for license applications to the United States, Europe, and Japan. Its use is not yet mandatory for license applications submitted to CBER but is strongly preferred by the Agency. The sponsor's plans for organizing the content of the application (traditional BLA format or CTD format) and the submission type (paper vs. electronic) should be discussed at the pre-BLA meeting.

The results of pivotal efficacy and safety studies will be presented at the pre-BLA meeting and the adequacy of these data to support the intended label claims will be discussed. The sponsor's plans for analysis and formatting of the integrated clinical data for submission in the license application should also be presented for Agency review and comment. As a result of these discussions, additional analyses or specific data tabulations that are critical to review of the application may be requested by the Agency.

The Pediatric Research Equity Act of 2003, as amended in 2007, requires that license applicants submit with their application either an assessment of the safety and efficacy of the investigational product in the pediatric population, an agreement from FDA for deferral of such studies until a specified date after license approval, or a full or partial waiver of the pediatric research requirement due to the specific nature of the product and/or indication. If the sponsor wishes to defer pediatric studies to the post-licensure period (or obtain a full or partial waiver), this plan should be discussed with the FDA at the pre-BLA meeting. The Agency's concurrence with the pediatric research plan as captured in the formal minutes from the meeting should be submitted as evidence of the agreement at the time of BLA submission.

The pre-BLA meeting is also an appropriate time to discuss plans for any post-approval clinical study or studies that will be performed as an element of a pharmacovigilence plan for the new vaccine. Frequently, observational studies are conducted post-licensure to obtain confirmatory evidence of efficacy under conditions of actual use, and an enhanced understanding of safety, including rare adverse events. For certain products with known or potential risks based on nonclinical or clinical studies or safety information for related products, appropriate strategies for risk minimization in the post-licensure period should be discussed (see FDA Guidance for Industry, Development and Use of Risk Minimization Action Plans [RiskMAP], March 2005).

The pre-BLA meeting is a critical meeting for discussion of any issues related to the transition from clinical to commercial manufacture. Any changes in the manufacturer, facility, or equipment that accompany the scale-up from the Phase 3 process to the commercial process should be presented, and the appropriate approach to establishing the comparability of the Phase 3 and commercial products should be discussed. Other topics may include the final specification for release of commercial product, the procedure for lot release by CBER, and the timing of the Pre-Approval Inspection of the manufacturing facility or facilities.

Finally, the pre-BLA meeting may be used by the sponsor to obtain clarification as needed of the regulatory procedures for submission, filing, and review of license applications in BLA or CTD format, including information related to electronic applications (eBLA or eCTD) if the sponsor plans to submit electronically.

Other Meetings with FDA

Other meetings (Type A and Type C) may be requested during the IND process. However, due to time and resource limitations, CBER will determine whether or not a face-to-face meeting is required to address the issue(s) under consideration. Examples of such issues include major changes in the manufacture or testing of product that require CBER input, major changes in clinical investigational plans, or major changes in protocol design or statistical analysis plans. Often, telephone conversations are adequate to address these issues, and can circumvent the need to expend resources on a face-to-face meeting.

Certain products with the potential to treat or prevent serious or life-threatening disease, or products identified for priority development as medical

countermeasures to a bioterrorist attack, are eligible for additional meetings with FDA in order to accelerate the path to licensure. As mentioned previously, such products may be granted "fast track" designation which provides for regular and frequent communication between the sponsor and FDA throughout product development. An End of Phase 1 meeting is recommended for such products in order to discuss the design and scope of Phase 2 studies. Potentially, for high priority products, a well-designed and well-controlled Phase 2 study may provide sufficient data for licensure, with commitments to collect confirmatory information regarding the safety and efficacy of the product in post-approval studies.

Other Types of FDA Communication

The most important methods of communication used by CBER during the IND process are the clinical hold letter and the "non-hold" comment letter. A clinical hold letter is issued when FDA determines that insufficient information has been provided or a clinical study has been inadequately designed to ensure the safety of subjects participating in the trial (21 CFR 312.42). Even when no clinical hold is imposed for a protocol, comment letters may be provided and may be comprehensive. CBER reviewers will attempt to identify clinical and product manufacturing issues early enough in the IND process so that the sponsor can begin to make any changes or other plans necessary to support a potential license application. Extensive CBER comments should not necessarily be viewed in a negative light by the sponsor. If at any time during the IND process the sponsor does not understand a reviewer's comment or some aspect of the IND process, the sponsor should contact the IND project manager in order to discuss the most appropriate way to get advice or clarification.

THE CONTENT OF THE IND

The initial IND submission proposing the first Phase 1 study to be conducted with a new investigational product is referred to as an "original" submission. The FDA has 30 days in which to review the original IND and determine whether the investigational product is sufficiently safe for human clinical trials. Although during the life of an IND, FDA reviews all protocols submitted to determine their adequacy to demonstrate safety and effectiveness of an investigational product, the 30-day review of the original IND submission is the only waiting period required of sponsors. If FDA finds that the information provided in the original IND is not sufficient to ensure the safety of the clinical trial subjects, the IND may be placed on clinical hold, as discussed above. FDA will inform the sponsor of this decision, usually by telephone, within the initial 30-day review period, and will provide a written description of the issues that require resolution within 30 days following the imposition of the clinical hold. If, following the 30-day IND review period, the sponsor has not been notified of a clinical hold, the study may be initiated. Thus, for time-efficient and cost-effective product development, it is critical that the original IND contain all of the information necessary to establish the safety of the investigational product, the adequacy of the proposed clinical trial design, and the measures in place to protect the rights and safety of human subjects.

21 CFR 312.23 describes the elements specified by regulation to be included in an original IND. Each of these elements is listed in Table 13.1 and is discussed in detail in the paragraphs below. Although the regulations at 21 CFR 312.23 also prescribe the order in which each element should appear in the application, INDs are now also accepted in CTD format. The order of the IND elements in CTD format will differ modestly from that specified by the IND regulations as shown in Table 13.1. The CTD is discussed in more detail later in this chapter.

Form FDA 1571

Form FDA 1571 (1571) must accompany the original IND application and all subsequent submissions to the IND. This form serves as the cover sheet for the submission, and specifies the nature and contents of

TABLE 13.1 The elements of an Investigational New Drug Application

9	Previous Human Experience
10	Additional Information

the submission. The 1571 is also a legal document that must include the signature of the sponsor's authorized representative. For an IND that is sponsored by an organization or individual outside of the United States, the 1571 must be countersigned by "an attorney, agent, or other authorized official who resides or maintains a place of business within the United States" [21 CFR 312.23(a)(1)(ix)]. Either the sponsor (with US representative countersignature) or the US representative can sign the 1571. An electronic version of Form FDA 1571 and instructions for its completion are available on the FDA website at <http://www.fda.gov/opacom/morechoices/fdaforms/CBER.html>.

Form FDA 3674

With the passage of the FDA Amendments Act of 2007, a new requirement was placed on sponsors of Phase 2 or Phase 3 clinical trials to submit a summary of information about the trial to the public clinical trials registry previously established by the US National Institutes of Health (http://www.clinicaltrials.gov). Sponsors are further required to certify their compliance with the registration requirement by completing and submitting Form FDA 3674 with certain regulatory submissions. This form should be included in any original IND submission. Form FDA 3674 may be downloaded from http://www.fda.gov/opacom/morechoices/fdaforms/FDA-3674_508.pdf.

Table of Contents

An original IND application may consist of several volumes and hundreds of pages of information. Thus, a comprehensive Table of Contents is essential to aid navigation through the submission. Typically, the submission will include "free-standing" documents, such as study protocols or test reports, that are independently paginated. Serial pagination, with numbering from the first through the last page of the entire submission, provides a mechanism for both the sponsor and the FDA to unequivocally reference specific pages or documents within the IND. The comprehensive or serial page numbering should be added to each page, in addition to any pre-existing page numbers, and should be cited in the comprehensive Table of Contents.

Introductory Statement

The technical sections of the IND (e.g., the clinical protocol or the nonclinical study reports) will be reviewed and evaluated primarily by FDA experts within the relevant disciplines. The introductory statement is therefore important to provide the entire FDA review team with a brief orientation to the investigational product, including its composition and proposed use, and the broad objectives of the clinical studies that are proposed. According to 21 CFR 312.23(a)(3), the introductory statement should include the name and biochemical description of the investigational vaccine, the formulation and planned route of administration, a description of any previous human experience with the product, including investigational or marketing experience in other countries, and a brief statement of the overall plan for clinical studies during the first year.

General Investigational Plan

The general investigational plan should provide a brief description of the clinical studies planned for the investigational product through the first year. The rationale for the proposed studies and their objectives, as well as a brief description of the study design (e.g., blinded vs. unblinded, inactive or active controls to be used, number of centers and approximate number of subjects) should be provided. Any known or potential risks of particular severity or seriousness should be described. It would also be appropriate to include a description of the longer-term clinical development plan, beyond the first year of study, to the extent that this can be anticipated. The information provided in this section is particularly useful to help the reviewer anticipate the need for resolution of difficult issues well in advance of upcoming protocols, for example, if the product must be approved under the "animal rule" (21 CFR 601.90-95; Federal Register Notice, 2002) because clinical efficacy studies are either unethical or impractical. If a sponsor is considering applying for fast track designation, it is appropriate to indicate that intention in this section of the IND.

Investigator's Brochure

The Investigator's Brochure is an informational document that must be provided to each clinical investigator participating in a clinical trial of the investigational vaccine. The Investigator's Brochure provides all available information on the investigational product that will assist the investigator in the conduct of the study and in the assessment of expected versus unexpected adverse events. Information to be included in the Investigator's Brochure is described in the IND regulations [21 CFR 312.23(a)(5)]. The document should include a brief description of the product, a summary of the pharmacologic, toxicologic, and pharmacokinetic behavior of the product in animals (and in humans, if known), a summary of information relating to the safety and effectiveness of the product in humans obtained from prior clinical studies,

and a description of possible risks and side effects of the product. The ICH E6(R1) document, "Guideline for Good Clinical Practice" (June 1996), provides details on the appropriate content and structure of the Investigator's Brochure.

Although an Investigator's Brochure is provided to each clinical investigator before a clinical study is initiated, new observations regarding the product, particularly in regard to adverse effects, must be communicated to all participating investigators. Thus, regular revisions to the Investigator's Brochure are expected, and should be prepared and issued as needed, and at least on an annual basis if clinical trials are ongoing. The Investigator's Brochure should be updated before submitting and initiating additional clinical studies under the IND. The updated Investigator's Brochure should also be submitted to the FDA as an amendment to the IND.

Clinical Protocol

A complete clinical protocol must be included in the original IND submission. In most cases, the original submission contains a Phase 1 protocol in which the sponsor proposes to evaluate the safety of the investigational new product in a small number of healthy, young adult subjects (e.g., 18–40 years of age) and, for a vaccine, to obtain an initial indication of its immunogenicity in humans (Goldenthal et al., 2004). Dose escalation or dose-ranging studies may also be performed during Phase 1, if appropriate design elements, such as staggered enrollment and interim safety data review, are incorporated to ensure the safety of study volunteers.

Phase 2 and Phase 3 studies are designed to assess immunogenicity and efficacy (protection from disease), in addition to safety (Goldenthal et al., 2004). Phase 2 studies may be used to further assess the immune response to a vaccine, potentially evaluating alternative immunological endpoints, dose, schedule, or route of administration. Phase 2 studies may also provide information regarding the most common side effects (adverse events) associated with product use.

Phase 3 studies are pivotal safety and/or efficacy studies that will serve as the basis for licensure. In certain instances, an original IND submission may include a Phase 2 or Phase 3 protocol, for example, if earlier stage clinical trials were conducted outside of the United States under the oversight of a foreign regulatory agency. If the original submission contains a pivotal Phase 3 study protocol, it is strongly recommended that the sponsor contact CBER to arrange a meeting prior to submission of the IND (see discussion on meetings above). In addition, details of all completed clinical trials should be included in the IND under Section 9, Previous Human Experience (see Table 13.1).

It should be noted that the prospective design of clinical studies and the strategy for overall clinical development will differ for each vaccine. Thus, it is essential to formulate a product-specific development program that maximizes the data from each study and reduces the overall timeline to BLA submission.

A clinical protocol must be submitted to the FDA for each study to be conducted under the IND, and should describe the procedures by which the trial will be conducted. The elements of a clinical protocol can be found in 21 CFR 312.23(a)(6)(iii). At a minimum, a protocol should include a statement of the objectives and purpose of the study, the criteria for patient inclusion and exclusion, the approximate number of subjects to be enrolled, a description of the design of the study, including the use of control groups or blinding procedures, the plan for dose administration and the duration of individual patient exposure to the investigational product, a description of the parameters to be monitored during the study, and the plan for evaluating the data to asses the safety and activity of the investigational product in human subjects. Detailed guidance regarding the content and organization of clinical protocols is provided in the ICH E6(R1) document, "Guideline for Good Clinical Practice" (June 1996). A well-organized and complete protocol in the original IND submission will facilitate the FDA's review and will provide the best assurance that FDA will permit the clinical study to proceed following its initial 30-day review.

It is recommended that a sponsor prepare a clinical trial outline, or CTO, internally as an initial step in the preparation of a protocol. The CTO may be used to facilitate internal discussion regarding optimal protocol design and overall clinical development program planning. A brief description of the elements of a CTO is provided in Table 13.2.

Each clinical protocol submitted to an IND file is typically accompanied by one or more completed copies of Form FDA 1572, "Statement of Investigator." A 1572 form must be completed for each clinical investigator participating in the study. The purpose of the form, in part, is to provide the sponsor with verification of the investigator's qualifications and to obtain the investigator's commitment to adhere to the protocol and to pertinent FDA regulations governing clinical trials. Although submission of the 1572 form to the IND is not formally required, IND regulations under 21 CFR 312.23(a)(6)(iii)(b), require that clinical protocols include the information collected on the 1572 (including the name and address of the

TABLE 13.2 Clinical trial outline sections and contents

Section	Contents
Protocol Title	Title and protocol number of the study. The protocol number is helpful for communication purposes.
Investigator	Name of Principal Investigator for the overall study or Principal Investigator at each participating site.
Sites	List of all sites participating in the study.
Objectives	Primary and secondary objectives. Is the study intended to assess safety, immunogenicity, or efficacy? Is the study focused on a specific sub-population?
Rationale	Description of the phase of development (Phase 1, 2, 3, or 4) and how this study fits into the clinical development plan for the product. If the study is being conducted solely for scientific purposes, and will not be used to support licensure, the scientific rationale should be supplied.
Preclinical Data	Summary of all relevant animal studies, including a brief description of each protocol and the results. GLP, non-GLP, and proof of concept studies should be described.
Human Data	Summary of any previous human experience with the product from studies conducted under the same or different INDs, from studies not conducted under IND, or from post-marketing experience in other countries where the product is already licensed. Relevant clinical experience with related products may also be included in this section.
Study Design	Brief description of the study design, including treatment groups (active and control groups), randomization (including the method), blinding (open-label, single or double-blind), and phase of study (Phase 1, 2, 3, or 4).
Use of Investigational Product	Dose, schedule, and route/method of administration.
Controls	Description of control group, if any.
Subjects	Number, age, gender, and health status.
Entry Criteria	Inclusion and exclusion criteria.
Monitored Parameters	Description of all clinical, laboratory, and other parameters used to determine how safety, activity, and/or efficacy will be monitored. This should include those parameters determined at the screening/baseline visit as well as any follow-up visits. It is helpful to include a table that summarizes all monitored parameters for each clinic visit over the course of the study.
Endpoints	Description of the primary and secondary clinical endpoints that will be determined to address the objectives of the study (e.g., geometric mean titer of vaccine-specific antibodies, or incidence of disease). If data are to be collected at multiple times during the course of the study, the timepoint(s) at which data will be evaluated for the primary endpoint should be prospectively identified. Information pertaining to the analytical method for endpoint analysis, including validation of the method, should be included, especially if the analytical method is unique.
Sample Size	Clinical and statistical justification for the sample size. Note that Phase 1 and Phase 2 studies are not usually "powered" for statistical significance.
Data Analysis	Plans for analysis of each primary and secondary endpoint. It is particularly important that Phase 3 studies have all analysis plans prospectively defined in a Statistical Analysis Plan (SAP). This section should identify the study populations to be included in each analysis (e.g., intent-to-treat, per protocol, or other subgroups) and the statistical tests to be used.
Interim Analyses	Plans for interim analyses of safety or efficacy data, if any, and how multiple "looks" at the data will be addressed in the statistical analysis.
Data Monitoring	If a data monitoring committee (DMC)[a] will review the ongoing conduct of the study (safety and/or efficacy), the responsibilities of this committee and any plans for communication between the committee and the sponsor and/or investigators should be described.
Other	Dose escalation, subject withdrawal, management of adverse events and any other prospectively defined procedures should be described.

[a]See FDA Guidance for Clinical Trial Sponsors: Establishment and Operation of Clinical Trial Data Monitoring Committees, March 2006.

investigator and a statement of their qualifications, the names of any sub-investigators working under the supervision of the investigator, the name and address of the research facilities where the study will be conducted, and the name and address of the reviewing Institutional Review Board, IRB). Submission of the 1572 form with the clinical protocol provides a convenient means to comply with this element of the IND regulations. An electronic copy of Form FDA 1572 and instructions for its completion can be found at <http://www.fda.gov/opacom/morechoices/fdaforms/CBER.html>. A draft FDA guidance pertaining to the use of Form FDA 1572 has recently been issued (July 2008).

Sponsors should be familiar with all of the FDA regulations pertaining to the conduct of clinical trials in human subjects. In addition to the IND regulations describing the content of clinical protocols, 21 CFR 312 Subpart D delineates the responsibilities of both sponsors and investigators in conducting clinical trials with investigational products. In addition, the FDA has issued regulations governing protection of human subjects under 21 CFR Part 50 (including the requirement for informed consent), the disclosure of financial interests by clinical investigators (21 CFR Part 54), and the function, organization, and operation of IRBs (21 CFR Part 56). Note that IRB approval is not a prerequisite for submitting an IND to the FDA, but is required prior to the initiation of any clinical study.

Finally, sponsors should be aware of FDA guidance pertaining to the design of clinical studies for investigational vaccines. Recent guidance (September 2007) has been issued pertaining to appropriate toxicity grading scales to be used for the healthy populations typically enrolled in preventive vaccine clinical trials. Other guidance documents for the clinical development of specific types of vaccines have also been issued (Table 13.3). Sponsors should check the CBER website for the most current vaccine clinical trails-related guidance (http://www.fda.gov/cber/vaccine/vacpubs.htm).

Chemistry, Manufacturing, and Controls Data

The Chemistry, Manufacturing, and Controls (CMC) section describes the methods used to manufacture the investigational product and the analytical methods and test results used to control the manufacturing process and the quality of the final product. The information to be included in this section is specified in 21 CFR 312.23(a)(7), and is summarized below:

(1) Drug substance. This section should include detailed information pertaining to the physical, chemical, or biological characterization of the drug substance; the name and address of the manufacturer and the general method for preparation of the drug substance; the analytical methods used to assure the identity, strength, quality, and purity and acceptable limits for these tests; and information to support stability of the drug substance during the toxicological studies and the planned clinical studies.
(2) Drug product. This section should include information regarding all components used in the manufacture of the investigational drug product and its quantitative composition; the name and address of the drug product manufacturer and a brief general description of the manufacturing and packaging procedure; the analytical methods used to assure the identity, strength, quality, and purity of the drug product and acceptable limits for these tests; and information sufficient to assure the product's stability during the planned clinical studies.
(3) Placebo. A brief general description of the composition, manufacture, and control of any placebo to be used in a controlled clinical trial.
(4) Labeling. A copy of all labels and labeling to be provided to each investigator.
(5) Environmental analysis requirements. A claim for categorical exclusion under 21 CFR 25.31 or an environmental assessment under 21 CFR 25.40.

The FDA product reviewers will thoroughly evaluate all information related to manufacture and testing of the investigational product, including:

- the origin and development of recombinant biological products;
- the manufacture and testing of master and working cells banks or virus banks;
- the source and quality attributes of raw materials;
- the certification of any animal-derived materials for freedom from adventitious agents;
- the detailed manufacturing process, including in-process testing to verify process performance;
- the analytical testing and acceptance criteria for release of bulk drug substance and the finished and filled, final container drug product;
- qualification (or validation) of analytical methods.

All drug or biological products, including investigational products, should be manufactured according

to current Good Manufacturing Practice (cGMP) guidelines. However, the implementation of cGMP is expected to occur in a phased manner as product development advances from early Phase 1 studies to pivotal studies enrolling hundreds or thousands of subjects. FDA has issued guidance defining the elements of cGMP that are applicable to the manufacture of product lots for Phase 1 clinical studies (FDA Guidance for Industry, July 2008). General cGMP guidelines applying to later stage clinical trial material and licensed drug or biological products are defined under 21 CFR 211.

The requirements for testing of licensed biological products prior to their release for distribution are described in 21 CFR 610. These regulations will apply to most vaccine products and should be consulted early in development when devising lot release specifications for clinical trial material. Release testing of biological products should include, at a minimum, tests for identity, potency, purity, sterility, and general safety. Table 13.4 provides some examples of analytical tests that might be applied to different types of vaccine products to provide assurance in the IND of their identity, potency, purity, safety, and other quality attributes.

Some additional considerations for analytical testing information to be supplied in the CMC section of an IND are discussed below.

i. In all cases, in-process and release testing must be conducted on the bulk vaccine drug substance, as well as the final, formulated and filled drug product. Tests conducted on the bulk drug substance need not be repeated on the drug product if the manufacturing steps for formulation and fill of the drug product would not affect the tested parameter (e.g., the relative content of an impurity).
ii. All vaccines require a test for potency. Potency is defined in the regulations (21 CFR 600.3(s)) as "the specific ability or capacity of the product, as indicated by appropriate laboratory tests or by adequately controlled clinical data obtained through the administration of the product in the manner intended, to effect a given result." ICH

TABLE 13.4 Examples of analytical tests to be included in the Chemistry, Manufacturing, and Controls section of an IND

Analytical tests	Recombinant or native purified protein antigen or inactivated viral or bacterial infectious agent	Live, attenuated infectious agent	Live, replication-defective, virally-vectored vaccine antigen	DNA plasmid-vectored vaccine antigen
Identity	Western blot	Nucleotide sequence	Nucleotide sequence of gene expression cassette	Restriction digest
	Amino terminal sequence	Specific neutralization	Specific antigen expression	Nucleotide sequence
	Mass spectrometry			
	Antibody binding assays (inactivated vaccines)			
Potency	In vivo immunogenicity	In vivo immunogenicity	In vivo immunogenicity	In vivo immunogenicity
	Antigen content	Infectious titer	Antigen expression in vitro	In vitro transfection efficiency
		Particle count		
Purity	SDS-PAGE	SDS-PAGE	SDS-PAGE	Agarose gel electrophoresis
	Immunoblot			
	HPLC			
Safety	General Safety	General Safety	General Safety	General Safety
	Sterility	Sterility	Sterility	Sterility
	Endotoxin	Endotoxin	Endotoxin	Endotoxin
	Mycoplasma	Mycoplasma	Mycoplasma	Host cell DNA
	Adventitious agents	Adventitious agents	Adventitious agents	
	Host cell DNA	Host cell DNA	Host cell DNA	
	Residual active infectious agent	Attenuation phenotype	Recombinant wild-type (replication competent) vector	
Quality	Residual process impurities (e.g., residual inactivating agent)	Residual host cell protein	Percentage of empty capsids	Percentage supercoiled
			Genetic stability	

guidance Q6B further defines potency as "the quantitative measure of biological activity based on the attribute of the product which is linked to the relevant biological properties." For a vaccine, the potency test result would optimally be shown to correlate with the protective efficacy of the product in humans. Potency assays may be conducted in vivo (challenge-protection assays or serological immunogenicity assays) or in vitro (e.g., infectivity assays for live viral or bacterial vaccines, antigen content for inactivated viral or bacterial vaccines, or induction of antigen expression for vectored vaccines). In vivo assays require large numbers of animals and the need to include a reference standard in every assay run in order to calculate the relative potency of the test sample. In vivo assays are also inherently more variable (less precise) than alternative in vitro methods (Gisonni-Lex, 2005; Petricciani et al., 2007). Some sponsors are therefore seeking to develop in vitro potency test methods early in development and to validate these methods based on clinical efficacy data or by comparison to previously validated potency assays (Schalk et al., 2005; Capen et al., 2007).

iii. The General Safety test is required for all biological products, including vaccines (21 CFR 610.11). The test is conducted on the vaccine final product to detect extraneous toxic substances that might not otherwise be detected by the other release tests conducted. Vaccine manufacturers may request an exemption from the general safety test requirement under 21 CFR 610.11(g)(2) at the time of BLA submission if it can be established that "a test of general safety is unnecessary to assure the safety, purity, and potency of the product or cannot be performed."

iv. Stability testing of the vaccine must be conducted to provide evidence that the vaccine remains stable throughout the duration of nonclinical studies conducted in support of human clinical testing, as well as the full duration of the planned clinical trial. The stability of both the bulk drug substance and the final container vaccine must be evaluated [21 CFR 312.23(a)(7)(iv)(a)]. Since extensive stability data for the clinical lot of vaccine are frequently not available at the time of an original IND submission, the FDA will often accept stability data from a representative lot of vaccine as initial evidence of stability with a commitment to conduct stability evaluation of the clinical lot of vaccine concurrently with the Phase 1study.

CBER has prepared numerous guidelines and "Points to Consider" documents to provide regulatory and technical guidance for sponsors (Table 13.5). Pertinent ICH guidelines include the Q5 quality guidelines for biotechnological products and the Q6B guideline for specifications for biotechnological/biological products. The United States Pharmacopeia also includes general chapters pertaining to the testing of biological products (Table 13.5).

Pharmacology and Toxicology Data

The purpose of this IND section is to present the results of preclinical studies performed in animal models or *in vitro*, which have led the sponsor to conclude that the investigational product is sufficiently safe for the initiation of clinical studies. The scope and design of the preclinical studies necessary to support the first Phase 1study of an investigational product will vary according to the nature of the product and the duration and design of the proposed clinical trials. Typically, pre-IND studies of a vaccine will include immunogenicity studies to establish the proposed dose or dose range to be evaluated in the clinic, evaluation of alternative routes of administration, assessment of any immune enhancement provided by the use of an adjuvant, and toxicological evaluation of the vaccine in at least one animal species at or above the planned maximum human clinical dose. For vaccine products, toxicology studies are typically conducted by administration of a multiple of the human clinical dose in absolute terms; in other words, the dose is not scaled to body weight or body surface area. For products formulated with a novel adjuvant, toxicity studies may need to include safety assessment of the adjuvant alone, as well as the antigen/adjuvant combination. While studies to evaluate the immunogenicity of the vaccine product do not necessarily need to be conducted according to GLP guidelines (21 CFR Part 58), any toxicology study intended to establish the safety of the product for human clinical use must comply with GLP regulations.

In some cases, "proof of concept" studies can be conducted in animal models to demonstrate that the investigational product displays the biological activity or efficacy intended in humans. However, the demonstration of activity in animals does not have to be, and often cannot be, absolutely analogous to the clinical activity that is ultimately desired. For example, if an investigational vaccine is shown to be immunogenic in an animal model, this may serve as sufficient evidence for conducting Phase 1 studies. Demonstration of protection against challenge following vaccination is usually not required prior to Phase 1.

The necessary package of preclinical studies required to support entry into human clinical trials

is an appropriate topic for discussion at the pre-IND meeting with FDA. Specific questions pertaining to the design of individual studies may also be discussed. Sponsors are encouraged to seek agreement from FDA to review draft preclinical protocols in advance of their execution, especially if the study is to be conducted in an unusual model system or with an unconventional study design.

Finally, the sponsor should consult 21 CFR Part 58—Good Laboratory Practice for Nonclinical Laboratory Studies, ICH guidelines regarding safety, as appropriate, and the World Health Organization Guidance on Nonclinical Evaluation of Vaccines (http://www.who.int/biologicals/publications/nonclinical_evaluation_vaccines_nov_2003.pdf) when conducting preclinical studies in support of an original IND submission (Table 13.6).

Although initial preclinical testing of a vaccine product may support entry into human clinical trials, additional nonclinical studies may be requested by the FDA as product development continues under the IND. The nonclinical studies required to support later stages of clinical development and the final license application should be discussed in detail with the Agency after the Phase 1 study is complete and further clinical evaluation of the vaccine is warranted. For prophylactic vaccines to be used in women of childbearing potential, an assessment of the potential reproductive toxicity of the product is often required. Note that the FDA has issued a specific guidance pertaining to developmental toxicity studies for preventive and therapeutic vaccines (see Table 13.6).

TABLE 13.6 Selected guidance pertaining to nonclinical toxicology and pharmacology testing of vaccines

Source	Title
FDA	Guidance for industry: considerations for developmental toxicity studies for preventive and therapeutic vaccines for infectious disease indications (February 2006)
FDA	Guidance for industry: considerations for plasmid DNA vaccines for infectious disease indications (November 2007)
WHO	World Health Organization guidance on nonclinical evaluation of vaccines (November 2003)
ICH	S6: Preclinical safety evaluation of biotechnology-derived pharmaceuticals (July 1997)

Genotoxicity and carcinogenicity studies are normally not needed for vaccines, but might be required if the vaccine vector has oncogenic potential or if a novel adjuvant is included in the vaccine formulation. Safety pharmacology studies are also generally not required unless data from other studies suggest that the vaccine may have an effect on a physiological function other than the immune system (World Health Organization Guidance, 2003). Thus, the requirements for nonclinical evaluation of an investigational vaccine may evolve as new nonclinical and human clinical data are collected and evaluated.

The Pharmacology and Toxicology section of the IND should provide FDA reviewers with the relevant data pertaining to the immunological and toxicological effects of the vaccine observed in animal models. This section should include a detailed description of the design of the studies conducted (including any deviations from the design during study conduct), and a summary presentation of the results obtained. In addition, according to 21 CFR 312.23(a)(8)(ii), the toxicology portion of the IND should include "for each toxicology study that is intended primarily to support the safety of the proposed clinical investigation, a full tabulation of data suitable for detailed review." This should consist of complete line listings of the individual data points for each animal in the study, along with summary tabulations of the data. Usually, sponsors will comply with this requirement by appending the study report to the IND submission. Note that unaudited draft reports are acceptable for submission in the original IND since FDA has acknowledged that there are rarely any significant changes between the unaudited and final, audited study results (FDA Guidance for Industry, November 1995). However, note that if an unaudited draft report is supplied with the original IND, the final audited report must be submitted to the IND file within 120 days of the initiation of clinical studies. The updated information should highlight any differences between the unaudited report submitted for review and the final audited study report. Individual data listings are usually not required for studies focused on the immunological response to vaccination. The appropriate contents of the Pharmacology and Toxicology section of the original IND should be discussed with CBER prior to IND submission.

Previous Human Experience

This section of the IND should provide summaries of previous clinical trials of the investigational vaccine, whether conducted in the United States or overseas, or relevant information from trials of related products or components. For example, this section might include information on foreign clinical studies not conducted under an IND, or safety data from studies using the same vaccine vector to be used in the proposed Phase 1 study, but with modest changes to the encoded antigen. For products administered with a novel adjuvant, any prior clinical trials experience with the adjuvant should be described. The summary information should include a detailed outline of the study design as well as a thorough summary of the results, including statistical analysis, where applicable. It is understood that for many Phase 1 products, there will be no prior human experience to be reported in the original IND.

Additional Information

This section of the IND provides sponsors with an avenue to submit any other relevant information in support of the proposed clinical study, including publications and meeting abstracts. Prior IND correspondence may also be included in this section, for example, to provide documentation of specific agreements reached during the pre-IND meeting.

ELECTRONIC INDs

CBER has developed programs and policies to accommodate electronic submission of INDs (eINDs). In March 2002, the FDA published its final guidance on eINDs entitled, "Providing Regulatory Submissions to CBER in Electronic Format—Investigational New Drug Applications (INDs)," which provides instructions for the organization and assembly of eINDs. eINDs can be submitted via the FDA's electronic submissions gateway (ESG) or via CD-ROM in portable document format (PDF).

The guidance recommends that companies interested in submitting an eIND should contact CBER's Electronic Submissions Coordinator(s) at least 3 months prior to the planned eIND submission date in order to arrange for an informal demonstration or "test" submission of the eIND. The coordinators have been willing to arrange demonstration submissions with less advance notice, but CBER will require approximately 45–60 days to review the electronic files in the test submission and determine whether the files have been generated in accordance with the FDA eIND guidance. The content of the eIND is not considered during this review. If the review indicates that the eIND has been adequately generated, then the sponsor will be notified and allowed to proceed with

the formal submission of the eIND. It should be noted that, once a sponsor has initiated submission of an IND in electronic format, all subsequent amendments to the IND file must also be made electronically.

INDs IN COMMON TECHNICAL DOCUMENT FORMAT

The ICH has developed a CTD that may be used for submission of licensing applications for drug products in the United States, the European Union, Japan, and other nations adhering to the ICH framework. The CTD is composed of five "modules" that include administrative information (Module 1), summary information (Module 2), detailed product quality information (Module 3), pharmacology and toxicology information (Module 4), and clinical information (Module 5). The organization of the CTD document is described in the 2004 ICH guideline M4(R3): Organization of the Common Technical Document for the Registration of Pharmaceuticals for Human Use. Although the CTD was designed for submission of licensing applications at the completion of clinical development, the FDA will accept original IND submissions that are organized according to the CTD outline. The advantage of this approach is that, as information amendments (described below) are submitted to the IND over the course of clinical development, the CTD exists as a "living document" that becomes increasingly detailed and populated as the product approaches licensure. Available guidance for mapping the required elements of the IND to the CTD Table of Contents is provided by the "FDA eCTD Table of Contents Headings and Hierarchy" (Updated July 2005), available on the FDA website at http://www.fda.gov/Cder/regulatory/ersr/ectd.htm. INDs in CTD format may also be submitted electronically as an "eCTD." (See FDA's June 2008 guidance entitled, "Providing Regulatory Submissions in Electronic Format—Human Pharmaceutical Applications and Related Submissions Using the eCTD Specifications.") Sponsors should discuss plans for submission of an original IND in CTD format with the FDA review team at the pre-IND meeting.

MAINTENANCE OF THE IND

An IND becomes "in effect" or "active" within 30 days of its receipt by FDA unless the FDA notifies the sponsor that the IND has been placed on clinical hold. The IND will remain in effect throughout product development, and will be updated or "amended" by the sponsor with new information as clinical development advances to Phase 2 and Phase 3 studies. The IND file should be a central repository for all information relevant to the safety and efficacy of the investigational product, including information regarding product manufacture and testing, toxicological evaluation in animal models, and testing for safety and efficacy in human clinical trials. From the FDA's perspective, maintenance of the IND file is essential for the performance of its regulatory mission to ensure the safety and adequacy of human clinical trials. For the sponsor, maintaining an up-to-date body of data and information in the IND will enable FDA's review staff to provide meaningful advice on product development issues as they arise, or to anticipate and avert potential problems before they occur.

Certain types of information, by regulation, must be submitted as amendments to the IND. All new clinical trial protocols must be submitted for FDA review as "protocol amendments" (21 CFR 312.30). For all protocols submitted subsequent to the original IND, the sponsor is not obligated to wait for the Agency's comments or approval prior to study initiation; however, it is strongly recommended that the sponsor allow time for Agency review in order to avoid the potential for a clinical hold after the study has begun enrolling subjects.

Significant changes to an existing protocol or the addition of a new investigator to an ongoing study are also protocol amendments that must be submitted to the IND.

"IND safety reports" [21 CFR 312.32(c)] are used to inform the Agency of any unexpected and serious adverse reaction associated with the use of the investigational product or any new finding from nonclinical studies that suggests a significant risk for human subjects. This category of information must be reported to the Agency as an "initial written report" as soon as possible (and no later than 15 calendar days after the sponsor's receipt of the information). Note that unexpected, fatal, or life-threatening adverse experiences must be communicated to the Agency by telephone or facsimile within 7 days of receipt of the information. Serious and unexpected adverse events should be evaluated for their significance in light of other safety information and followed-up to determine their outcome. The results of subsequent investigations should also be reported promptly to the Agency in the form of a "follow-up to a written report." The FDA will review the information received and determine whether additional data are required or there should be changes in the design or conduct of the ongoing clinical study.

A third category of IND amendment is the "annual report." No later than 60 days after the anniversary date on which the IND went into effect, the sponsor should submit an annual report for the FDA review staff that summarizes the status of ongoing clinical investigations, updates the IND with a current summary of CMC information, safety data from completed nonclinical studies, and safety and efficacy information from human clinical trials. The annual report should also preview the nonclinical and clinical studies planned for the coming year. The annual report serves as an administrative summary of IND activity over the previous year and should not be used to convey new information about product or clinical development. The appropriate content of an IND annual report is outlined in 21 CFR 312.33.

Finally, "information amendments" (21 CFR 312.31) are amendments that provide other types of essential information not included in a protocol amendment, IND safety report or annual report. Such amendments may contain CMC information such as significant changes to the manufacturing process or to the specifications for product release; nonclinical information, such as a toxicology study report; or clinical information, including clinical study reports, or updates to the Investigator's Brochure. Most product development data will be submitted to the IND in an information amendment.

Other types of IND amendments include "response to clinical hold," "response to FDA request for information," and "general correspondence," such as a change to the sponsor's authorized representative or the submission of a meeting request. All IND amendments must be accompanied by a completed Form FDA 1571, which specifies the type of information included in the submission. It is also advisable to include a cover letter with the amendment that clarifies the context and purpose of the submission.

PREPARING FOR THE BIOLOGICS LICENSE APPLICATION

In the later stages of product development under the IND process, sponsors must begin preparations for submission of a BLA/CTD and for commercial manufacture of the vaccine upon approval. As mentioned previously, the pre-BLA meeting with the FDA should be scheduled well in advance of the intended BLA filing date, and may be used to present preliminary data from the pivotal Phase 3 clinical trial(s) establishing the safety and efficacy of the product, and to discuss the format and content of the application itself. It may be necessary to schedule a separate meeting to discuss CMC issues, including (for example) final specifications for commercial product and any necessary changes in the commercial manufacturing scale or process. Questions specifically related to commercial facility design may be addressed by requesting a Type C meeting with the Division of Manufacturing and Product Quality at CBER. In the months leading up to submission of the licensing application, sponsors must plan for completion of analytical method validation, manufacturing process validation, and the manufacture of consistency lots according to the planned commercial process. The manufacturing facility should begin preparations for a pre-approval inspection (PAI) by FDA. In addition, Clinical Study Reports for pivotal clinical trials must be prepared for submission to the IND file, and/or with the original license application, and clinical trial records should be organized for inspection by FDA's Bioresearch Monitoring group.

ICH has issued guidance documents to assist sponsors in the preparation of a license application in CTD format (Table 13.7) many of which have been adopted by FDA; however, IND sponsors should be aware of regional requirements specific to the United States. These include specific administrative information to be included in Module 1, region-specific quality documentation to be provided in Module 3, and an integrated summary of clinical effectiveness and safety to be included in Module 5 (Table 13.7). Additional guidance has been provided by FDA for applications in electronic format (available on the FDA website at http://www.fda.gov/cder/Regulatory/ersr/ectd.htm).

Submission of an original BLA opens a new file and a new chapter in regulatory interactions with the Agency, and marks the transition from the IND process described in this chapter to the independent process for marketing application review and approval, and product commercialization.

CONCLUSIONS

The submission of an original IND is a significant step in the development of a new vaccine for the treatment or prevention of infectious disease. In this chapter, we have emphasized the importance of regular and ongoing communication throughout the IND process between sponsors and the CBER review staff through meetings, teleconferences and written submissions to the IND file. Sponsors should also review and stay up to date with FDA and ICH guidance documents that provide essential product and clinical development information. By maintaining positive and productive interactions with FDA,

CHAPTER

14

U.S. Regulatory Issues Related to Vaccines against Emerging Infectious Diseases

Philip R. Krause
Division of Viral Products, Office of Vaccines Research and Review,
Center for Biologics Evaluation and Research, Food and Drug Administration,
Bethesda, MD, USA

OUTLINE

ABSTRACT

The primary goal of the U.S. vaccine regulatory process is to provide assurance that vaccines are consistently safe and effective. This chapter summarizes the issues and regulatory process for development and licensure of vaccines in the United States, with particular emphasis on emerging infectious diseases. As is the case for all vaccines, vaccines to prevent emerging infectious diseases must fulfill the science-based regulatory requirements for safety and efficacy, but the special nature of these infections can make vaccine development more challenging, both

from scientific and regulatory standpoints. Regulatory requirements are generally organized by phase of clinical development, with emphasis on safety throughout the development process, and on efficacy and immunogenicity later in development. Specific issues associated with assays and cell substrates must be considered throughout development. Frequent reference to the underlying regulations and sources of guidance is useful to assure that important issues are addressed. Regulatory processes that may have particular relevance to emerging infectious diseases include the Orphan Drug Program, Accelerated Approval, the Animal Rule, the Fast Track Program, Priority Review, Treatment IND, and Emergency Use Authorizations.

INTRODUCTION

In the United States, vaccines are regulated as biological products by the Center for Biologics Evaluation and Research (CBER) of the Food and Drug Administration (FDA). The primary responsibility for review of vaccine applications lies within CBER's Office of Vaccines Research and Review.

The laws related to vaccine development are implemented by Title 21 of the Code of Federal Regulations, the section that includes regulations for foods and drugs. Subchapter A covers general requirements for product development, including environmental impact considerations (Part 25), human subject protection (Parts 50 and 56), and regulations governing nonclinical laboratory studies (Part 58). Subchapter C includes general requirements for all drug products, including their labeling (Part 201), advertising (Part 202), and current good manufacturing practices (cGMP, Parts 210–211). Subchapter D covers requirements for drugs for human use, including regulations for investigational new drugs (INDs, Part 312), adequate and well-controlled clinical trials (Part 314), and Orphan Drugs (Part 316). Subchapter F (Sections 600–680) covers biological products, including establishment standards, inspection, and adverse experience reporting (Part 600), licensing (Part 601), and general biological product standards (Part 610).

In addition, CBER publishes "Guidance Documents" (previously called "Points to Consider" documents) that represent current thinking on various issues related to the review of biological products (including vaccines). These include nonbinding recommendations for fulfilling regulatory requirements, and are meant to help sponsors of biological products understand CBER's interpretation of the regulations. Guidance documents with special relevance to vaccine manufacture are summarized in Table 14.1.

The International Conference on Harmonization (ICH) (International Conference on Harmonization, 2008, http://www.ich.org) also provides general guidance on manufacture and testing of pharmaceuticals, including vaccines. The ICH documents represent an international consensus regarding acceptable approaches to product manufacture, including that of vaccines. While ICH documents are published in series depending on whether they address quality, safety, efficacy, or multidisciplinary issues, the documents related to quality of biotechnology products (prefixed with a "Q5") are quite relevant to vaccine manufacture and testing. These include Q5A on viral safety evaluation, Q5B on analysis of expression constructs in cells, Q5C on stability testing, Q5D on cell substrates, and Q5E on comparability of products subject to changes in manufacturing processes.

In addition, the World Health Organization (WHO) has an "Expert Committee on Biological Standardization," which publishes international guidelines for vaccines (World Health Organization, 2008). These guidelines do not have the force of law in the United States, but do represent an international scientific and regulatory consensus regarding good practices in manufacture and testing of biological products, including vaccines.

This chapter summarizes regulatory issues impacting the development of vaccines against emerging infectious diseases, in the context of a summary of some nonregulatory vaccine development issues.

NONREGULATORY ISSUES IMPACTING U.S. DEVELOPMENT OF VACCINES AGAINST EMERGING INFECTIOUS DISEASES

Emerging infectious diseases present special problems with regard to vaccine development. Although regulatory issues are sometimes cited as obstacles to rapid product development (Stern and Markel, 2005), and it does take some time to fulfill regulatory requirements to demonstrate the safety and efficacy of a candidate vaccine, the major obstacles to development of vaccines against emerging infectious diseases have generally not been regulatory in nature. There are scientific challenges associated with vaccine development, and these are often greater for vaccines against emerging infectious diseases. These scientific challenges may translate into economic challenges.

Guidance for Industry: Emergency Use Authorization of Medical Products
Guidance for Industry: Special Protocol Assessment

Note: All documents are available online at http://www.fda.gov/cber/guidelines.htm/.

Economic factors influence the development of all vaccines, and may be more likely to influence vaccines against emerging infectious diseases than other products. In recognition of the special considerations associated with emerging infectious diseases, programs and pathways have been put in place to address these obstacles.

Novel vaccines, especially those against emerging infectious diseases, are more likely to use newer technologies. Developing assurance that these new technologies lead to safe and effective vaccines requires a deep level of scientific understanding. This review covers regulatory assessment of some of these scientific issues—including the need to address issues associated with using new types of cells to produce viral vaccines (see "Other Nonclinical Issues That Affect All Stages of Development"), the need to develop potency assays that predict vaccine safety and efficacy (see "Other Nonclinical Issues That Affect All Stages of Development"), and the need to develop "surrogate markers" in humans or animals that predict vaccine efficacy (see "Phase III"). However, in many cases,

the development of the underlying science is more a research than a regulatory question. Other scientific obstacles may affect vaccine development at an even earlier level—for example, antigens in combination with vaccines may interfere with one another, related vaccines could theoretically cross-react, and new adjuvants may be necessary to develop vaccines that effectively prevent some diseases (but stronger adjuvants may have increased risk of reactogenicity). In addition, it is always a greater challenge to develop vaccines in the United States against diseases that do not affect people in the United States, whether they are global diseases or emerging infectious diseases.

In many cases, the scope of the threat from an emerging infectious disease is unknown at the time when vaccine development would optimally occur. Some emerging infectious diseases may produce worldwide pandemics, as occurred with HIV, but the scope of this threat would have been difficult to predict in the early 1980s, as AIDS was being defined as a clinical syndrome. Nonetheless, it is widely accepted that there would be a robust U.S. and global market even for a partially effective HIV vaccine. However, SARS initially evoked worldwide concern, leading to rapid deployment of public health countermeasures including quarantine of infected and exposed individuals, and was relatively rapidly contained with the last reported human case in 2004. At the present time, the level of market demand for a potential SARS vaccine is unclear. Given this market uncertainty, it is not difficult to understand the reluctance of some pharmaceutical companies to invest in the development of vaccines for emerging infectious diseases.

Reports from the Institute of Medicine (IOM) repeatedly highlighted the importance of market issues in addressing vaccine availability. A 1992 IOM report highlighted the unfavorable ratio between profits and risk of failure, and the risks of potential liability claims for injuries or deaths attributed to vaccine administration (Lederberg et al., 1992). This report suggested a need for additional economic incentives to develop vaccines, stockpiling of selected vaccines, and the development of "surge" vaccine production capabilities.

Liability concerns are also a potential obstacle to development of vaccines against emerging infectious diseases. While these liability concerns may in part be addressed by the National Vaccine Injury Compensation Program [reviewed in Evans (2006)], which provides compensation to individuals injured by covered vaccines and provides liability protection for industry, it may not initially be clear whether a vaccine under development will ultimately qualify for this program, especially if it is directed at an emerging infectious disease.

Although it is nearly universally accepted that vaccines against potential pandemic influenza strains would be widely used once strains with the ability to be efficiently transmitted from human to human are isolated in the field, it is unclear what the full antigenic composition of those strains will be. Any vaccine development that occurs too far in advance of the emergence of the actual strains that the vaccine is intended to immunize against runs the risk of suboptimal immunogenicity (Smith, 2006). Moreover, the lead times necessary to develop such vaccines may permit some antigenic drift, leading to lower efficacy than desired, even in the context of routine influenza immunization. The uncertainty of the timing of the event that would trigger the market for pandemic influenza vaccines makes it difficult to decide on the ideal timing for vaccine production. This uncertainty, in turn, makes it unlikely that private market forces alone would lead to the widespread availability of pandemic influenza vaccines (Stohr and Esveld, 2004). Recent legislation has made government funds available to support development of the next generation of influenza vaccines, with an emphasis on pandemic influenza issues (Department of Health and Human Services, 2005, http://www.hhs.gov/pandemicflu/plan/). Heightened concern about pandemic influenza has led to substantial government activity in this area, including the development of a pandemic influenza plan.

In the United States, the federal government, mostly through the National Institutes of Health (NIH) (Fauci, 2005), the FDA (Zoon, 1999), the Centers for Disease Control and Prevention (CDC), and the National Vaccine Program Office (NVPO) has played a pivotal role in preparing the nation's public health infrastructure for the threat of emerging infectious diseases. By funding research in these areas, the government stimulates the development of scientifically valid approaches to developing vaccines in this critical public health arena. Should a larger need (and an accompanying larger market) arise, a basis for more rapid development and manufacture of these vaccines already exists.

Recent concerns about bioterrorism have increased the likelihood that vaccines against some emerging infections will find a market in the United States. When new infectious diseases emerge in the United States, it may not always be immediately clear whether or not their emergence resulted from the deliberate introduction of a pathogen. The Project Bioshield legislation of 2004 established a secure funding source for purchase and stockpiling of vaccines related to national security, increased the authority and flexibility of NIH to expedite national security-related biological research, and established an Emergency Use Authorization (described in more detail in "Project Bioshield and

Emergency Use Authorizations") for critical national security-related biological countermeasures. While the emphasis of Project Bioshield is on national security and bioterrorism, vaccines against etiologic agents of emerging infectious diseases that overlap with those targeted by Project Bioshield may find markets in the United States as a result of its government sponsorship of vaccine purchases.

Nonetheless, the additional obstacles to development of vaccines against emerging infectious diseases are superimposed on those associated with more routine vaccine development. Even routine vaccines may not be as profitable as other pharmaceutical products. The incentives and disincentives associated with the development of vaccines against emerging infectious diseases will play an important role in their ultimate availability in the United States.

OVERVIEW OF THE U.S. VACCINE REGULATORY REVIEW PROCESS

The primary purpose of the regulatory review process is to assure that marketed products are safe and effective. The regulatory process also plays an important role in the protection of human subjects, helping to assure the relative safety of investigational products and the appropriateness of clinical studies. To accomplish this, the manufacturer must demonstrate safety, purity, potency, efficacy, manufacturing reproducibility, and compliance with cGMP. Legally binding regulations relevant to vaccines are published in the Federal Register, and are summarized each year in the Code of Federal Regulations. The U.S. regulatory review process is described in detail in the underlying regulations and in other publications (Baylor and Midthun, 2004).

In the United States, vaccines are evaluated for possible licensure by the FDA. The Advisory Committee on Immunization Practices provides official guidelines for the use of licensed vaccines (Centers for Disease Control and Prevention, 2008, http://www.cdc.gov/vaccines/recs/nip/default.htm). The Centers for Disease Control and Prevention (CDC) also plays an important role in studying the epidemiology of vaccine-preventable diseases, and in coordinating the responses of state and local public health authorities.

Vaccines differ substantially from other tools in the public health armamentarium. Vaccines are among the most effective public health measures ever devised, having successfully been used to eradicate natural smallpox from the globe and natural poliovirus infections from the Western hemisphere. The morbidity in the United States associated with every vaccine-preventable disease has decreased dramatically with the introduction of vaccines (even against those agents that have not been eradicated), including measles, mumps, rubella, pertussis, Haemophilus influenzae type B meningitis, meningococcus, pneumococcal infections, varicella, and influenza. Some of the very high effectiveness of vaccines is attributable to herd immunity, when vaccination rates are sufficiently high, interruption of transmission among the vaccinated prevents infection even in the unvaccinated, who are less likely to be exposed to the pathogen (Anderson and May, 1991).

However, vaccines designed to prevent infectious diseases are generally administered to healthy individuals, in many cases children—thus, in spite of their success, there is low public tolerance for safety concerns with vaccines (Plotkin, 1991). Moreover, vaccines are unusual among FDA-regulated products because many states mandate universal vaccination of children prior to attendance at day care or school—thus, except when declined for religious reasons, vaccination is not a matter of choice for most U.S. citizens.

These circumstances lead to a need for vaccines to be very safe products (Chen et al., 2001). Maintenance of herd immunity depends on high vaccination rates, which in turn depend on high levels of public confidence in the safety of vaccines. Thus, the incredible success of vaccines depend largely on the public's confidence that approved products have been thoroughly reviewed by the FDA, and that the best, most current scientific principles have been applied to that review.

Over time, as concerns regarding rare or even theoretical safety issues with vaccines have evolved, manufacturers and the U.S. government have acted to assure that vaccines are as safe as possible. For example, although very effective, oral polio vaccine is no longer used in the United States, due mostly to an approximately one in a million chance of vaccine strain reversion that can cause vaccine-associated paralytic polio in vaccine recipients. When polio was widespread, this risk was considered a reasonable trade-off for the benefits of the vaccine, but this clearly is no longer the case. The U.S. government authorities moved quickly to reduce the number of thimerosal-containing vaccines, when concern was raised regarding the possibility that ethyl mercury in thimerosal could cause adverse consequences in vaccine recipients, even in the absence of clear scientific evidence of harm (Center for Biologics Evaluation and Research, 2008, http://www.fda.gov/Cber/vaccine/thimerosal.htm).

The thoroughness of the FDA's vaccine regulatory review process thus provides the public with a high degree of confidence that vaccines are safe. While regulatory requirements may occasionally be seen by

some as burdensome, all regulatory decisions regarding vaccines take into account the best available scientific practices. The direct engagement of active laboratory-based researchers at CBER in the vaccine review process helps to assure that all decisions have a scientific foundation. When CBER scientists identify areas in which more data are needed in order to support regulatory decision making or to simplify review, intramural funding of CBER research allows these data to be objectively gathered (Korn, 1997; FDA Science Board Subcommittee on Science and Technology, 2007, http://www.fda.gov/ohrms/dockets/ac/07/briefing/2007-4329b_02_01_FDA%20Report%20on%20Science%20and%20Technology.pdf). By providing its objective pre- and post-marketing review of vaccines, the FDA thus plays an important role in assuring not only that vaccines are safe, but also that the public's confidence in their safety is justified.

In the following discussion of the U.S. regulatory process, reference is made to regulations and to guidance documents. As scientific advances are made, and as new needs are identified, these references may be updated, new laws may be passed, and new guidance documents may be issued. Updates on available CBER-issued guidance documents are available on the Internet (Center for Biologics Evaluation and Research, 2008, http://www.fda.gov/Cber/vaccine/thimerosal.htm). Table 14.1 lists current (as of January 2008) CBER guidance relevant to vaccines.

Pre-IND Vaccine Development

Prior to filing of an IND application, sufficient data to support a first use of a product in humans must be gathered. While FDA review focuses heavily on safety at this stage of development, the expense of thoroughly evaluating the safety of a potential vaccine may not be considered justified by vaccine sponsors unless preclinical data also support the likely efficacy of the product in humans. Prior to filing an IND, it is also necessary to develop a plan and the necessary facilities to manufacture a vaccine that meets standards for use in human clinical trials. General principles on nonclinical evaluation of vaccines have been promulgated by the WHO (World Health Organization, 2005).

It is a general principle of drug development that new drugs should be shown to be safe in appropriate animal models before they are first tested in humans. Appropriate toxicology tests, including animal autopsies and microscopic examination of organs, can provide assurance that vaccine products do not contain toxic proteins or other components. The general goals of toxicology tests are to determine whether it is reasonable to test the product in humans via a given route and schedule of administration, to determine appropriate starting doses, and to provide guidance regarding clinical parameters that should be more closely monitored during the human safety studies. Although FDA has not issued official guidance on toxicology studies for vaccines, general recommendations coauthored by FDA toxicology reviewers are available (Chang et al., 2003). These recommendations suggest administration of the product under good laboratory practices (GLP) conditions to a minimum of 20 animals of a relevant species (10 males, 10 females) via the intended route and schedule (plus one additional dose) at a minimum of the (non-mass adjusted) human dose, with intervening physical examination, clinical observations, and laboratory tests, and with animal sacrifices and thorough histopathology examinations of half the animals at 1–3 days after the last inoculation and half at 21 days after the final inoculation. These recommendations are consistent with those issued by the WHO on preclinical testing of vaccines (World Health Organization, 2005).

Potential virulence of the vaccine strain is a major safety issue for live attenuated vaccines. To assure that a vaccine will be safe in humans, there should be a strong scientific basis for believing that any infection with the vaccine strain will be mild, generally milder than that caused by the wild-type pathogen. This issue may be addressed in appropriate animal models, when such models are available and can be scientifically justified. For attenuated viruses, the genetic stability of the organism, including demonstration that the virus does not revert to a more virulent phenotype, may be particularly important.

For viruses that have the potential to be neurotropic (usually based on an understanding of natural disease with wild-type virus, and/or on preclinical toxicology studies), neurovirulence is another potential safety issue. Neurovirulence testing originally was developed by Dr. Albert Sabin to permit evaluation of live-attenuated polio vaccine. In the context of this vaccine, Dr. Sabin demonstrated that the inoculation of monkey brains made it possible to identify virus strains that had reverted to a phenotype making them more likely to cause vaccine-associated paralytic polio in humans (Sabin, 1985). Although neurovirulence testing was performed on a lot-by-lot basis for oral poliovirus vaccine, this issue has been addressed for most live neurotropic virus-based vaccines by showing that vaccine strains or master seed viruses have been sufficiently attenuated in appropriate animal models.

As new vaccine technologies are developed, FDA may provide guidance documents regarding the appropriate evaluation of these technologies. For

example, a guidance document on DNA vaccines provides specific information regarding appropriate in vitro and in vivo studies to support the use of these vaccines in clinical trials (Center for Biologics Evaluation and Research, Guidance for Industry: Considerations for Plasmid DNA Vaccines for Infectious Disease Indications, 2007).

Although pregnant women are not the primary target for most vaccines, the potential for vaccination of pregnant women must be considered. FDA has issued specific guidance on the topic of reproductive toxicology studies for vaccines indicated for women of reproductive age (Center for Biologics Evaluation and Research, 2000, http://www.fda.gov/cber/gdlns/reprotox.pdf). Unless the vaccine is specifically intended for use in pregnant women, reproductive toxicology studies may be performed in parallel with clinical development, as long as the clinical studies include appropriate exclusion criteria. By the time clinical studies that could include pregnant women are initiated, these studies should be completed. In some cases, the creation of a pregnancy registry allows the compilation of additional data post-licensure (Food and Drug Administration, 2002, http://www.fda.gov/cber/gdlns/pregexp.pdf).

Pre-Phase I testing should also address the safety of any unusual components or novel adjuvants that a vaccine contains. When there is prior human experience with the same substance in the same or a different context, this information can be helpful.

Cell substrate issues and the setting of specifications are relevant to all stages of product development, and are discussed in "Other Nonclinical Issues that Affect All Stages of Development."

The Phases of an Investigational New Drug (IND) Investigation for Vaccines

The conduct of studies under IND is governed by regulations (21 CFR 312 Investigational New Drug Application, 2007). Prior to licensure, clinical studies are designated as Phase I, Phase II, or Phase III. Phase I studies represent the first human uses of the product, and focus on sufficient demonstration of safety to support expanded Phase II studies. In Phase II, additional data (focusing both on safety and immunogenicity) generally are obtained for proof of concept to support the performance of a Phase III efficacy study. The bulk of data to support licensure, though, come from Phase III studies.

Phase I

The primary focus of Phase I clinical studies is evaluation of safety. Phase I clinical studies generally represent the first human use of a candidate vaccine. Thus, these studies often are performed with dose escalation, starting with lower and increasing toward higher doses. Because of the focus on safety, there is generally no need for Phase I studies to be placebo controlled.

Although for many drugs, one purpose of Phase I studies is to obtain information regarding the maximum tolerated dose, vaccine candidates are ideally sufficiently safe so that a maximum tolerated dose is not reached in a Phase I study. Thus, maximum doses in vaccine Phase I studies are often chosen based on practical considerations, such as manufacturing capabilities, as well as the need to assure that the safety of doses required for optimal immunogenicity has been adequately studied. Doses used in Phase I studies must be justified by appropriate preclinical studies.

An original submission IND is required to adhere to the content and format specified in the relevant regulations (21 CFR 312.23 IND content and format, 2007). The IND should include all the results from the pre-IND phase of testing, together with all the information needed to evaluate the proposed Phase I clinical trial. This includes information about the specific lots of vaccine to be used and their testing, including proper identification, quality, purity, strength, and source materials used. The description of the clinical trial should include information about the study design, clearly defined eligibility (and exclusion) criteria, and information regarding the safety follow-up of vaccinees. Information regarding the qualifications of the investigators and adherence to the regulations pertaining to Institutional Review Boards (IRBs) is also required. Unless the sponsor is also the investigator, a copy of the investigator brochure also must be included (21 CFR 312.55 Informing Investigators, 2007).

Because the major focus of Phase I studies is on safety, the safety criteria utilized either for dose escalation or for suspension of the study receive particular scrutiny. These criteria will, of course, depend on the inclusion criteria for the study. However, it is expected that most vaccines should be sufficiently safe that they do not induce major laboratory abnormalities, and if such abnormalities occur during Phase I studies, there should be a plan to investigate them. Safety of individuals not in the study also may be an issue. For example, it may be necessary to defer vaccine recipients from blood donation or to restrict the receipt of certain live vaccines to individuals who are unlikely to be exposed to immunocompromised individuals.

There are regulatory requirements (21 CFR 56.108 IRB functions and operations, 2007; 21 CFR 312.32 IND safety reports, 2007) to report certain serious adverse events in a clinical trial to the IRB and FDA,

within specified periods of time. Toxicity grading scales used in Phase I studies should reflect the population being immunized and expected adverse reactions. Adverse events are often graded on a 4-point scale, ranging from grade I (mild) to grade IV (severe). In general, any abnormal laboratory value is reported as at least a grade I (mild) toxicity. Prospective definition of the potential toxicities is important, because continuation of the clinical trial generally depends on the absence of significant toxicities. In some cases, specific toxicities may influence dose escalation, while in others, they may be tied to "stopping rules," that lead to an evaluation of whether the study should be continued or terminated. A CBER guidance document on toxicity scales for normal subjects in vaccine trials was recently issued (Center for Biologics Evaluation and Research, 2007, http://www.fda.gov/cber/gdlns/toxvac.pdf). In blinded studies (generally after Phase I), an independent data safety monitoring board may examine adverse reactions to determine whether a study should continue (International Conference on Harmonization, 1996, http://www.ich.org/LOB/media/MEDIA482.pdf).

Once an original submission IND, including a Phase I study, is received by the FDA, CBER will make a determination within 30 days regarding whether this study may proceed, or will be placed on "clinical hold" (21 CFR 312.42 Clinical Holds and Requests for Modification, 2007). The placement of a Phase I study on "clinical hold" generally indicates that important safety issues, best addressed during the pre-IND phase of development, have not yet been resolved sufficiently to assure that the product is safe enough to use in a clinical study. Other reasons for a Phase I clinical hold include insufficient qualifications of clinical investigators, inadequacy of the investigator's brochure, insufficient information to assess risk, or exclusion of individuals who may benefit on the grounds of potential reproductive or developmental toxicity.

Phase II

According to the IND regulations (21 CFR 312.21 Phases of an investigation, 2007), Phase II studies include controlled clinical studies conducted to evaluate the effectiveness of the drug for a particular indication in patients with the disease under study, and to determine common short-term side effects. These studies are typically randomized, well controlled, closely monitored, and include no more than several hundred subjects. Phase II studies must be supported by safety data from appropriately designed Phase I studies, and the general considerations for Phase I studies generally also apply.

Vaccine Phase II studies thus tend to focus on immunogenicity and expansion of the safety database. These studies are generally designed to provide the information necessary to support a Phase III efficacy study, often including sufficient proof of concept for the manufacturer to justify progression to Phase III. This may include final dose selection. Phase II studies also support assay development and the development of surrogate markers that may be helpful in evaluating the results of clinical trials. Phase II study populations are generally chosen to predict responses in larger Phase III studies intended to lead to licensure. Phase II or Phase III studies may be placed on clinical hold for "design issues" if the protocol design is considered inadequate to meet the objectives of the study. These studies may also be placed on clinical hold for the same reasons as Phase I studies.

Phase III

Phase III studies are performed to determine efficacy of the product. Phase III also generally contributes the bulk of the safety data in support of licensure. Manufacturing reproducibility is normally also addressed during Phase III, through the production and testing of three consistency lots.

Although two clinical trials are considered the standard for licensure, one well-designed study can be adequate if the result is compelling, (e.g., based on robust data from a multicenter trial) (Food and Drug Administration, 1998, http://www.fda.gov/cber/gdlns/clineff.pdf).

The choice of endpoint of Phase III studies deserves special consideration in the context of emerging infectious diseases. The most commonly used endpoint for Phase III studies is efficacy in a randomized, double-blind, placebo-controlled field efficacy study. However, in some cases, the prevalence of the disease is too low to easily perform field efficacy studies. In other cases, the time required for severe complications of disease to develop may be long, thus making true efficacy studies more difficult to perform.

Where the disease is not life threatening and alternative treatments are available, it may sometimes be possible to perform challenge studies to demonstrate vaccine efficacy. For example, a challenge study was used to evaluate efficacy of live attenuated influenza vaccine (Treanor et al., 1999). In such challenge studies, the ability of the vaccine product to prevent disease may be evaluated against disease rates in an appropriate comparison group. However, challenge studies (whether placebo-controlled or not) can sometimes be unethical, especially when the disease is severe, the spectrum of disease is not well understood, or treatments are not available.

In some cases, scientifically justified surrogate markers that predict efficacy may be used as endpoints in Phase III studies. For example, immunological surrogates were used to license vaccines against hepatitis B, Hemophilus influenzae type B, and meningococcus. Every year, vaccines against new strains of influenza virus are licensed based primarily on immunological data showing antigenic relatedness between the vaccine and circulating influenza strains. Recently performed studies of human papillomavirus vaccine used prevention of infection with oncogenic serotypes of virus, together with prevention of pre-cancerous lesions, as a predictor of the vaccine's ability to prevent cancer (Koutsky et al., 2002). Considerable discussion has occurred regarding the development of appropriate surrogate markers for HIV vaccines, especially therapeutic vaccines, for which parameters associated with immune system function may well provide reasonable surrogate endpoints (Nabel, 2002). When surrogate markers are not well established, licensure may be pursued under the "Accelerated Approval" rules (see "Accelerated Approval").

Even if surrogate markers are not a part of the initial licensure, development of surrogate markers for protection against disease is critical both in vaccine development and as endpoints in subsequent comparability studies, as may be done to support post-licensure vaccine manufacturing changes or concomitant administration studies. Surrogate markers, which usually are validated in Phase III, provide clinical trial endpoints that can be used to predict outcomes without requiring actual efficacy trials to be done. Without such surrogate markers of efficacy it becomes very difficult to maintain an understanding of the product over time.

There is no requirement that efficacy studies be performed in the United States. Thus, it may be possible to design foreign vaccine efficacy studies for diseases that are not sufficiently prevalent in the United States to study. For example, substantial efficacy data for hepatitis A, Japanese encephalitis, and pertussis vaccines were obtained overseas. When the bulk of vaccine development has occurred overseas, the FDA carefully examines the data to assure that sufficient information exists to assure vaccine safety and efficacy in domestic U.S. populations, including explicit consideration of ethnic factors. Such information may be obtained by performing bridging studies in U.S. populations.

Guidance documents addressing the evaluation of vaccines in special populations or for specific indications are also sometimes issued. Guidances on clinical studies were recently made available by CBER for evaluating new influenza vaccines (Center for Biologics Evaluation and Research, 2006, http://www.fda.gov/Cber/gdlns/trifluvac.htm; Center for Biologics Evaluation and Research, 2007, http://www.fda.gov/Cber/gdlns/trifluvac.pdf). An additional guidance on HIV vaccine trials for pediatric populations was also recently issued (Center for Biologics Evaluation and Research, 2006, http://www.fda.gov/Cber/gdlns/pedhiv.pdf). A recently passed law requires the evaluation of products in pediatric populations, when there is a likelihood that they may benefit children (FDA Amendments Act of 2007, 2007). Later-phase vaccine studies may need to be reported to the Clinical Trials Databank (Food and Drug Administration, 2004; FDA Amendments Act of 2007, 2007).

It is not always possible to design Phase III studies that meet these criteria. Under those circumstances, the Animal Rule may be used to show efficacy (see "Animal Rule").

Meetings with FDA during Product Development

FDA generally encourages and values effective communication between sponsors and reviewers. FDA does not generally recommend piecemeal discussion of issues associated with a product, but generally prefers to consider as much information as possible, in order to evaluate all aspects of the development plan in context. However, meetings may separately focus on chemistry, manufacturing and control issues (Food and Drug Administration, 2002, http://www.fda.gov/cber/gdlns/pregexp.pdf), or on clinical issues. Even when meetings do not take place, there may be significant back-and-forth discussion between a sponsor and FDA, in the form of written communication in the context of the IND.

Meetings between the FDA and sponsors often occur at the pre-IND stage, the end of Phase I (for products that have been designated as "fast track"), end of Phase II, and pre-Biologics License Application (BLA) filing. Specific regulations govern the end of Phase II and pre-BLA meetings (21 CFR 312.47 Meetings, 2007). Additional guidance exists on meetings for products covered under the Prescription Drug User Fee Act (Food and Drug Administration, 2000, http://www.fda.gov/cber/gdlns/mtpdufa.pdf).

Biologics License Application (BLA)

Biological products, including vaccines for human use, are licensed under the authority of Section 351 of the Public Health Service Act (42 USC. 262). The

Code of Federal Regulations specifies general requirements for biological products (21 CFR 600 Biological Products, 2007), and also summarizes licensing regulations (21 CFR 601 Licensing, 2007). Under these provisions, licensure requires the demonstration of safety, purity, and potency. Safety is defined as "the relative freedom from harmful effect to persons affected, directly or indirectly, by a product, when prudently administered, taking into consideration the character of the product in relation to the condition of the recipient at the time." Purity is defined as "relative freedom from extraneous matter in the finished product, whether or not harmful to the recipient or deleterious to the product. Purity includes but is not limited to relative freedom from residual moisture or other volatile substances and pyrogenic substances." Additional requirements regarding purity are specified by regulation (21 CFR 610.13, Purity, in Code of Federal Regulations, 2007). Potency "is interpreted to mean the specific ability or capacity of the product, as indicated by appropriate laboratory tests or by adequately controlled clinical data obtained through the administration of the product in the manner intended, to effect a given result." It is necessary for the product to have sufficient stability to maintain these attributes throughout the dating period. Vaccines must also adhere to the "General Biological Products Standards" (21 CFR 610 General Biological Products Standards, 2007).

BLAs are accepted in electronic Common Technical Document form, which allows manufacturers to file harmonized applications in multiple countries (Food and Drug Administration, 2005, http://www.fda.gov/cber/gdlns/esubapp.htm). License applications generally include all information required to evaluate the product, and thus stand alone, without needing to rely on reference to previously submitted materials.

During the licensure evaluation process, the conduct of the IND clinical studies may be closely examined in a process called "bioresearch monitoring," which involves inspection of IND sites to assure appropriate conduct of studies and record keeping. In addition, particular scrutiny is devoted to the label claims (including indication) made by the sponsor (and the regulations regarding labeling were revised in 2006) (21 CFR 610, subpart G: Labeling Standards, 2007; 21 CFR 201, Labeling, 2007). The manufacturing establishment (21 CFR 600, Subpart B Establishment Standards, 2007) and ability to adhere to current good manufacturing processes (21 CFR 210 and 211 Current Good Manufacturing Practice in Manufacturing, Packing, or Holding of Drugs, 2007) are also closely examined, including a pre-licensure inspection of the facilities.

In evaluation of a BLA, FDA will often consult with the Vaccines and Related Biological Products Advisory Committee (VRBPAC) [see "Vaccines and Related Biological Products Advisory Committee (VRBPAC)"].

Post-Marketing Phase

Under conditions of real-world use, the manufacturer is required to obtain and report information regarding the safety of licensed products (21 CFR 600, Subpart D Reporting of Adverse Experiences, 2007; Food and Drug Administration, 2001, http://www.fda.gov/cber/gdlns/safety031201.pdf).

Additional post-marketing safety surveillance is performed through the Vaccine Adverse Events Reporting System (VAERS), which is maintained by the CDC and the FDA to collect patient- and physician-initiated reports related to vaccine safety (Iskander et al., 2004). Data from VAERs are periodically analyzed to identify potential vaccine safety signals that merit further follow-up.

Recent legislation increased the ability of the FDA to require post-marketing studies (FDA Amendments Act of 2007, 2007). Even prior to this legislation, at the time of licensure, many vaccine manufacturers committed to perform additional post-licensure studies. Some of these studies may be in the context of Accelerated Approvals or Animal Rule approvals, while others may be related to obtaining more detailed information about the safety or duration of efficacy of a vaccine. For example, the manufacturer of a rotavirus vaccine agreed to perform additional studies of intussusceptions at the time of licensure, and the manufacturer of varicella vaccine agreed to perform long-term studies to better understand the duration of vaccine efficacy (Krause and Klinman, 1995), to also allow a better understanding of product performance once wild-type boosting of vaccine responses became less prevalent. Annual reports of post-marketing studies are required (21 CFR 601.70 Annual Progress Reports of Post-marketing Studies, 2007).

Once a product is licensed, changes to the indication or method of manufacture may be submitted as supplements to a BLA (21 CFR 601.12 Changes to an approved application, 2007), which (depending on the scope of the changes) often require FDA approval prior to implementaion. The FDA also performs inspections of the facilities used for the manufacture of licensed products (21 CFR 600, Subpart C Establishment Inspection, 2007). The FDA also examines test results on vaccine lots prior to marketing, and may also perform its own testing, providing additional assurance of product performance.

Other Nonclinical Issues that Affect All Stages of Development

Chemistry, manufacturing, and control issues that need to be addressed in order to obtain licensure are summarized in a guidance document (Center for Biologics Evaluation and Research, 1999, http://www.fda.gov/Cber/gdlns/cmcvacc.pdf). In this section, a summary of cell substrate issues and setting of specifications is provided.

Cell Substrate Issues

Because emerging infectious diseases may be associated with new viruses, the possibility exists that the vaccine may require novel cell substrates for optimal growth and manufacturing efficiency. This may be true for vectored vaccines, for which a replication-defective or replication-deficient virus will grow only in specific cell types that provide a missing growth factor, and may also be true for live-attenuated or inactivated vaccines.

Guidance documents particularly relevant to cell substrate issues include the Draft Guidance for Industry: Characterization and Qualification of Cell Substrates and Other Biological Starting Materials Used in the Production of Viral Vaccines for the Prevention and Treatment of Infectious Diseases (Center for Biologics Evaluation and Research, 2006, http://www.fda.gov/cber/gdlns/vaccsubstrates.htm) and ICH document Q5A (International Conference on Harmonization, 1999, http://www.ich.org/LOB/media/MEDIA425.pdf).

Introduction of new cell substrates for vaccine manufacture, especially for live-attenuated vaccines, is a complex matter. The earliest viral vaccines were produced in primary cells obtained directly from animals, such as calf lymph used to produce smallpox vaccines, or monkey kidney cells used to produce polio vaccines. In the 1950s, vaccine experts believed that production of vaccines in nonhuman, normal cells would be the best way to assure vaccine safety and freedom from the theoretical risk of oncogenicity associated with cell substrate components that would inevitably be a part of the vaccine. When SV40 was discovered as a contaminant both of Rhesus monkey kidney cells and of early poliovirus and adenovirus vaccines, the wisdom of this approach was questioned. Although poliovirus vaccine strains were treated with antibody to remove SV40, and production was changed to African Green monkey kidney cells (in which SV40 contamination, if it occurs, is more readily detected), reports that SV40 DNA could be detected by polymerase chain reaction in samples from individuals with various human cancers led to renewed concern over this historical contamination event. Although an IOM report concluded that there was insufficient evidence to accept or reject a hypothesis of causality between SV40-containing polio vaccines and cancer (Stratton et al., 2002), the fact that these concerns developed shows the high degree of importance of assuring that vaccine cell substrates are free of adventitious agents and are safe to use for vaccine production.

Over time, new vaccines, such as the rubella vaccine and the varicella vaccine, were produced using normal human diploid cells. The ability to readily bank these cells allows the performance of one set of exhaustive tests on a master cell bank to provide a high degree of assurance that adventitious infectious agents are not present. Other vaccines continue to be produced in primary cells, including eggs and other avian-derived cells. A recently approved rotavirus vaccine is produced in continuous Vero cells. Some investigational vaccines are produced in weakly tumorigenic cells, under defined circumstances that quantify the theoretical risk of oncogenic events, with limitations on the total quantity of cell substrate DNA and with thorough testing to assure that there is no reasonable chance that residual components of the cell substrate could be oncogenic.

The need to pay attention to the cell substrate used for vaccine production extends to a need to pay attention to the cells and the conditions used for development of a vaccine seed. If a vaccine seed has been passaged in poorly characterized cells, or may have been exposed to untested biological reagents (such as serum or trypsin), the potential for contamination with viruses that might infect the cells or biological reagents exists. Thus, even very early in vaccine development, it is critical to document sources and lot numbers of such reagents, and if complete testing of cell substrates is not feasible, retention of cell substrate samples to allow later testing could be very useful. Using carefully devised protocols, vaccine seeds that have been exposed to unknown cells or reagents may sometimes be purified (e.g., by serial plaque purification). However, the recommended approach is to consider and address cell substrate issues as early in vaccine development as possible.

To assure that vaccines are free of agents of transmissible spongiform encephalopathy (TSE), it is important to consider the sourcing of serum and other animal or human-derived vaccine materials used in vaccine manufacture. CBER's current thinking on this topic is made available on the internet (Center for Biologics Evaluation and Research, 2007, http://www.fda.gov/cber/bse/bse.htm)

Summaries of recent international meetings further address issues associated with introduction of new cell substrates (Sheets and Petricciani, 2006).

Specifications, Potency, and Stability

Specifications for biological products are defined (21 CFR 600.10 Personnel, 2007) as "the quality standards (i.e., tests, analytical procedures, and acceptance criteria) provided in an approved application to confirm the quality of products, intermediates, raw process materials, container closure systems, and other materials used in the production of a product." Adherence to specifications at the time of lot release helps to assure that a product will be safe and effective throughout its dating period. Thus, development of appropriate specifications for a product is a critical component of product development.

According to regulation, potency refers to the specific ability or capacity of the product, as indicated by appropriate laboratory tests or by adequately controlled clinical data obtained through the administration of the product in the manner intended, to effect a given result. Potency assays are laboratory tests that may be applied to individual lots of product, in order to predict that they will achieve the desired effect. Normally, for a vaccine or other biological product, the potency reflects the quantity of active ingredient. Because of the complexity of vaccines, though, it often is important for the potency assay to provide not only an indication of quantity, but also the total activity of that active ingredient. For many products, it is important to distinguish potency from strength; strength refers to the quantity of the main ingredient in the product, while the term "potency" implies that information is available to predict the capability of that ingredient to achieve clinical benefit.

Potency assays play an important role throughout the product development life cycle. While fully validated assays may not be required until licensure, it is important to have a good understanding of vaccine potency starting even before Phase I. Each progressive phase of development is based on the assumption that potency was correctly determined in previous studies. Thus, doses tested in Phase I studies rely on the assumption that potency was accurately determined in the supporting animal studies. In turn, Phase II and Phase III studies rely on the assumption that potency was accurately determined in supporting safety and immunogenicity studies. Once the product is licensed, potency assays are used to assure that marketed product contains a quantity of active ingredient similar to that which was shown to be safe and effective in the clinical trials. When there are gaps in this understanding of potency, interpretation of the data, and possibly the progress of the product through the regulatory process, are in jeopardy.

As clinical development progresses, measurement of potency may change. At the time a product is first developed, it may not be known what in vitro characteristics are likely to correlate with clinical benefit. This may be particularly unpredictable before clinical trials have tested product with a range of potencies, sometimes measured in different ways. The need to understand the performance of assays over time and through clinical development suggests the value of maintaining stable reference preparations against which potency results may be standardized, and of retaining (under conditions of high stability) samples of material used in clinical development, in the event retesting of potency in updated assays should become necessary.

In addition to prediction of clinical benefit, potency assays ideally have other attributes. The need to ultimately validate these assays implies that they should have characteristics that are amenable to validation [for a more detailed discussion of assay validation, see ICH document Q2(R1)] (International Conference on Harmonization, 2005, http://www.ich.org/LOB/media/MEDIA417.pdf). Larger amounts of potency ideally should correlate with greater activity or effect (preferably, with linear or first-order kinetics). Potency assays should also be useful in monitoring product stability—degradation of product over time should be detectable and measurable using the selected potency assays. In addition, potency assays should be selected such that they can be reproducibly performed with reasonable precision—if assay variability is too high, it may become too difficult to manufacture product within the potency range necessary to assure both adequate efficacy at end-expiry and safety at release.

For vaccines, potency assays often detect the ability of the product to achieve a desired effect in a cell culture system or other in vitro assay. For example, for live virus vaccines, potency assays may be related to infectivity in cell culture assays. For inactivated virus vaccines, potency assays may be related to the total amount of viral antigen present in the product, sometimes using conformation-dependent immunoassays that are capable of detecting product degradation. Potency may also be assayed in animal models. However, animal models are more difficult to use, are time consuming, and frequently have greater variability than in vitro assays, suggesting the value of attempting to identify in vitro predictors of efficacy and safety early in product development.

To assure that vaccines remain potent and safe through the dating period, it is important to understand the stability of the vaccine. Stability studies normally focus on potency and safety measures and on factors that are likely to affect potency or safety, but product stability also can be determined based on the presence of a potentially deleterious degradation

product. A recent WHO guidance further addresses vaccine stability (World Health Organization, 2006, http://www.who.int/biologicals/publications/trs/areas/vaccines/stability/en/index.html).

For some relatively labile vaccines, it may be important to use information about product stability to understand the doses of vaccine that are actually given during a clinical trial. End-expiry potency specifications are generally set based on a vaccine dose that is effective in a clinical trial—the specification implies that doses below this level may not be effective. Vaccine release potency specifications are generally set based on a statistical analysis of end-expiry potency, the dating period of the vaccine, the stability of the vaccine through that dating period, and the potential errors in measurement of vaccine potency and stability. Specifications on other vaccine parameters, such as moisture or pH, may be based on the conditions under which vaccine stability was studied. Still other specifications may represent product quality parameters, such as residual components of manufacture (such as albumin) or safety parameters, such as sterility and adventitious agent tests. Generally, specifications describe the range of quality parameters under which the product is shown to be safe and effective.

Additional information regarding product quality may be obtained by monitoring the manufacturing process, independently of final specification results. It may be desirable to use test results to monitor the production process, to provide early warnings that some aspect of production may be drifting out of control, even if the final product is within the range of the specifications. Attributes appropriate for monitoring the manufacturing process are generally selected based on a good understanding of the scientific principles underlying product manufacture, and may be subject to validation, as appropriate (Lubiniecki et al., 2003; Ganzer et al., 2005).

If a licensed product fails to meet a specification, it cannot be released to the public without specific FDA approval, generally obtained via a BLA supplement. Considerations in setting lot release specifications for live virus vaccines are discussed in recent articles (Gombold et al., 2006a, 2006b).

Vaccines and Related Biological Products Advisory Committee (VRBPAC)

The Vaccines and Related Biological Products Advisory Committee (VRBPAC) serves as the principal external advisory board to the FDA in considering issues associated with the study and licensure of vaccines. In addition, the VRBPAC provides external oversight of OVRR's laboratory research programs, to help assure their excellence and continued contributions to public health.

Questions for the VRBPAC typically relate to design of studies under IND (including the question of whether safety issues have been adequately addressed), to fundamental issues underlying licensure of new vaccines (such as safety, efficacy, testing, or manufacture), or to the expansion of indications for existing vaccines into new populations.

By charter, the VRBPAC includes 12 voting members including a Chair. These members typically include one technically qualified person who is associated with consumer interests. A non-voting industry representative, as well as additional outside experts relevant to the topics under discussion may also supplement the Committee.

The VRBPAC schedule, as well as minutes and materials associated with past meetings, are available at the FDA Web site (Center for Biologics Evaluation and Research, 2006, http://www.fda.gov/Cber/advisory/vrbp/vrbpmain.htm).

SPECIAL REGULATORY PATHWAYS THAT CAN ADDRESS EMERGING INFECTIOUS DISEASES VACCINE ISSUES

Certain special regulatory pathways are potentially of relevance to the development of vaccines against emerging infectious diseases. These include the Orphan Drug Program, Accelerated Approval, the Animal Rule, Fast Track Programs, Priority Reviews, Treatment INDs, and Emergency Use Authorizations.

Orphan Drug Program

The Orphan Drug Act (Orphan Drug Act, 1983) specifies several advantages for developers of products designed to treat diseases or conditions that are rare in the United States. A rare disease or condition is defined as one that either affects fewer than 200,000 people in the United States, or if it affects more, there is no reasonable expectation that development costs could be recovered from U.S. sales alone.

The Act provides that the secretary of HHS will provide written recommendations regarding clinical and nonclinical development programs for products designated as Orphan Drugs. Moreover, the Act provides that if an Orphan Drug is licensed, no competing product will be licensed for seven years, unless it is shown to be clinically superior to the original

Orphan Drug. Sponsors of Orphan Drugs are encouraged to make these products available under Treatment INDs, even prior to licensure, to individuals who have the rare disease, and for whom an alternative treatment is not available. In addition, the Act provides for government funding to support the development of Orphan Drugs.

The implementation of the Act is described in the Code of Federal Regulations (21 CFR Section 316 Orphan Drugs, 2007). Major Orphan Product activities are coordinated by the FDA's Office of Orphan Products Development, including the administration of a grants program that funds clinical studies in support of the development of Orphan Products. This mechanism has been used to fund vaccine studies, including clinical studies for vaccines against Q fever, and of a live-attenuated cytomegalovirus vaccine.

Vaccines against infectious diseases may be designated as orphan products, although this designation has historically been rare, and obstacles to development of orphan vaccines are perceived to exist (Lang and Wood, 1999). Because most vaccines are preventive, rather than therapeutic, FDA interprets the 200,000 person cutoffs in the Act to refer to the number of individuals for whom the vaccine would be indicated as of the date of designation of the product as an Orphan Drug. Examples of such products (as of January 2008) are shown in Table 14.2. These include an investigational live-attenuated vaccine directed against Japanese encephalitis virus, manufactured by Boran Pharmaceuticals in Seoul, Korea, which was designated as an Orphan Product in 1999, and a baculovirus-produced protein subunit vaccine against parvovirus B19, manufactured by Medimmune, Inc., indicated to prevent aplastic crises in individuals with sickle cell anemia. More recently, an Epstein-Barr virus gp350 vaccine, designed to prevent post-transplantation lymphoproliferative disease, was designated as an Orphan Product. An example of a licensed vaccine-related Orphan Product is Vaccinia Immune Globulin, used to prevent complications of vaccinia immunization, manufactured by Dynport Vaccine Company, in Frederick, MD. This product was designated as an Orphan Drug in 2004, and received licensure in 2005.

Accelerated Approval

Accelerated Approval rules permit licensure of a product based on surrogate endpoints, where it is not practical to rapidly study endpoints that directly indicate clinical benefit. Rules governing Accelerated Approval of biologics, including vaccines, are promulgated in the regulations (21 CFR 601, subpart E Accelerated Approval of Biological Products for Serious or Life-threatening Illnesses, 2007). These rules apply to biological products that have been studied for their safety and effectiveness in treating serious or life-threatening illnesses and that provide meaningful therapeutic benefit to patients over existing treatments. The Accelerated Approval regulations authorize FDA to license a biological product on the basis of adequate and well-controlled clinical trials showing an effect on a surrogate endpoint that is reasonably likely, based on epidemiologic, therapeutic, pathophysiologic, or other evidence to predict clinical benefit, or an effect on a clinical endpoint other than survival or irreversible morbidity. Where there is uncertainty as to the relationship between the study endpoints and actual clinical benefit, licenses granted under the Accelerated Approval mechanism must also

TABLE 14.2 Vaccine-related products that have been designated as orphan products

Product	Indication	Sponsor
Cytomegalovirus DNA vaccine with plasmids expressing pp65 and gB genes	Prevention of cytomegalovirus (CMV) viremia, and asociated clinically significant CMV disease complications in at-risk	Vical Incorporated
Japanese encephalitis vaccine (live, attenuated)	Prevention of Japanese encephalitis	Boran Pharmaceuticals
Vaccinia Immune Globulin (Human) Intravenous	Treatment of severe complications from the smallpox vaccine	DynPort Vaccine Company LLC
Recombinant Epstein-Barr virus gp350 glycoprotein vaccine: Brachet, 12, B-6041-Gosselies	Prevention of post-transplantation lymphoproliferative disorders in pediatric recipients of solid-organ transplantation	Henogen S.A.
Parvovirus B19 (recombinant VP1 and VP2; S.frugiperda cells) vaccine	Prevention of transient aplastic crisis in patients with sickle cell anemia	MedImmune, Inc.

be supported with post-marketing studies to verify and describe the actual clinical benefit of the product.

In cases where a well-established surrogate marker exists and is known to predict clinical benefit, evaluation under the Accelerated Approval mechanism is unnecessary, and does not lead to a requirement for post-marketing studies. However, for most emerging infectious diseases, the establishment of surrogate markers for efficacy may be very difficult early in the course of product development to allow their use without verification by post-marketing studies, as specified under the Accelerated Approval rules.

In addition, the FDA has the authority, for safety reasons, to restrict the distribution and use of products approved using the Accelerated Approval rule, prior to verification of clinical benefit in the post-marketing studies. This may include limitation of product use to physicians who possess certain training or experience, to certain types of facilities, or to certain types of medical procedures. However, any such limitations must be commensurate with the actual safety concerns presented by the product.

Licenses granted under Accelerated Approval may be withdrawn if the post-marketing studies fail to show the anticipated clinical benefit, if the postmarketing studies are not performed with due diligence, if post-marketing restrictions cannot assure the safe use of the product, if the sponsor fails to adhere to any post-marketing restrictions, if the promotional materials are false or misleading, or if other evidence shows the product not to be safe and effective under its conditions of use.

Animal Rule

Vaccine efficacy may generally be shown either in clinical trials under field conditions, by demonstration of efficacy in challenge studies (where ethical), or by demonstration that the vaccine induces an immunological correlate of human protection (subject to verification in post-marketing studies if the correlate is not well established and licensure is obtained under Accelerated Approval). In some cases, it may be necessary to develop a vaccine under conditions where none of these three pathways are feasible. For example, a disease may not be prevalent enough to allow scientifically valid vaccine efficacy trials in humans to be performed, performance of challenge studies may be unethical, and human correlates of protection may not be well understood. The Animal Rule was promulgated (21 CFR 601.90 subpart H Approval of Biological Products when Human Efficacy Studies Are Not Ethical or Feasible, 2007; 21 CFR 314.610 Approval based on evidence of effectiveness in studies in animals, 2007) in order to provide a pathway to licensure for such products. Vaccines designed to prevent many emerging infections may fall into this category.

According to the Animal Rule, the FDA may grant a license based on animal efficacy data when definitive human efficacy studies cannot be performed due either to ethical or practical reasons. The Animal Rule also may not be used if any other regulatory pathway to approval exists, such as Accelerated Approval based on surrogate markers. Moreover, the Animal Rule is not necessarily a faster pathway to approval than other regulatory pathways. The animal efficacy data must establish that there is a reasonable likelihood that the product would produce clinical benefit in humans. The use of the Animal Rule requires the following: (1) reasonably well-understood pathophysiological mechanisms by which the disease agent causes toxicity (i.e., disease) and by which the product would prevent or substantially reduce that toxicity, (2) demonstration of efficacy in more than one animal model reasonably expected to predict effect in humans, or in a single well-characterized animal model that has been shown to predict human response, (3) a clear relationship between the endpoint of the animal study and the desired outcome in humans (i.e., prevention of death or major morbidity), and (4) sufficient pharmacokinetic, pharmacodynamic, or other data exist to support selection of an appropriate human dose.

Animal Rule studies supporting an efficacy claim must be performed in accordance with preexisting requirements for GLP (21 CFR 58 Good Laboratory Practices for nonclinical laboratory studies, 2007) and the Animal Welfare Act (7 USC. 2131).

The Animal Rule does not eliminate any of the other requirements for U.S. licensure, but is merely intended to allow the substitution of animal for human efficacy data under circumstances where there is no alternative. Thus, a sufficient human safety database must be obtained. Moreover, the use of the Animal Rule is subject to three additional conditions: (1) submission of a plan for performance of post-marketing studies that verify and describe the biological product's clinical benefit, and a requirement to perform such studies with due diligence when they become feasible and ethical, (2) the potential for FDA to restrict the distribution and use of the product, to assure its safety, and (3) the requirement to provide specific patient labeling describing the basis for approval, risks, and other relevant information to each patient who receives a product licensed by the Animal Rule.

In designing Animal Rule efficacy studies, it is thus particularly important to consider the desired label indication and its relationship to the study endpoints,

the appropriate vaccine dose for the animal studies, and the appropriate challenge dose and its route of exposure. If the development plan includes the use of laboratory assays to bridge animal and human data (e.g., immunogenicity assays), these assays should be validated for use both in human and animal samples. Statistical considerations, including sample size and power calculations, also influence the design of Animal Rule efficacy studies.

FDA generally recommends extensive discussion with the Agency if the use of the Animal Rule to support product efficacy is anticipated.

Fast Track Program

FDA also has mechanisms to facilitate the review of products that demonstrate the potential to address unmet medical needs and are intended to treat life-threatening or serious conditions. These programs are called "fast track" programs, and were originally codified by law in 21 USC 356, Section 506.

A guidance document (Food and Drug Administration, 2006) provides further details regarding the definition of a serious condition (at a minimum, the condition should be associated with morbidity that has a substantial impact on day-to-day functioning). A drug is deemed to be intended to treat a serious condition if it is being evaluated for its effect on a serious manifestation or symptom of the condition or its ability to prevent the condition, when it is scientifically reasonable to assume that preventing the condition will prevent the serious consequences. A medical need is considered to be unmet when there is no previously existing available therapy for the condition, when a benefit to using the new product instead of or in combination with previously existing therapies is shown, or when all previously existing therapies were approved under the Accelerated Approval regulations. FDA also will evaluate the potential of the product to address these unmet medical needs. A product may be designated for Fast Track at any time prior to licensure in the drug development process.

Designation as a Fast Track product provides several advantages to a sponsor. Meetings and frequent communication between the sponsor and FDA are strongly encouraged, including an end-of-Phase-I meeting. Because Fast Track products are intended for rapid evaluation, this end-of-Phase-I meeting is particularly important for mapping out the development and regulatory plan.

The major advantage of Fast Track designation occurs during the application review process. Because the criteria for entry into Fast Track and for obtaining Priority Reviews are similar, Fast Track products are often eligible for Priority Review. In addition, FDA may consider permitting partial submission of Fast Track license applications (i.e., early submission of some sections, such as the CMC or Toxicology Sections) when the clinical studies are finished or near completion but are not yet ready to be submitted to the license application, and when FDA agrees that preliminary evaluation of the clinical data supports a determination that the product may be effective. While early submission of some portions of the application does not change FDA's review timelines, it often permits early communication regarding important review issues, and thus increases the likelihood that the review can be completed in a single cycle.

Fast Track products also are eligible for approval under the Accelerated Approval regulation (see "Special Regulatory Pathways that can Address Emerging Infectious Diseases Vaccine Issues: Accelerated Approval"), when they meet those criteria.

Priority Review

The CBER, which is responsible for regulation of vaccines, designates a BLA as a "priority" if the product, if approved, would be a significant improvement in the safety or effectiveness of the treatment, diagnosis, or prevention of a serious or life-threatening disease. Products selected for Priority Review receive regulatory Action Letters (either Complete Response letters or Approval Letters) on a more rapid timetable than those designated as standard applications, in conformance with the Prescription Drug User Fee Act mandated timelines. In 2005, a Priority Review was assigned a timeframe of 6 months, while a standard review was assigned 10 months to the time of regulatory action.

The similarity in the language that describes criteria for Fast Track and Priority Review suggests that Fast Track applications would normally be considered for Priority Review. However, the language of the Priority Review criteria, requiring that the product be a significant advantage in safety, effectiveness, diagnosis, or prevention would appear to set a higher standard than that for Fast Track, in which an unmet medical need is defined on the basis of demonstrable benefit relative to previously existing treatments, rather than on the basis of "significant improvement."

Nonetheless, many vaccine products designed to address emerging infectious disease issues could be interpreted as meeting the basic criteria for Priority Review.

Treatment IND

Investigational drugs may sometimes be used for unapproved indications, not as part of a clinical trial, under a Treatment IND (21 CFR 312.34 Treatment use of an investigational new drug, 2007). The purpose of the Treatment IND regulation is to facilitate the availability of promising new drugs to seriously ill patients as early in the drug development as possible, and to obtain additional data on the drug's safety and effectiveness. Normally, drugs may be made available under Treatment IND during or after Phase 3 investigations, although this may sometimes occur during Phase 2, in the case of a life-threatening illness. To qualify, the drug must be intended to treat a serious or immediately life-threatening disease, there must be no available comparable or satisfactory alternative to treat that stage of the disease in the intended patient population, the drug must be under investigation in clinical trials (or all clinical trials must be completed), and the sponsor must be pursuing marketing approval with due diligence. Use of a drug under Treatment IND requires compliance with IND process safeguards, including those governing informed consent and institutional review boards. The regulations also provide conditions under which the FDA may deny Treatment INDs.

Early in the 2004 influenza vaccination season, vaccine shortages caused by the shutdown of one manufacturer's production led to markedly increased demand relative to supply. To meet this demand, some influenza vaccine manufacturers with vaccines licensed in other countries offered the use of their vaccines to U.S. populations under IND (HHS Buys 1.2 Million Doses of Flu Vaccine, 2005). Thus, Treatment IND was shown to be a potential option for distribution of investigational vaccines to at-risk U.S. citizens.

Project Bioshield and Emergency Use Authorizations

In the case of public health emergencies, use of unapproved products (or use of approved products for unapproved indications), including a waiver of GMP requirements, may be authorized under the Project Bioshield Act of 2004, codified as FD&C Act Section 564, or 21 USC. 360bbb-3. Such an Emergency Use Authorization requires declaration of an actual or potential emergency by the Secretary of HHS. This declaration may follow the determination by the Secretary of Defense that a military emergency or the potential for a military emergency exists. The declaration lasts until the emergency is considered to no longer exist, or for one year. The Secretary of HHS may renew the declaration in one-year increments. Each such declaration must be published in the Federal Register. Emergency Use Authorizations under this law require the Secretary of HHS to determine, after consultation with the NIH and the CDC Directors, that the specified agent can cause a life-threatening or serious disease or condition, it is reasonable to believe that the product may be effective, and that the known and potential benefits of the product outweigh the potential risks, and that there is no reasonable alternative. Such products may only be used if the health care providers and recipients are adequately informed of the circumstances and the known risks and benefits of the product, if appropriate means of monitoring for adverse events are in place, and if appropriate manufacturer record keeping takes place. The legislation does not confer on the government the authority to require either manufacturers to produce vaccines or individuals to take them. A recently issued guidance document provides further information on Emergency Use Authorizations (Food and Drug Administration, 2007, http://www.fda.gov/oc/guidance/emergency-use.html).

In January 2005, the Secretary of HHS published an Emergency Use Authorization for the use by the military of anthrax vaccine for the indication of preventing inhalation anthrax. In this case, a court injunction had previously prevented the military from continuing its anthrax vaccination program, due to legal concerns about the original basis for licensure of the vaccine. The Emergency Use Authorization thus allowed the military to resume its anthrax vaccination program (on a voluntary basis).

Emergency Use Authorization under the Project Bioshield Act thus provides a mechanism by which products intended to address rapidly evolving public health emergencies may be quickly made available to the public. This does not, however, address the means to obtain the manufacturing capacity that would be required for widespread vaccination, even if authorized under the authority granted by this law.

CONCLUSIONS

The U.S. regulatory process balances the need to make new and innovative vaccines, that positively influence public health, with the need to assure that the vaccines and the procedures used to test them are safe. While emerging infectious diseases present special challenges to the regulatory process, new approaches provide pathways by which these vaccines may be licensed.

As challenges like those posed by emerging infectious diseases are further discussed, it is likely that the regulatory process will evolve to further clarify and perhaps even provide new pathways to licensure for vaccines to prevent them. It will remain important for those working in rapidly occurring disease areas to keep abreast of these regulatory innovations.

Vaccine Safety

John D. Grabenstein
Merck Vaccine Division, West Point, PA, USA

OUTLINE

ABSTRACT

Vaccines are typically given to healthy people to keep them healthy. As a result, vaccines are the class of medications least tolerant of adverse reactions. If all medications were arrayed along a spectrum portraying degrees of safety, today's licensed vaccines would appear toward the end labeled "safest." To provide vaccines with the highest standards of safety, vaccine developers, regulators, and immunization program administrators work to minimize the types and frequency of adverse reactions that occur after vaccination. The key to assessing vaccine safety effectively is to be objective and to assess carefully all available data. Figuratively, one's eyes and ears must always be open to new findings. In assessing vaccine safety, it is important to differentiate cause-and-effect relationships from mere temporal relationships. This helps avoid the post hoc, ergo propter hoc fallacy. The incidence and severity of adverse reactions to immunization can be measured with greatest objectivity in randomized, double-blinded, placebo-controlled trials. But the acceptability of a vaccine's adverse-reaction profile is not fixed in an absolute sense across all time and space. Rather, a series of judgments are made, especially in relation to differing degrees of disease burden (and hence, vaccine value) over time or in different settings. This chapter describes multiple historical examples of vaccine-safety issues, including issues that evolved over the course of years or decades. These examples are instructive to scientists planning vaccine-safety evaluations for future vaccines or vaccination programs. Vaccines have succeeded so well that many of these vaccine-preventable diseases are virtually unheard of by clinicians or the public. Separating true causes from false ones is vitally important for both society and individuals. Using a disciplined, rational, methodical approach to attributing blame where appropriate, or clearing a vaccine's reputation where there is no basis for a link, continues to be the proper approach. Using the tools of science, scientists are most likely to find the truth and least likely to fool themselves about vaccine safety. The key to assessing vaccine safety is to be objective, assess carefully all available data, and be open to new findings.

Vaccines are typically given to healthy people to keep them healthy. Because of this, vaccines are the class of medications least tolerant of adverse reactions. To create vaccines with the highest standards of safety, vaccine developers, regulators, and immunization program administrators work to minimize the types and frequency of adverse reactions that occur after vaccination. These actions and judgments are undertaken in light of a vaccine's benefit in preventing an infectious disease (Nordenberg, 1999; Meadows, 2002; Grabenstein, 1999).

In pharmaceutical development, "efficacy" and "safety" are terms of art frequently used in tandem. Just as efficacy is an intricate construct, qualitatively and quantitatively, so is safety. The key to assessing vaccine safety effectively is to be objective and to assess carefully all available data. Figuratively, one's eyes and ears must always be open to new findings.

If all medications were arrayed along a spectrum portraying degrees of safety, today's licensed vaccines would appear toward the end labeled "safest." In contrast, cancer chemotherapeutic agents, renowned for their adverse-reaction profiles, would appear toward the end labeled "least safe." Yet the actions of pharmaceutical regulators [e.g., the U.S. Food and Drug Administration (FDA)] to license or approve medications involve a determination of "safety" for both ends of this spectrum. Regulators define safety as relative freedom from harmful effects when prudently administered, taking into account the characteristics of the medication relative to the condition of the patient (Nordenberg, 1999; Meadows, 2002; Title 21 U.S. Code of Federal Regulations). In other words, vaccines and chemotherapeutics are held to different standards, and yet each is acceptably safe under likely circumstances of clinical practice.

Within the category of vaccines, different vaccines have various degrees of safety (Grabenstein, 2006; Joellenbeck et al., 2002). Modern, highly purified versions of influenza vaccines would be among those considered "safest." Smallpox vaccine would be at the other end of the safety spectrum for vaccines, given the rare and unusual adverse reactions vaccinia viruses can produce (Advisory Committee on Immunization Practices, 2001, 2003; Centers for Disease Control and Prevention, 2003a, 2003b). And yet smallpox vaccine can still be given to many people with an acceptable level of safety, given sufficient screening, exemptions, and education (Grabenstein and Winkenwerder, 2003; Poland et al., 2005).

Because vaccines contain exogenous proteins or other large molecules, they rarely share a propensity to cause anaphylaxis (Grabenstein, 1997). All parenteral vaccines cause injection-site swelling, erythema, and other localized reactions at rates that vary by route of administration, degree of antigenic purity, adjuvant content, and other factors. All vaccines are typically associated with systemic symptoms, such as headache, myalgia, and fatigue (Grabenstein, 2006; Joellenbeck et al., 2002). The risk and consequence of these adverse reactions is considered acceptable in relation to preventing the morbidity and mortality of the infections the vaccines prevent (Grabenstein, 2006).

It is interesting to consider the rates of injection-site and systemic symptoms that occur among the placebo control arms of vaccine clinical trials. For example, a clinical trial of a vaccine to prevent Lyme disease (Lymerix, GlaxoSmithKline) included a double-blinded study arm of volunteers who received a placebo containing aluminum hydroxide (Steere et al., 1998). In this study, injection-site soreness occurred in 7.6% of aluminum hydroxide recipients along with arthralgia in 3.5%. Diary cards recorded symptoms related or possibly related to injection during the first 3 days in 53% of the "placebo" recipients. Similar rates for adverse reactions from aluminum-containing placebo injections were seen in trials of a quadrivalent human papillomavirus vaccine (Gardasil, Merck) (Joura et al., 2007; Garland et al., 2007; FUTURE II Study Group, 2007).

Such findings (as well as the more common use of isotonic sodium chloride placeboes) illustrate several points. Merely inserting a needle beneath the skin (perhaps into a muscle compartment) and injecting a liquid result in biological and mechanical effects, even in the absence of antigen. When people are asked to record symptoms and sensations over an interval of time, they may note things that otherwise would pass unnoticed during their daily activities. These include the background rates of headache, myalgia, fatigue, and other transient symptoms that occur in the absence of antigenic stimulation.

RATIONAL SAFETY

The incidence and severity of adverse reactions to immunization can be measured with objectivity in randomized, double-blinded, placebo-controlled trials. But the acceptability of a vaccine's adverse-reaction profile relies on human judgment. This judgment for any given vaccine is not fixed in an absolute sense across all time and space. Rather, a series of judgments can be made, especially in relation to differing degrees of disease burden (and hence, vaccine value) over time or in different settings.

When smallpox (variola infection) was commonplace, the rare adverse reactions resulting from

smallpox vaccination were widely considered acceptable (Fenner et al., 1988). Once smallpox was eradicated as an endemic disease, national authorities judged that it was appropriate to limit smallpox vaccinations to laboratorians, military personnel, and others who might confront maliciously released variola virus (Advisory Committee on Immunization Practices, 2001, 2003; Centers for Disease Control and Prevention, 2003; Grabenstein and Winkenwerder, 2003).

Similarly, when poliomyelitis was a substantial domestic risk, national authorities judged the use of the attenuated poliovirus vaccine to be appropriate, even though the viruses in the vaccine could rarely revert to virulence and cause paralytic poliomyelitis (about one per 2.4 million vaccine doses distributed) (Advisory Committee on Immunization Practices, 1997). Once poliovirus infections were contained globally, poliovirus immunization policy in the United States shifted first to a combined schedule of inactivated and oral vaccines and then to an inactivated poliovirus vaccine exclusively (Advisory Committee on Immunization Practices, 1997, 1999b, 2000). Yet the ability of the attenuated poliovirus vaccine to be delivered orally continues to be advantageous in endemic areas. This illustrates how two different policies can be rational in the same place at two points in time (e.g., the United States in the 1980s versus 2000 and later) or in two places at the same point in time (e.g., the United States and Nigeria in 2007).

Rotavirus gastroenteritis hospitalizes over 1% of American children and kills one per 200,000 children in the United States. An oral rotavirus vaccine was licensed in August 1998 (RotaShield, Wyeth) (Advisory Committee on Immunization Practices, 1999). Clinical trials detected intussusception (a telescoping of the intestines) in both the vaccine and placebo groups, enough to warrant mention of the condition in the vaccine's labeling (i.e., package insert), but regulators did not consider this risk sufficient to withhold licensing. A few months after distribution of the vaccine expanded widely in clinical use (i.e., transitioning from tens of thousands to millions of vaccinees), routine safety surveillance systems within the United States identified an elevated but still rare risk of intussusception (Centers for Disease Control and Prevention, 1999a, 2004a; Advisory Committee on Immunization Practices, 1999). Those controlled studies revealed an attributable risk of one case of intussusception per 5,000–12,000 vaccine recipients. Attributable risk refers to the additional risk contributed by the vaccine, above the baseline risk of life without the vaccine. The manufacturer responded by stopping distribution of RotaShield in the U.S. commercial market in July 1999. A second rotavirus vaccine (RotaTeq, Merck) was licensed only after evaluation of three trials involving more than 70,000 volunteers to assess the attributable risk of intussusception (Advisory Committee on Immunization Practices, 2006).

Given that the morbidity and mortality burden of rotavirus gastroenteritis in developing countries with inadequate sanitation far exceeds the level within the United States, a situational dilemma develops. The U.S. domestic situation apparently left Wyeth unwilling or unable to distribute RotaShield in developing countries, as the vaccine was considered unacceptably risky in a premier market. But that "riskiness" was judged against the background of the United States, where the burden of rotavirus gastroenteritis is substantially less than in the developing world (i.e., a lesser achievable benefit to contribute to a vaccine's benefit-to-risk ratio).

ASSESSING SAFETY

Development of new vaccines progresses through animal and laboratory studies (i.e., preclinical studies) and then a series of clinical trials of escalating size and complexity.

Although no absolute lines delineate the stages of clinical investigation, the progress of drug research is usually conceived in a three-phased manner (see Chapter 12) (Grabenstein, 2006; Beatrice, 1991; Food and Drug Administration, 2007a). Phase I typically involves safety testing and pharmacologic profiling of the safe dosage range in 10–100 healthy human volunteers. Phase II provides the first controlled studies, the first tests of effectiveness against a disease in several dozen to several hundred volunteers. Phase II studies begin defining proper doses and regimens, assessing efficacy and safety. Phase III involves expanded clinical trials in several hundred to several thousand patient volunteers. These studies provide evidence of safety and efficacy in adequate and well-controlled clinical trials, sometimes called pivotal clinical trials. When a manufacturer concludes that it has scientifically established the safety and efficacy of a vaccine, it submits a Biological License Application (BLA) to the FDA or analogous documents to regulators in other countries (see Chapter 13).

Safety assessment continues after a vaccine is licensed, in what are called phase IV studies or post-marketing surveillance. "Post-marketing" could more properly be termed "post-licensing" because these data accumulate during (not after) widespread marketing of the vaccine for routine clinical use. After licensing, a manufacturer may undertake additional

clinical studies to obtain information about longer follow-up intervals, other populations, and other uses or to assess benefits or adverse effects in greater detail. Some of these studies are tracked at an FDA Web site (Food and Drug Administration, 2007).

Another component of post-marketing or post-licensing surveillance takes the form of retrospective pharmacoepidemiologic research into automated clinical databases. The Vaccine Safety Datalink (VSD), coordinated by the Centers for Disease Control and Prevention (CDC), is a well-known example of following the healthcare encounters of vaccine recipients and similar nonrecipients in the databases of a consortium of health maintenance organizations (DeStefano, 2001; Mullooly et al., 2004; Davis et al., 2005). A similar effort of the U.S. Department of Defense (DoD) to assess the health of U.S. service members is called the Defense Medical Surveillance System (Joellenbeck et al., 2002; Lange et al., 2003, Arness et al., 2004; Payne et al., 2007). Relevant to immunization programs for emerging biothreats, the VSD is developing the capacity for earlier detection of vaccine-safety signals, known as rapid-cycle analysis (Davis et al., 2005).

Earlier in this chapter, we considered the allusion of keeping one's eyes and ears always open to new findings. The always-open avenue for submitting adverse events after immunization in the United States (even if no clinical trial is underway) involves the Vaccine Adverse Event Reporting System (VAERS) coordinated by the CDC and the FDA (Singleton et al., 1999; Centers for Disease Control and Prevention, 2003; Varricchio et al., 2004). VAERS collects reports of unexpected adverse events from clinicians and the public. Similar programs are conducted in Canada (the Vaccine-Associated Adverse Events Surveillance System, VAAESS), the United Kingdom (the "yellow card" system), and other countries, often under the rubric of pharmacovigilance systems.

Reports to VAERS and its counterparts result from spontaneous decisions of a clinician or a patient to inform the CDC and the FDA of an adverse event. This requirement for action by the reporter is a significant limitation due to human factors related to reporting behaviors and information bias. Reports of medical conditions to systems like VAERS are certainly related to immunization in time, but they do not establish that a cause-and-effect relationship exists. Reporting rates cannot be assumed to be true incidence rates (Singleton et al., 1999; Centers for Disease Control and Prevention, 2003; Varricchio et al., 2004). Even so, VAERS and its counterparts are an important component of a vaccine-safety surveillance system. These systems are valuable for their role in collecting an open-ended array of information from anywhere at any time and ability to identify signals worthy of further evaluation using less biased study designs. Spontaneous reporting systems like VAERS are important for identifying rare, unexpected events.

Summing up all the people enrolled in phase I through III studies, few vaccines have been assessed in more than 50,000 people at the point of licensing. Still, this number is an order of magnitude larger than the few thousand people in the average clinical trial dataset for other pharmaceutical development programs. Larger study sizes in vaccine trials help rule out adverse events rarer than with cardiac, respiratory, or other categories of medications.

If a vaccine causes an adverse reaction, it is important for society to recognize it as soon as possible and respond appropriately. But jumping to the conclusion that two events are causally related in the absence of objective evidence is scientifically improper. Jumping to a conclusion can delay finding the true cause for an illness. For example, assuming that egg allergy was linked to anaphylaxis after measles–mumps–rubella (MMR II, Merck) immunization may have delayed recognition of the role of gelatin allergy (Khakoo and Lack, 2000; Pickering, 2006).

SAFETY THROUGH DIALOGUE AND EDUCATION

One of the principal ways to prevent adverse reactions is to withhold a vaccine from people who should not receive it (Grabenstein, 2006). Who is susceptible to anaphylaxis usually cannot be predicted. But the replicating characteristics of live vaccines provide a rational basis for assuming that such vaccines are unsuitable for people whose immune systems are compromised and who might not be able to staunch viremia or bacteremia after immunization. Thus, yellow fever, smallpox, and measles–mumps–rubella vaccines may be withheld from people with suppressed immune systems.

People who provide immunization services are not always the primary-care providers, who know the medical histories of vaccine-eligible people. The principal way to determine the underlying health conditions that might contraindicate (bar) specific immunizations is by interviewing ("screening") the vaccine candidate and/or by reading the candidate's earlier medical records. The most common temporary or permanent contraindications to immunization include the following:

- Acute illness on the day of evaluation for immunization (typically of a magnitude to warrant

additional medical care): Defer immunization until the candidate feels better.
- Allergies (i.e., immediate hypersensitivity) to vaccine components (e.g., anaphylaxis, laryngeal swelling): If this is a life-threatening allergy, the contraindication may be permanent.
- Prior reactions to immunization (e.g., substantial swelling at immunization site): Depending on the specifics of the patient's case, the contraindication may be temporary or permanent.
- Pregnancy, most often in the case of live vaccines: Certain subunit vaccines may be actively recommended for pregnant women (e.g., influenza, hepatitis B, meningococcal, tetanus–diphtheria), based on her personal risk of exposure to a preventable infection (Grabenstein, 2006).
- Immune deficiency: With regard to live viral or bacterial vaccines, related to serious disease (e.g., acquired immune deficiency syndrome, certain cancers), immune-suppressing medications (e.g., alkylating agents, antimetabolites, prolonged high-dose corticosteroids), or radiation therapy: For subunit vaccines, immune deficiency may impair efficacy, without safety implications per se. The degree and nature of the suppression will bear on whether the contraindication is temporary or permanent. In all cases, individual risk–benefit assessments are warranted (Grabenstein, 2006).
- Recent receipt of a blood product or immune globulin, applicable to certain live vaccines (e.g., MMR, varicella): Immunization should be deferred several months to allow time for catabolism of neutralizing antibodies (Grabenstein, 2006).
- Underlying disease conditions: Some underlying conditions will identify indications for immunization (e.g., diabetes and pneumococcal and influenza vaccines) and other conditions may identify contraindications to immunization (e.g., neurologic or rheumatologic conditions still evolving at the time of screening for immunization) (Grabenstein, 2006; Fenichel, 1999).

Another way to avert or mitigate adverse reactions after immunization is through education of the vaccinee. For example, vaccinees should be given clear expectations of what adverse reactions to expect after immunization (e.g., sore arms, fever, headache). They should be instructed to seek medical assistance if symptoms after immunization persist more than a few days or if they exceed a threshold that seems reasonable. In the case of smallpox (vaccinia) vaccination, education is important for preventing transfer of live vaccinia viruses from the vaccination site to some other site on the body or a close contact of the vaccinee (Grabenstein, 1997; Centers for Disease Control and Prevention, 1999). In this example, education averts adverse reactions.

Appropriate counseling should lead to understanding among vaccinees that no vaccine should be expected to be perfectly protective. Breakthrough (relatively milder) cases of chickenpox may occur in varicella-vaccinated people (Advisory Committee on Immunization Practices, 2007b). Breakthrough influenza infection may occur in influenza-vaccinated people (Advisory Committee on Immunization Practices, 2007), as can adenoviral, rhinoviral, and other viral infections that may be misattributed to influenza virus.

PROBLEMS INHERENT TO A PRODUCT

History records several problems in vaccine manufacturing that manifested early in the experience with certain vaccines. In early 1942, some of the first lots of yellow fever vaccine were manufactured with human serum albumin that inadvertently contained hepatitis B virus (Sawyer et al., 1944a, 1944b; Parish, 1965). Among ~2.5 million service members immunized from suspect lots, ~330,000 were infected with hepatitis B virus and at least 84 died (Parish, 1965; Seeff et al., 1987; Norman et al., 1993).

In April 1954, some early lots of the "Salk" vaccine, inactivated poliovirus vaccine, were not processed appropriately, allowing live polioviruses to contaminate the vaccine (the so-called Cutter incident). Over 200 people were paralyzed by this industrial accident (Parish, 1965; Nathanson and Langmuir, 1963; Smith, 1990; Offit, 2007).

Also in the 1950s, poliovirus and adenovirus vaccines were recognized to be contaminated with the simian virus 40 (SV40). Multidecade follow-up studies have not found evidence of any delayed adverse effect of the SV40 exposure (Brown and Lewis, 1998; Strickler et al., 1998; Institute of Medicine, 2002). Similarly, evaluation of avian leucosis virus and endogenous avian retrovirus contamination of yellow fever and measles–mumps–rubella vaccines has not identified any related harm in vaccine recipients (Waters et al., 1972; Hussain et al., 2001, 2003).

Although no other examples similar to the hepatitis B and poliovirus contamination incidents have occurred in modern times, it is wise to keep one's eyes and ears open whenever a new vaccine is introduced. The FDA requires much more extensive clinical studies and testing than was applied in the 1940s and 1950s. Even so, the rotavirus vaccine example illustrates how

the number of people given a vaccine after licensure permits assessment of rare events that may not have been fully understood during clinical trials.

Safety is not the only thing that needs to be monitored with the initial widespread use of a new vaccine. Influenza vaccines were first widely used in the mid-1940s. Vaccine experts were surprised in the late 1940s to realize that influenza immunization was not as effective in preventing infection as it had been a few years earlier (Parish, 1965). From this surprising finding came the realization that influenza viruses change their surface proteins, with a corresponding requirement for a new influenza vaccine formulation each year to keep pace.

EXPANDED USE

During clinical trials, before licensing, the average vaccine is given to thousands of people. Adverse reactions occurring with a frequency of one per 50,000 vaccinees or more rarely would not be expected to be recognized during clinical trials of that magnitude. Large-scale immunization programs may provide additional safety data to help identify previously unrecognized adverse reactions to immunizations.

When the smallpox vaccination program resumed in the United States in December 2002, the U.S. Department of Health & Human Services (DHHS) and the DoD collaborated on parallel but mutually reinforcing surveillance projects among the civilian and military cohorts to be vaccinated (Grabenstein and Winkenwerder, 2003; Poland et al., 2005; Baciu et al., 2005; Centers for Disease Control and Prevention, 2004). Each department implemented a vigorous program to identify adverse events among widely dispersed vaccinees across the country for the DHHS and civilian vaccinees and on four continents and dozens of ships at sea for the DoD and military vaccinees. The DHHS and the DoD pooled the adverse-event cases they identified and provided the full case series to an independent panel of civilian physicians who comprised a joint work group drawn from the members of the CDC's Advisory Committee on Immunization Practices and the DoD's Armed Forces Epidemiological Board. Although the civilian and military vaccinees differed in demographic characteristics, the collaborative approach subjected all the adverse-event data to a common analytic framework.

Within this massive vaccinia safety surveillance project, multiple subanalyses were conducted. For example, the DoD commissioned an electronic symptom diary that accepted telephonic and web-based entries, which provided the first analysis of the progression of the lesion at the vaccination site in a kinetic fashion (Olmstead et al., 2005, 2006). Both the DoD and the DHHS conducted traditional symptom surveys that added to the knowledge base for primary smallpox vaccination of adults. In several ways, the 2002–2007 experience has provided a greater evidence base to the accumulated knowledge through the 1970s (Fenner et al., 1988).

Although sporadic cases of myocarditis had been reported after smallpox vaccination in Europe and Australia (notably in Finnish military trainees), it was not recognized with the widespread use of the New York City Board of Health (NYCBOH) strain of vaccinia virus used in the Dryvax brand (Wyeth) (Fenner et al., 1988; Lane et al., 1971; Lane and Millar, 1971). The conventional wisdom was that the NYCBOH strain was a safer vaccinial strain in this regard, with a lesser risk of encephalitis, compared to vaccinial strains used in Europe (Fenner et al., 1988). Nonetheless, the DoD reported its first case of myocarditis after smallpox vaccination in February 2003, the 10th case in March, and then published a case series of 18 patients a few months later (Halsell et al., 2003). The cases typically presented with severe chest pain in the second week after smallpox vaccination disproportionately among adult male Caucasian primary vaccinees (Arness et al., 2004). Recovery has generally been prompt, judged by recovery by electrocardiogram, echocardiogram, cardiac enzymes, and graded exercise stress test, although a subset reported continued fatigue and chest discomfort (Eckart et al., 2004). Additional study of these patients is underway.

Myopericarditis may have resulted from NYCBOH vaccination in the 1960s but been underrecognized because cardiac enzymes and imaging technologies were immature. In the 1960s, the first time most people received smallpox vaccination was as infants, unlike the recent experience with primary vaccination of young adults. This serves as yet another reminder to keep one's eyes and ears open, even if a substantial body of historical data is available.

CAUSE AND EFFECT?

In assessing vaccine safety, it is important to differentiate cause-and-effect relationships from mere temporal relationships (Grabenstein and Wilson, 1999; Grabenstein, 1999, 2000, 2001a). This helps avoid the post hoc, ergo propter hoc fallacy.

What should be expected in the health of someone who just received an immunization? What is that person's likelihood of developing asthma, Guillain-Barré syndrome (GBS), a heart attack, cancer, infertility, epilepsy, lupus, or any other condition? As a starting

point, the vaccinee should have the same expectation of good health as a comparable unvaccinated person. Conversely, the vaccinee has the same expectation of a future medical problem as the unvaccinated person as well. It is unreasonable to expect zero cases of asthma, GBS, heart attack, or other conditions in a group of 1000 or 10,000 or 100,000 vaccinees. Nonetheless, surveillance data collected from vaccination programs may be helpful in assessing whether medical problems in vaccinees exceed the baseline expectation.

If there is no increased rate of illness among vaccinated people, relative to a proper comparison with similar unvaccinated people, there is evidence of no cause-and-effect relationship, at least according to the statistical power of the cohort evaluated.

A cause-and-effect relationship cannot and should not be ruled out entirely, however. The studies may not have been large enough to rule out rare effects or effects of small magnitude. Scientists must keep an open mind, of course, striving to avoid the words "never" or "always."

Although GBS has a reputation as being caused by immunization, its most common cause is an infection, especially with *Campylobacter* bacteria (Pickering, 2006; Grabenstein, 2001b; Kuwabara, 2004). GBS is a demyelinating disease that damages nerves, causing temporary weakness. From 80% to 85% patients recover fully from GBS. The general population has a risk of about one case of GBS per 60,000 people per year. Therefore, our baseline expectation is that GBS will occur among a large cohort of vaccinees, although an appropriate time interval (or "time window") must be applied to assure a fair comparison. The risk of GBS has been slightly elevated among influenza vaccine recipients in some years and some cohorts (perhaps 1–10 cases per million vaccinees), but not others (Grabenstein, 2001b; Lasky et al., 1998; Haber et al., 2004).

As this chapter is being written, the CDC and the FDA are investigating a cluster of GBS cases in recipients of a meningococcal protein-conjugated vaccine (Menactra, Sanofi Pasteur), attempting to measure the attributable risk in an unbiased manner and in perspective to the risk of a meningococcal disease in the population for whom immunization is recommended (Centers for Disease Control and Prevention, 2006a, 2006b). The analysis is complicated by seasonal variation in GBS incidence and Menactra administration, which both appear to increase independently in summer months.

Hepatitis B immunization can prevent liver cancer (Grabenstein, 2006), and human papillomavirus immunization can prevent cervical cancer (Advisory Committee on Immunization Practices, 2007). Can immunization cause cancer? Soon after SV40 was discovered in 1960, SV40 was found to be a contaminant of monkey kidney cells that is used to manufacture inactivated (and to a lesser extent oral) poliovirus vaccines. In 1961, the government required all poliovirus vaccines to be free of SV40, but more than a million people had already received vaccine doses containing this virus (Brown and Lewis, 1998; Strickler et al., 1998; Institute of Medicine, 2002). SV40 can cause some cancers in rodents. Recently, researchers found SV40 in people with rare cancers (e.g., ependymomas, osteosarcomas, mesotheliomas), but many of these people were too young to have received poliovirus vaccines containing SV40. So if unvaccinated people have SV40 virus in their tumors, one needs to ask whether vaccinated people with these rare cancers are more likely to involve SV40 than unvaccinated people. Evidence shows that the risk is the same, not elevated. There is no indication to date that an increased risk due to SV40 exists. (Brown and Lewis, 1998; Strickler et al., 1998; Institute of Medicine, 2002).

The same logic applies to other adverse events. A fraction of unvaccinated pregnant women will spontaneously miscarry their fetuses. With this rate as a starting point, we then expect a comparable fraction of vaccinated pregnant women to miscarry. Similarly, we need to know how often a heart attack, leukemia, thyroid disease, diabetes, or any other health problem happens among unvaccinated people before we can begin to assess whether vaccination increases the baseline (or background) rate.

The ideal situation is to know how often the adverse event happens among people who share every other risk factor except immunization. In such a setting, the comparison group would have the same age distribution, gender mix, underlying health status, and other personal characteristics as those of people who get the vaccine. Returning to the GBS example, it might help to know the specific incidence rates of GBS among adolescents, 20- to 45-year-old adults, as well as people 65 years or older, depending on the specific comparison being made. This helps compare apples to apples, and preferably red delicious apples to red delicious apples. Only from the baseline can elevations above baseline be recognized.

Whenever the symptom or condition is known to occur among people who have not been vaccinated, one needs to know whether the condition happens more often in vaccinated people than in a comparable group of unvaccinated people. A stepwise process has been proposed for this kind of analysis (Grabenstein, 1999, 2000, 2001a).

Any vaccine program administrator should plan for the occurrence of heart attacks among adult vaccinees. Shortly after the 1976 swine influenza

immunization program began, several heart attacks on the same day in the same city among influenza vaccinees triggered a series of media reports that shook public confidence in the vaccine (Rubin and Hendy, 1977). Objective analyses showed that the deaths corresponded to the expected background death rate among unvaccinated people, but delayed reporting of this perspective did little to restore confidence in 1976.

Similarly, several smallpox vaccinees developed angina, heart attacks, or other ischemic events during 2003. Data among U.S. military personnel indicated that smallpox-vaccinated and -unvaccinated personnel developed ischemic events at comparable rates (Centers for Disease Control and Prevention, 2004). The DoD smallpox vaccinee population is younger on average than the DHHS population, but the DoD population included more than 80,000 vaccinees 40 years or older. An epidemiologic analysis of observed ischemic cardiac events occurring within 3 weeks of immunization among civilian vaccinees between January 24, 2003, and August 22, 2003, compared to best estimates of expected numbers of incident cardiac events in a similar population, did not support an increase in ischemic cardiac events within this population (Baciu et al., 2005; Centers for Disease Control and Prevention, 2003c). The myocardial infarction (MI) cases and MI-associated deaths observed among DoD and DHHS vaccinees within 3 weeks of vaccination at that point exceeded the point estimates of expected MIs and deaths, but both observations remained within the 95% predictive interval for these events. Still, smallpox vaccination program administrators kept in place the cardiac exemption criteria hastily imposed when the ischemic cases were first recognized. The conservative approach was adopted in a setting in which the incidence rate of variola infection was still zero, the backdrop against which to compare the vaccine's benefit-to-risk ratio.

During the comparisons and contrasts of military and civilian smallpox vaccinees, the issue of generalizability came up several times. Fitness requirements for military service exceed those of some civilian occupations, but not all. People fit for military service are generalizable to civilian first responders (e.g., police, fire and ambulance personnel) and other employment sectors with expectations for cardiovascular stamina. What group is analogous to civilian healthcare workers? Physicians and nurses' health studies offer possibilities, as would employed beneficiaries of health maintenance organizations and other occupational groups.

Anthrax vaccine adsorbed (BioThrax, Emergent BioSolutions) has been the target of prolonged skepticism, with assertions that the vaccine is associated with an extraordinary variety of adverse health effects. To provide an objective basis for assessing the vaccine's safety profile, the DoD conducted an extraordinary array of post-marketing safety studies. These studies involved cohort studies of acute symptoms (Pittman et al., 2001a, 2001b, 2002a, 2002b; Wasserman et al., 2003; Hoffman et al., 2003; Rehme et al., 2002; McNeil et al., 2007), hospitalizations (Joellenbeck et al., 2002; Lange et al., 2003), disability evaluations (Sulsky et al., 2004), and reproductive outcomes (Wiesen and Littell, 2002; Catherino et al., 2005) as well as secondary review of the spontaneous reports to VAERS (Sever et al., 2002, 2004). Several of the cohort studies span multiple years after immunization (Joellenbeck et al., 2002; Lange et al., 2003; Sulsky et al., 2004; Catherino et al., 2005; Pittman et al., 2004). Multiple studies employed active surveillance, defined as data collected at fixed time points, without relying on a recipient to take a special effort to report a symptom or condition (Pittman et al., 2002a, 2002b, 2004; Wasserman et al., 2003). Other studies featured systematic surveillance, that is, data collected automatically and electronically, without any reporting action required by a clinician or vaccinee (Lange et al., 2003; Rehme et al., 2002; Sulsky et al., 2004; Catherino et al., 2005).

After the National Academy of Sciences heard from vaccinees and comprehensively reviewed the accumulated scientific data, the academy concluded that anthrax vaccine has an adverse-reaction profile similar to other adult vaccines (Joellenbeck et al., 2002). The anthrax immunization program also pointed out needed improvements in the way the DoD exchanges information with military personnel and provides clinical immunization services in general. Skepticism about the value of anthrax immunization among military personnel was largely resolved after the anthrax bio-attacks of fall 2001 showed the public the lethality of anthrax spores.

PLANNING APPLIED TO PANDEMIC INFLUENZA

To assess the general principles discussed above, let us now consider a pandemic influenza scenario. Similar scenarios involving other public health emergencies could be envisioned. This scenario assumes use of two hypothetical vaccines to prevent A/H9N9 influenza infection. One vaccine is a subunit (split-virion) influenza vaccine administered intramuscularly, and the other is a live, attenuated influenza virus

vaccine administered as an oral capsule. Neither of the products actually exists.

In a hypothetical pandemic of A/H9N9 influenza, the news media would likely herald a rising number of human cases and deaths due to the pandemic, as the virus spread across the globe. But the time needed to manufacture and distribute hundreds of millions of vaccine doses could lag behind pandemic spread of a lethal virus. This would likely create a scenario of "vaccine euphoria" and (perhaps irrational) vaccine demand, which are further discussed below.

With more than 50 years of experience with injectable whole- and subunit-virion A/H1N1, A/H2N2, A/H3N2, and other influenza virus vaccines, program administrators would have a substantial body of knowledge from which to base policy decisions. And yet the influenza vaccine formula has differed almost every year since 1945 (Grabenstein, 2006), so in some sense, we have 1–2 years of experience at the viral strain level with ~40 different (albeit similar) influenza vaccines.

Even with the immense experience with smallpox vaccine in the mid-20th century, new findings related to myopericarditis came to light in 2003 (Grabenstein and Winkenwerder, 2003; Poland et al., 2005; Arness et al., 2004; Halsell et al., 2003; Eckart et al., 2004). The intermittently elevated risk of GBS after influenza immunization, including the 1976 swine influenza vaccine incident, means that program administrators must focus on a potential association with A/H9N9 (Grabenstein, 2001b; Lasky et al., 1998; Haber et al., 2004). Similarly, heart attacks and ischemic disease must be monitored closely, for reasons cited above.

The United States has an increasing amount of experience with live, attenuated intranasal influenza vaccines, first licensed in 2003 (FluMist, MedImmune) (Grabenstein, 2006). The hypothetical A/H9N9 oral vaccine capsules in this scenario may be difficult for small children to swallow. The relative safety of a live, attenuated vaccine for pregnant women and immunecompromised people will likely be unknown. While the subunit A/H9N9 vaccine could be preferred for these subgroups, it is possible that local shortages of the subunit vaccine might force people to face uncertain risks in the setting of local incidence of the pandemic infection.

While many people would be glad to have access to either of the hypothetical A/H9N9 vaccines, some would shun them out of distrust of the government or for other reasons. Behavioral scientists and risk communicators will be important members of the vaccine program team at all levels: national, regional, state, and local.

What are the common features of infectious crises? Decades ago, when hundreds of thousands of Americans contracted diphtheria, poliomyelitis, or measles each year, few people stopped to ask about vaccine side effects. Vaccines have succeeded so well that many of these vaccine-preventable diseases are virtually unheard of by clinicians or the public. This phenomenon has caused some people to scrutinize side effects of vaccines, forgetting about the disease that the vaccines have successfully vanquished. Some aspects of this situation warrant the label "vaccine phobia."

On the other hand, what might be termed "vaccine euphoria" has occurred with meningococcal polysaccharide vaccine in the midst of meningococcal outbreaks (Grabenstein, 2001a; Gold, 1992; Hume, 1992; Centers for Disease Control and Prevention, 1999). Demand for meningococcal vaccine in community outbreaks arises periodically, even if the desire for the vaccine in such settings may exceed an objective assessment of the vaccine's utility.

For example, public clamoring for meningococcal polysaccharide vaccine during an early 1998 outbreak in Rhode Island exceeded the health department's plans (Centers for Disease Control and Prevention, 1999). The health department planned to offer meningococcal vaccine to all state residents between 2 and 22 years of age over the course of 6–12 months. Long lines and media attention caused that plan to be condensed into 6–8 weeks.

If called upon to oversee the safety surveillance system for a new vaccine or a vaccine suddenly expanded to a larger population, it may be helpful for a vaccine program administrator to consider a multifaceted approach. There are several useful data collection methods that include active (or systematic) and spontaneous surveillance covering all key demographic categories of interest (e.g., adults, children, elderly, pregnant women) over a variety of time windows (e.g., 72 h, 2 weeks, longer). Obviously, a thorough literature search of accumulated or "established" knowledge to inform subsequent study designs is also important.

To collect common and acute symptom data, active surveillance systems could be implemented in selected clinics, perhaps using electronic symptom diaries (e.g., entries via telephone or Internet). To collect data about rare adverse events, large linked databases can be used to survey large populations. Ideally, these databases will permit comparison and contrast of similar vaccinated and unvaccinated cohorts. To complement the two approaches described in the paragraph above, a spontaneous data collection system (e.g., VAERS)

will allow unanticipated adverse events to come to light for definitive evaluation by other means.

RISK COMMUNICATION

There is a divergence, a tension, between the way scientists approach vaccine safety and the way many members of the public do so. Good scientists gather evidence in a manner that minimizes bias. They take care to rule out competing explanations for an observation before they would assert that "A" caused "B" (Grabenstein and Wilson, 1999; Grabenstein, 1999, 2000, 2001a; Brewer et al., 2007; Glik, 2007; Dittmann, 2001).

Such self-discipline is not required, of course, among the general public. People believe what they wish. And in our society, they also are free to voice, and even shout, their opinions whether or not those opinions have an objective basis in fact.

When it comes to hearing about new situations, some people are entranced, and even mesmerized, by anecdotes, stories of individuals like themselves. Human nature tends to identify with individuals. As a result, documentaries and news magazines often begin by introducing the audience to a man, woman, or child affected by the subject of the story. Depicting events in the lives of these people personalizes the story, helping the author or scriptwriter connect with the audience.

Media stories exploring relationships between vaccines and their adverse events often focus on a family. Some member of such a family may have autism, multiple sclerosis, or some other serious health condition. This family will be searching for an explanation for the tragedy. The family may state, or the narrator may imply, that immunization could or should be considered the reason for the tragedy.

However, how can we tell whether a vaccine caused the problem? Is some other process really to be blamed? Separating true causes from false ones is vitally important for both society and individuals. Above, we have considered cause-and-effect in general and several health problems (e.g., GBS) in particular. Using a disciplined, rational, methodical approach to attributing blame where appropriate, or clearing a vaccine's reputation where there is no basis for a link, continues to be the proper approach. Using the tools of science, we are most likely to find the truth and least likely to fool ourselves about vaccine safety.

The key to assessing vaccine safety is to be objective, assess carefully all available data, and be open to new findings.

OUTLINE

ABSTRACT

The majority of vaccines licensed for controlling infectious disease of veterinary species today are based on technology that was introduced by Jenner using live vaccines and Pasteur using killed whole organism vaccines 200 and 100 years ago, respectively, yet this former technology has not stopped several successful vaccination programs from being developed. Much of veterinary vaccinology is driven by the realities that exist in raising production animals or working in veterinary practice, where making a living depends on keeping the animals healthy, because

it is an industry where vaccines are like insurance policies—protection from events that one hopes never happen. For example, the USDA recognizes these varying levels of protection in the way that they allow label claims: (1) "aids in disease control," (2) "for the prevention of disease," and (3) "for the prevention of infection." Additionally there may be indirect protection, or herd immunity, that results from vaccination of sufficient numbers of animals in a given population resulting in the reduction of the ability of a disease to transmit through the vaccinated individuals. The perception that vaccines provide sterilizing immunity, where the disease agent does not establish an infection, while widely held, is generally unfounded and largely unrealistic. Recent advances, especially in the last 15 years in genomics, proteomics, biotechnology, immunology, pathogenesis, and vaccine formulation and delivery have dramatically changed our approach to vaccine development. When used optimally, vaccines have been shown to prevent disease, reduce the need for pharmaceutical intervention, and improve the health and welfare of animals, and indirectly people as well. The challenge in developing an optimal vaccination program is in dealing with the great diversity that exists within the animal world, and as such there probably is no single optimal program for all occasions. While there is no magic solution to optimizing vaccination programs for animals, nonetheless, a solid understanding of the animal's innate and environmental risk factors as well as the variables such as stress will enable the development of tailored vaccination schedules that best meets the needs of the animal. The use of vaccines in animal health is not restricted to the protection of morbidity and mortality of the animal hosts themselves, but they are regularly employed as key elements in public health programs. When appropriate biopreparedness, management modeling strategies, and contingency plans of the future are linked with (1) protective DIVA vaccines against zoonoses, (2) effective predictive modeling, and (3) deployable implementation policies, control, and prevention of serious zoonotic diseases of man and animals will become more achievable at local, state, and national levels.

MAXIMIZING STRENGTH AND DURATION OF PROTECTIVE IMMUNITY

Novel Vaccine and Delivery Systems

Novel Vaccines

The majority of vaccines licensed for controlling infectious disease of veterinary species today are based on technology that was introduced by Jenner using live vaccines and Pasteur using whole killed vaccines 200 and 100 years ago, respectively. Although these vaccines have been very useful in reducing economic losses to the industry, they were primarily produced by empirical processes with little knowledge of animal physiology, host responses to vaccines including the importance or relevance of Th1 versus Th2-like immune responses in controlling infection or the importance of specific virulence factors of the pathogen. However, recent advances, especially in the last 15 years in genomics, proteomics, biotechnology, immunology, pathogenesis, and vaccine formulation and delivery have dramatically changed our approach to vaccine development. As a result of these advances, we believe that the next generation of vaccines should be safer and more cost-effective.

Live Attenuated Vaccines

Historically, live attenuated vaccines were generated by repeated passage of the pathogen in vitro under different conditions that randomly generate mutants that have reduced virulence. Indeed, the majority of the live attenuated vaccines on the market today have been generated by this approach (van Oirschot, 1997). The selection of mutants can be further enhanced by exposing the pathogen to mutagenic agents or growing the pathogen at low temperatures. Under any of these conditions there is no control of which specific genes are mutated, nor is there control over the extent of attenuation. Thus, it requires testing each of these individual passaged agents to finally arrive at a level of attenuation that is acceptable.

Finally, since many mutations can be point mutations, there is a high probability of back mutation and reversion to virulence once introduced into the animals. Possibly the best example of this ability to revert to virulence is with polio virus where the oral polio virus given to humans contains a single-point mutation which can rapidly revert to a virulent form upon replication in vivo (Greensfelder, 2000). However, even with these potential problems, many very effective live vaccines are licensed and have had a major role in disease reduction even though the safety of these vaccines is of concern.

Fortunately, with more knowledge of each pathogen and the genes involved in inducing protection and virulence, it is possible to target specific genes involved in attenuation. By deleting an entire gene from the pathogen to attenuate the organism using genetic engineering techniques, the safety profile of the vaccines can be dramatically improved. This approach is not only safer, because it is more difficult to acquire a whole gene which would lead to reversion than it is to modify a point mutation, but it is also possible to

modulate the degree of attenuation. This is important to ensure that adequate replication of the attenuated vaccine occurs, to induce optimal levels of protective immunity but not cause any pathology. A final advantage of using live vaccines is that they can be delivered by the natural route of infection to provide protection at the natural site of entry (i.e., mucosal protection). However, even with all these advantages, these approaches are under much greater scrutiny by regulatory agencies than the less safe conventional methodology of attenuation, thereby, adding significantly more expense to the licensing of many potentially valuable vaccines needed by the industry.

Currently, the more popular method of attenuation is to delete or incapacitate an entire gene that is not required for replication. However, it is also possible to introduce temperature-sensitive (TS) mutations which would reduce the pathogens ability to replicate at temperatures present in the lower respiratory tract. Thus, the vaccine could infect the upper respiratory tract and induce immunity, but have limited replication in the lower respiratory tract where damage could lead to complications such as pneumonia and possibly death. In addition to introducing this single TS mutation, one could introduce multiple TS mutations, thereby providing a much safer and stable attenuation than is currently possible with conventional TS mutants. This approach is very attractive for many respiratory infections, but especially for influenza viruses where TS mutants are currently in use for control of equine influenza (Townsend et al., 2001).

By deleting nonessential genes, a vaccine can be designed to reduce the virulence of a pathogen. However, it is also possible to make vaccines by deleting essential genes, which will completely prevent the replication of the vaccine in vivo. This type of mutation results in replication defective organisms, making the vaccine totally safe. Such an approach has been used for a variety of different prototype vaccines. The principle behind this approach is that it is possible to culture the vaccine in vitro by supplying the elements required for replication. Once the agent is introduced in vivo, where the element is absent, the agent undergoes an abortive infection. However, during this abortive infection, sufficient antigens are produced to induce immunity. These types of defective vaccines can be produced against a number of different organisms. A variation on the replication defective vaccines approach is one where a specific gene is introduced requiring a specific metabolite or compound to replicate (Donnenberg and Kaper, 1991). This allows controlled replication in vitro as well as in vivo as long as the required compounds are introduced with the vaccine or individuals are fed the specific compound for a period of time to allow the vaccine to replicate in vivo. On removal of the required compound, the agent dies. These types of approaches are easy to introduce into bacteria for making bacterial vaccines. These types of vaccines should remove the concern about shedding of organisms in environments as they would rapidly die in the environment because of lack of complementary growth components.

Possibly the greatest advantage of live genetically engineered vaccines is the fact that these vaccines can be used as vectors to carry protective proteins from other pathogens. Thus, it is possible to immunize an individual against not only the organism that has been attenuated, but also against antigens which are being carried by the vector. Thus, a single immunization can protect individuals from a variety of diseases. This approach is gaining considerable interest from the veterinary biopharmaceutical industry since it would make vaccine production and delivery much more economical with a single vector carrying multiple vaccines manufactured in a single step. Furthermore, there should be no interference between the antigens as is often seen with multiple agents at the time of vaccination. Currently, over a dozen viral vaccines based on a pox virus vector are licensed in veterinary medicine (Gerdts et al., 2006). Similarly, a number of companies are developing adenovirus-based vectors (Reddy et al., 1999a, 1999b). In the case of poxvirus-based vectors, one can either use mammalian or avian poxviruses as vectors. Since avian poxviruses undergo abortive replication in mammalian cells, they are gaining significant market share where they have been licensed. Thus, the safety concerns outweigh any genetic engineering concerns. The most recent report of developing solid immunity of monkeys to Ebola/Marburg and lassa virus following a single immunization with a VSV recombinant has created significant excitement using VSV as a potential vector (Jones et al., 2005). However, in all these instances of vectored vaccines, one is always concerned about the impact of preexisting immunity to the vector on the potential efficacy of the vaccine. The possible reason that the monkeys were totally protected from Ebola following VSV-vectored immunization versus adenovirus-vectored immunization is the fact that the monkeys were naïve to VSV.

Currently, it is possible to develop live vectored vaccines using bacteria or viruses as carriers, which then can be delivered by natural routes of infection, and by mass administration by aerosol or in feed or water, which is critical for the poultry industry. This approach overcomes a need to handle individual animals and also overcomes the disadvantage of

needle delivery. In addition, these vectors can be used to induce immunity in ovo (Rautenschlein et al., 1999). Currently, in ovo vaccination has gained significant popularity due to the ease of handling and providing immunity very early in life of poultry. In addition to carrying genes from other pathogens, these vectors can also carry immunomodulatory genes to act as adjuvants to enhance the efficacy of the vaccine (Raggo et al., 1996; Giavedoni et al., 1997). Although these vectored vaccines have many advantages, consideration must be given to the antigen being delivered. For example, one would not choose a viral vector when immune responses to carbohydrate or lipopolysaccharide (LPS) antigens are needed. In contrast, a bacterial vector would be ideal for such a vaccine. Similarly, one would not choose a bacterial vector to deliver a viral protein whose confirmation is very sensitive to posttranslational modification. Thus, the appropriate vector is as important as the antigens being delivered by that vector.

Killed and Subunit Vaccines

Conventional killed vaccines are produced by inactivating the infectious agents so it cannot replicate in the host, but without altering immunogenicity of the protective proteins. Thus, all the proteins of the infectious agent are present in the vaccine, but the nucleic acid has been damaged to the extent that the agent cannot replicate. Unfortunately, many inactivating agents do have an impact on immunogenicity by damaging or altering specific proteins, therefore, it is important to achieve a balance between full inactivation and reduction of immunogenicity (Ferguson et al., 1993). Unfortunately, with some infectious agents, especially those that may aggregate, it is not possible to have inactivating agents penetrate the aggregate and, as a result, some outbreaks of disease have occurred due to improper inactivation (Brown, 1993). Thus, there continues to be a search for new inactivating agents. For all inactivated vaccines it is critical that the protective antigens are present at the concentration sufficient to induce an immune response. In bacteria, many virulence factors may be extracellular secreted proteins, therefore, they are not present in sufficient quantities in whole inactivated organisms to induce protective immunity. Possibly, the best examples are the RTX toxins in the *Mannheimia*, *Actinobacillus*, and *Pasteurellae* species (Shewen and Wilkie, 1982). These antigens are critical for effective vaccination, but are secreted and, therefore, are not present in whole, killed inactivated vaccines. To overcome this problem, companies have "spiked" the whole killed inactivated vaccines with culture supernatant containing the RTX toxins. Second, some virulence factors are only expressed under specific physiological conditions, i.e., iron-regulated proteins, thus, care must be taken to ensure that bacteria are cultured under the appropriate conditions to express the putative protective antigens (Deneer and Potter, 1989b, 1989a).

Since most inactivated vaccines are poorly immunogenic, they often require adjuvants to enhance their immunity. Many of these adjuvants and formulations cause tissue reactions (see below). Furthermore, they generally induce a good humoral immune response with minimal cell-mediated or mucosal immunity. In many cases, these later responses are critical for optimal protection. In addition, many of these vaccines are delivered by needles that may break and remain in the animal for long periods of time. This is both painful for the animal and is of concern to the consumer who might encounter such a foreign object in the meat. However, many very successful vaccines have used these technologies and continue to be used by the industry.

A variation on the theme of killed vaccines is that of subunit vaccines. Instead of developing vaccines containing all the antigens of the pathogen, it is possible to identify the few critical proteins that are involved in inducing protection and use them as a vaccine. Theoretically, it is possible to purify the proteins from any conventionally produced vaccine. However, this is very expensive, therefore, it is much more economical to clone the gene and produce it as a subunit vaccine using biotechnology approaches. Before embarking on a subunit vaccine program, it is critical to identify the critical antigens for incorporation into a vaccine and then produce these antigens in a commercial setting. Fortunately, our knowledge regarding the critical proteins and ability to isolate the genes coding for these proteins has become relatively routine in the last decade. Thus, the protective antigens for most important infectious disease agents in veterinary medicine are now known. For those agents where we still need to identify the putative protective antigen, we can use comparative biology and genomics to identify them relatively quickly. However, identification is only the first step in a vaccine production program. Once the antigen is identified, it must be produced in a commercially viable system.

For bacterial antigens, production in bacterial systems is relatively straightforward. These proteins can be produced either as secreted proteins or as inclusion bodies. However, for viral or parasitic antigens, the extent of posttranslational modification required to retain the three-dimensional structures dictates that they can be produced in eukaryotic

systems to ensure their immunogenicity. Although these are often more expensive and difficult to scale-up, they are required especially for viral glycoproteins. Since viral glycoproteins are generally anchored in cell membranes, this requires destruction of cells to purify the glycoprotein. To overcome this impediment, it is possible to remove the transmembrane anchor and allow secretion of the protein (Kowalski et al., 1993). This not only increases the yield, but also reduces the purification cost, thereby making the vaccines affordable for livestock application. Significant advances in production of subunit vaccines are being made by expressing antigens in plants, which confer most of the posttranslational events present in mammalian cells. Further advantages are that it is possible to target the vaccine antigen to oil bodies in the plant (van Rooijen and Moloney, 1995). This makes the vaccine very thermostable, allowing ease of purification and, more importantly, the vaccine is already incorporated in the metabolizable oil adjuvant. Although there are currently no licensed vaccines produced in plants, it is envisaged that this will occur shortly as a number of companies are currently testing a number of such vaccines.

DNA Vaccines

The newest addition to our armamentarium in vaccination is genetic vaccination or polynucleotide vaccines, commonly referred to as DNA vaccines. The concept of DNA vaccination is extremely simple in that a plasmid expressing a gene encoding the antigen of interest is injected into an animal, which then expresses the protein (vaccine) of interest. Thus, the animal acts as the bioreactor to produce the vaccine and, consequently, the animal is immunized. This simple process does not require any downstream protein purification, although it does require plasmid purification and abolishes the need for adjuvants. Another advantage, depending on the route of administration, is that these vaccines generally induce both humoral and cellular immunity. This is primarily because the antigen is produced endogenously and all posttranslational modifications are similar to those seen following regular viral infections. Furthermore, improvements in both enhancing immunity as well as driving the cell-mediated arm of the immune system has been achieved by coadministration of these DNA-based vaccines with plasmids encoding IL-12 and IL-15 (Hanlon et al., 2001).

Although the concept is simple, the actual events that must occur to make DNA vaccination possible are many. First, efficiency of transfection is very low. Thus, few plasmids actually get into the nucleus and express antigen. To overcome this problem various methods have been used to increase transfection including: (1) electroporation, (2) formulation in different polymers or lipid-based vesicles, and (3) mechanical delivery using air or gene guns (reviewed by van Drunen Littel-van den Hurk et al. (2004)). Second, in the case of RNA viruses or bacterial genes, it is often necessary to introduce introns and remove cryptic splice sites to ensure expression occurs even after entry of the plasmid into the nucleus. Altering codon bias has also proven in some cases to enhance expression. The effects made to enhance the efficacy of DNA vaccines in livestock have been reviewed on a number of occasions (Babiuk et al., 2000, 2002). Possibly the most efficient method of delivery of genetic vaccines is the use of alphavirus replicons (Schultz-Cherry et al., 2000). Since alphaviruses naturally target cells for infection, they are ideal delivery vehicles. Using the alphavirus replicons system, the envelope can be engineered in such a way that it more efficiently targets the antigen-presenting cells (dendritic cells) for active targeting of vaccines. Since the replicons are not able to reproduce they are deemed to be safe.

Although there are still many hurdles to overcome to make DNA vaccination routine in many species, the first DNA-based vaccine has already been licensed to control West Nile virus in horses. With the regulatory path having been set, it is highly likely others will be licensed shortly.

Differentiating Infected from Vaccinated Animals (DIVA) Vaccines

Previously, agricultural disease surveillance and eradication programs were largely based on the serological confirmation of infection and the destruction or quarantine of herds to limit the spread of disease. Due to the reliance on serological confirmation, most countries banned vaccination against exotic diseases. Possibly, the best example of such an approach is with foot-and-mouth disease. The introduction of foot-and-mouth diseases into countries that are normally free of this disease results in quarantine and slaughter to eradicate disease rather than to conduct ring vaccination. Since ring vaccination would result in serological positive animals the country would continue to be considered "infected" as long as there were serologically positive animals in the country. However, the application of a serological test to differentiate between vaccinated and infected animals has a potential to change this practice. As countries move to eradication of endemic diseases or controlling novel introduced diseases through vaccination programs

it is critical to develop robust detection systems which differentiate vaccinated (immune) animals from naturally infected animals which might be carriers of the disease. This aspiration has led to the development of DIVA vaccines where vaccines lack one or more highly immunogenic proteins, but still contain the critical proteins needed for inducing protection. Since the vaccine lacks a specific protein, a companion diagnostic test is developed which can serologically differentiate infected from vaccinated animals (DIVA). Although DIVA vaccines/diagnostic tests can be used with conventional killed vaccines, for example, the killed FMD vaccines do not induce antibodies to the viral nonstructural proteins (NSPs) (Clavijo et al., 2004), the trend is to use gene deleted or subunit DIVA vaccines.

The first gene deleted vaccine was used to eradicate pseudorabies virus. This vaccine, was the result of a natural deletion of the glycoprotein (gE) gene from the virus (van Oirschot et al., 1986). This vaccine was used for decades to control pseudorabies virus in pigs and was known as the Barta strain. Coincidentally, it also has a gE deletion, which then could be used as a marker for differentiating vaccinated animals from latent carriers of the disease. As a result of the first DIVA vaccine, many areas are now free of pseudorabies virus. Although the pseudorabies virus was a naturally occurring virus, the availability of recombinant DNA technology, combined with our knowledge of gene sequences, and the ability to identify nonessential genes in many pathogens and delete them provides us with a great opportunity to develop DIVA vaccines for almost any infectious disease. As a result of these initial successes, several marker vaccines are already commercially available and their role and contribution to disease eradication appears promising. However, for DIVA vaccines to be embraced by the industry there will need for support by various levels of governments including the livestock industry to ensure that the biopharmacy industry develops these vaccines. For example, there are opportunities to develop DIVA vaccines for foot-and-mouth disease, but the international community does not yet appear to be willing to embrace vaccination against foot-and-mouth disease in countries which are normally foot-and-mouth disease free (Clavijo et al., 2004). In the case of foot-and-mouth disease, a DIVA test is available based on the detection of antibodies to NSPs that is the preferred diagnostic method to distinguish viral infected carrier animals from vaccinated animals, but is not yet embraced by the international trade community. Thus, even though the better technology is available, this will not guarantee that the technology will be embraced by the industry or the global community. Thus, some of these vaccines and their acceptance will not only be driven by economics to the individual producer, but it is also often politically motivated by trade interests and macroeconomic issues. Thus, once a country is declared disease-free that country can use its disease-free status as an effective trade barrier to keep out livestock from countries that are not disease-free. As more confidence is developed in DIVA vaccines and the diagnostic tests are simpler to perform, it is hoped that the entire globe would embrace these types of vaccines and reduce the accidental introduction of exotic diseases into countries or if introduced, will reduce the number of animals that are needlessly slaughtered to return the country to disease-free status.

Formulation and Delivery

Regardless of the type of vaccine developed, if it is not formulated or delivered properly, the full benefit of the vaccine will not be achieved. This is important because how it is formulated and delivered will dramatically influence the quality as well as the magnitude of the immune response generated. For example, a parenterally administered nonreplicating vaccine will induce only a systemic immune response, but have very little ability to induce mucosal immunity. Currently, there is extensive evidence to suggest that delivering the vaccine to mucosal sites is the most effective way to induce mucosal immunity. Another advantage of mucosal delivery is that the animal also develops systemic immunity, in addition to mucosal immunity. In addition to broadening the immune response, mucosal immunity has other advantages such as avoiding the pain and injection site reactions, and broken needles, etc. associated with parenteral injection. This route of administration can also be less expensive, but depending on management systems, may be more difficult to perform. For example, wild range cattle are not very receptive to intranasal delivery of vaccines; therefore, oral delivery may be more attractive in these circumstances. Unfortunately, despite many experimental reports few oral vaccines are licensed for livestock. The reason for this is the lack of effective delivery systems that target the gut-associated lymphoid tissue (GALT). The difficulty of delivering vaccines to the GALT is a result of a combination of many factors including degradation of the antigen and various physiological barriers. For example, in the ruminant, traversing the rumen to the intestine where the GALT is provides a major challenge. However, despite these challenges a number of promising developments are being pursued.

Since many viruses and bacteria can survive the gastrointestinal tract they are being used as vectors for vaccine development for providing oral or mucosal delivery. Possibly, the best example of such a vaccine is the vaccinia-vectored rabies vaccine. In this case, the rabies glycoprotein is inserted into a vaccinia virus which is then incorporated into bait for the control of rabies virus in wildlife (Brochier et al., 1991, 1995). The advantage of such an approach is that if one chooses a thermostable vector, the vaccine remains viable in the environment for significant lengths of time. Second, one does not need to trap the individual animals since they routinely encounter the bait during their normal activities, as they eat the bait they get vaccinated (Brochier et al., 1995). Similarly enteric bacteria such as *Salmonella* can also be used as vectors for carrying a variety of vaccine antigens. Although the safety issues prior to release of these vectors into the environment are very thoroughly investigated there is always a concern, possibly unwarranted, about the potential consequences of release of recombinant agents into the environment. To overcome this concern, interest is developing in oral delivery systems for nonliving antigens. This is possible by encapsulating the antigen in novel polymeric microparticles. These particles can be produced from a range of polymers, which protect the antigen from degradation in the gastrointestinal or respiratory tract and target these vaccines to the tonsilar crypt cells or Peyer's patches of the gastrointestinal or respiratory tract, respectively.

For microparticles to be effective, they must be engulfed by the M cells of the Peyer's patches. Significant work has focused on investigating the optimal size of particles for effective uptake. Uptake can also be modulated by changing the charge, hydrophobicity and linking of specific ligands to the particles to target the vaccine to M cells. For example, the size of polylactide-coglycolide (PLG) microparticles has been studied extensively with regards to their uptake and transport to lymph nodes. If one could generalize, which is risky, particles of $<10\,\mu m$ are taken up easier by the Peyer's patches than particles $>10\,\mu m$. This is the case with both PLG and alginate particles (Eldridge et al., 1993; Kim et al., 2002). The current interest in producing nanoparticles for various drug-delivery systems is also being exploited for vaccine delivery and has shown that smaller particles are better than large particles for uptake. Thus, it is clear that size is very important for the efficient uptake of microparticles carrying vaccine antigens. Furthermore, since the mucosa has a negative charge, positive-charged particles are more effective in uptake than negative-charged particles. Another approach for enhancing uptake of microparticles is to link various lectins to the microparticles which then can specifically target M cells (Pappo et al., 1991; Mantis et al., 2002). In addition to being able to directly target microparticles to the oral mucosa, interest is also increasing in being able to use these microparticles to develop single dose vaccines, whereby microparticles of different composition are employed with some particles releasing antigen immediately upon uptake and others releasing antigen at 1–2 weeks after uptake (Cleland et al., 1998; Tamber et al., 2005). This approach is especially attractive since it would provide a priming of the immune system upon vaccination and a booster later on. This has recently been demonstrated with an HIV vaccine in baboons (Cleland et al., 1998). To further enhance the efficacy of microparticles as delivery vehicles it is possible to incorporate adjuvants with the antigen in the microparticles and not only deliver the antigen but also provide the immune system with a boost. Incorporation of saponin-derived adjuvants (QS-21) or CpG ODNs into microparticles have been shown to enhance immune responses to the antigens incorporated in the microparticles (Hunter et al., 2001; Diwan et al., 2002). Although PLG microparticles have been the most extensively studied oral delivery microparticle systems, numerous other microparticles have also been investigated. These include polycapralactone (PEC), starch-based microparticles, alginate microparticles, and most recently polyphosphazenes (Payne et al., 1995; Benoit et al., 1999; McNeal et al., 1999; Wikingsson and Sjoholm, 2002; Rydell and Sjoholm, 2004). The reason for investigating other formulations is that the generation of PLG microparticles generally requires organic solvents and upon degradation in the intracellular environment generates an acidic environment. In some cases this is very detrimental to preservation of different epitopes. This is possibly the reason that incorporation of *Brucella ovis* in PEC microparticles was much more effective in protecting animals from challenge with live *B. ovis* versus encapsulation of the same antigen in PLG which did not confer protection (Murillo et al., 2001). It is also interesting to note that the quality of the immune response induced by the PEC microparticles was associated with a Th1-like response, whereas those induced by PLG encapsulated antigen was associated with a Th2-like immune response.

Significant studies have also been conducted with alginate microparticles in various animal species including cattle, rabbits, and chickens (Bowersock et al., 1999). In each of these cases, oral delivery of the vaccines was enhanced when the antigens were encapsulated in the alginate particles and further enhancement was detectable if the microparticle also contained adjuvants. Due to the mild nature of

producing alginate microparticles, it is also possible to encapsulate live microorganisms, thereby protecting them as they transit the stomach to the gastrointestinal tract. This was clearly demonstrated by the ability to encapsulate bovine adenovirus in alginate microspheres and develop immune responses following oral administration of the virus (Mittal et al., 2000).

A most recent class of synthetic biodegradable polymers for vaccine delivery as well as acting as an adjuvant in itself is the polyphosphazenes. Numerous reports have documented that polyphosphazenes perform better than conventional adjuvants when incorporated with vaccines (Andrianov et al., 1998; Payne and Andrianov, 1998). Furthermore, it is possible to formulate polyphosphazenes into microparticles with no organic solvents. Thus, the procedure is extremely mild and one captures the benefit of microencapsulation as well as adjuvanticity all in one type of particle. Although these polyphosphazene microparticles have proven to be very effective in preliminary studies in mice, they require further investigation for application to livestock and companion animals. Although we have identified the areas of current interest and research in microencapsulation and delivery of vaccines in microparticles, it must be emphasized that there are very few studies in large animals demonstrating the application of microparticle formulated antigens for oral immunization. Clearly, much more work is required in large animals but the knowledge that is gained regarding the needs to stimulate the GALT, the size of microparticles, and charges to enhance immune responses combined with preliminary studies in a number of veterinary species demonstrating their potential utility is encouraging and needs to continue to be pursued.

Due to the rather poor immunogenicity of most inactivated and subunit vaccines, they almost always require combination of the vaccine antigen with adjuvants to be effective. The current adjuvants can be classified into: (1) mineral salts, (2) synthetic adjuvants, (3) oil emulsions, (4) plant products, (5) lipid-based vehicles, (6) bacterial products, and, finally (7) molecular adjuvants or cytokines or any combination of the above (Cox and Coulter, 1997). In humans, only aluminum salts or MF-59 are licensed, whereas in veterinary medicine many different adjuvants are in current use. Unfortunately, the exact mechanism by which most adjuvants work is not fully understood and different adjuvants probably have different mechanisms of action. These range from creating a depot of the antigen to attract antigen-presenting cells to the site of vaccination to creating a cytokine environment at the vaccination site to help expand the immune reactive cells. Regardless of the mechanism of action, most licensed adjuvants do not possess all the required features of an ideal adjuvant, therefore, the quest continues for better adjuvants, which not only induce a balanced immune response, but also are safe and do not induce any injection site reactions.

Since many of the adjuvants attract cells of the immune system to the site of injection, one requires a fine balance between attracting the appropriate cells required for induction of immunity, but not cause overstimulation resulting in unwarranted injection site reactions. Indeed, it has been estimated that in cattle, these injection site reactions cost approximately $8/injection site as a result of the need for trimming (van Donkersgoed et al., 1999). It is for this reason that most injections are now given subcutaneously in the neck where meat cuts are of less quality. In the case of cats, aluminum adjuvants have been implicated in fibrosarcomas (Burton and Mason, 1997) and, therefore, the trend is to move to nonadjuvanted vaccines for cats. The major problem with most adjuvants is they generally induce a strong Th2-like immune response, but very little Th1-like immune responses. Because of these concerns, the quest continues for novel adjuvants that do not cause any adverse reactions, but still induce the desired response.

Currently, the most often used adjuvants include aluminum salts, which adhere antigen to their surface and act as a depot for the antigen which is then presented to the antigen-presenting cells infiltrating the injection site. Since the antigen needs to be absorbed to the aluminum salts, it is not surprising that all antigens do not absorb efficiently and require precise pH's for their absorption (Claesson et al., 1988). Another disadvantage of aluminum salts is that they generally induce only Th2-like responses with little cell-mediated immune responses.

Oil emulsions are another very commonly used family of adjuvants in veterinary vaccines. These oil emulsions vary from mineral to plant oils and can be oil in water or water in oil emulsions. The major problem with mineral oils is that they are nonmetabolizable, leading to residues and injection site reactions. To overcome these problems, metabolizable oils are replacing mineral oils. Many of these metabolizable oils are plant-based. In addition to using plant-derived oils, other plant components with immunomodulatory properties are also used, either in combination with oils or alone (Kensil et al., 1991; Wu et al., 1992). Possibly the best known plant-derived adjuvant is saponin (Quil A) or various fractions of Quil A, best known as QS21. One of the mechanisms of action of QS21 is its ability to stimulate cytokines, which help create the environment required to drive the immune response. To further enhance the activity

of QS21, it is possible to combine them with other lipid components to form ISCOMs or cage-like structures containing the antigen of interest (Cox et al., 1998; Morein et al., 2004). Thus, ISCOMs act both as delivery vehicles and enhance immunity to the antigen incorporated into the ISCOMs. Currently, most ISCOM-based vaccines incorporate viral glycoproteins into the ISCOM. These vaccines can be delivered either parenterally or mucosally, and can induce both antibody and cellular responses (Takahashi et al., 1990; Morein et al., 2004). One of the disadvantages of ISCOMs is the poor loading capacity and the difficulty of incorporating nonmembranous antigens into ISCOMs (Reid, 1992). Similar to ISCOMs, liposomes have been used experimentally with excellent results. In addition to use with subunit vaccines, lipid-based delivery systems are also efficient in delivery of DNA-based vaccines (Zelphati and Szoka, 1996).

Early vaccines containing whole killed bacteria demonstrated that these vaccines induced significant reactions, which led to the suggestion that many of these components could be good adjuvants. Indeed, this was proven to be a correct assumption. Many of these bacterial products, whether they are LPS or various toxins (cholera toxin, *Escherichia coli* LT, etc.) or bacterial DNA generally induce cell signaling, primarily through Toll-like receptors (TLRs), and production of cytokines or chemokines. It is because of this activity, excessive stimulation can lead to adverse reactions. To overcome these excessive reactions, less toxic analogs of each of these bacterial components are being developed (Ulrich and Myers, 1995).

One of the least reactogenic bacterial components currently showing significant promise as an adjuvant is CpG (Krieg et al., 1999). These are specific synthetic oligonucleotide sequences that signal through TLR-9 receptors. Significant work in the last decade has identified specific CpG motifs that can stimulate both Th1 and Th2-like immune responses (Weeratna et al., 2000). Furthermore, they are active both with recombinant and conventional vaccines (Ioannou et al., 2002). In addition, they are active following in ovo delivery (Gomis et al., 2004).

Since many of the above adjuvants act through their ability to induce cytokines at the injection site, and since cytokines are critical for induction of immunity, numerous investigators have attempted to incorporate cytokines into vaccine formulation with limited success (Heath, 1995). The greatest concern with cytokines as adjuvants is the difficulty of maintaining the current concentration of the cytokine that will drive the immune response without overstimulation with toxic consequences. A recent report of using killed pseudomonas bacteria containing interferon gamma as an adjuvant demonstrated excellent adjuvanticity with no adverse effects (Gaertner et al., 2005). Thus, there is a high probability of eventually using such molecules as adjuvants.

ENHANCING FOOD SAFETY WITH IMPROVED VACCINES

The use of vaccines in animal health is not restricted to the protection of morbidity and mortality of the hosts themselves, but they are regularly employed as key elements in public health programs. Among the first widely and successfully applied applications of vaccines in the animal health were for rabies, a principle zoonotic disease for a variety of domestic and wildlife hosts (see Chapter 33). Classical inactivated rabies vaccines have been used to control this devastating disease in domestic animals and wildlife targets have been addressed with attenuated live approaches and most recently and successfully with a recombinant vectored vaccine. Of perhaps even more profound potential impact on public health is in the control of H5N1 avian influenza, where the use of conventional and recombinant vaccines have been demonstrated to significantly decrease the spread and virus within infected flocks, thereby reducing the spread of the virus vertically into the human population. Other zoonotic diseases for which vaccines have real and potential impact on incidence in the human population are brucellosis in ruminants, Nipah virus and Norwalk Agent in swine.

Focus will be on those diseases for which the exposure to the zoonotic is typically through the food chain. These vaccines carry their own special issues in that the agent may not always be a principal disease in the host, rather a commensal, or part of the host natural flora. *Campylobacter* in poultry and *E. coli* O157 are typical examples of these, with the disease agent residing as part of the host normal flora and only becomes of concern when humans are exposed to contaminated food.

Safety of the water and food supply has clearly led to greatest improvements in public safety in the last century and a half. Statistics from the British home office indicate that in 1900, 140 per 100,000 in the population of the UK died annually from food-related illnesses. Improvements along the food chain reduced that number to approximately 0.4 per 100,000 by 1980, where it has remained constant since then.

Before moving on to animal diseases and the vaccines used to control them, it must be noted that the very vaccines used in food producing animals must

in themselves not negatively affect the quality of the food. In the United States, production animals typically include beef, pork and poultry with minor inputs from the sheep and goat industry. The advent of modern vaccine technologies has provided tremendous benefits to large-scale production capabilities for these species and resulted in a positive economic impact with regard to cost of production for the primary producer and cost of product to the consumer. The use of vaccines in production animal medicine has translated into one aspect of the overall production scenario under the concept of "herd health management." The herd health management concept transcends prevention of disease, animal housing and environment, nutrition, and management issues; all of which have contributed to the low cost, bountiful, high quality food supply that this nation has enjoyed for many decades.

There are issues routinely faced by producers with regard to the application of vaccine technologies to production animals. These include the efficiency of mass vaccination, the impact on food quality due to local reactions at the vaccination site, and the rare but serious issue of broken needles at the site of injection. The application of mass vaccination technologies has been most successful in the commercial poultry industry with products that are typically administered by aerosol exposure or via drinking water systems. These technologies have been more difficult to apply to swine and beef primarily because of the design of those production facilities and the formulations currently required to achieve effective vaccine response.

The issue of injection site reactions is primarily associated with swine and beef production because most vaccines are still administered with a traditional syringe and needle approach. These issues are being addressed by targeting specific "low meat value" sites for injections, particularly the lateral neck region. This preserves the integrity and value of the high quality meat cuts associated with the leg and loin regions. In addition, vaccine formulations have improved with better selection of less reactive adjuvants, lower dose volume and targeting efficacy with subcutaneous injections instead of requiring intramuscular deposition of the antigen.

The issue of broken needles is more difficult to address, and the potential for a break always exists during herd vaccination procedures. Though rare, the discovery of a needle in a meat product typically makes headlines and results in damage to the reputation and marketing potential of the processor. Some export customers, specifically the Japan market, set a zero tolerance for broken needles that result in the use of metal detectors to screen meat shipments. If a positive signal is detected in a single sample at the port of entry, the entire shipment is subject to rejection. This is a major expense to the processor. One relatively new technology that holds promise to address the broken needle issue as well as the injection site meat quality issue is the administration of vaccines via needle-free devices.

Several companies are now producing and distributing needle-free devices for the administration of vaccines to swine and cattle. These devices either utilize existing vaccine formulations or more preferably utilize formulations specifically designed to take advantage of the needle-free route of administration. One advantage exploited by needle-free technology is the ability to target the most efficient population of antigen-presenting cells (plasmacytoid dendritic cells) that are concentrated in the dermis. These cells are typically bypassed with a needle injection. Targeting dendritic cells has the potential to reduce antigen quantity, reduce or eliminate the need for adjuvants, and significantly reduce the volume of injection. All of these factors address both the injection site meat quality and broken needle issues.

Other vaccine technologies that have emerged in recent years include the use of recombinant virus vectors and nucleic acid based vaccines. These technologies offer several potential advantages. They allow for the use of a vaccine that allows differentiation of infection from vaccine antigen exposure. This is critical in disease control situations, particularly when dealing with the introduction of exotic disease agents. In some instances, a recombinant vaccine will achieve a better immunologic response than can be obtained with the native antigen and the use of adjuvants may be reduced or eliminated. Nucleic acid vaccines offer a major advantage with regard to purity of the vaccine, elimination of adjuvants, the ability to overcome interference from maternal antibodies in young animals, and the opportunity to prime the immune system for a subsequent boost with a recombinant or native antigen formulation.

Prevention and control of infectious diseases in food animals will continue to be an issue faced by farmers and producers. Some agents are endemic in the respective species and others are highly contagious requiring fast diagnosis and rapid response to achieve control in the absence of vaccination. The other aspect of food animal vaccination that has come to the forefront in recent years is the potential for exotic agents to enter the United States either through natural or incidental routes or via intentional, terrorist introduction into the domestic herds or flocks.

One example of such a threat is influenza virus. The close proximity of people to swine and poultry in some Southeast Asia countries will continue to provide

the opportunity for coinfection of hosts with multiple influenza viruses. The potential for reassortment of the virus genome and emergence of strains highly virulent to livestock and human populations will always exist. Vaccination is a leading defense against such a threat.

Vaccines for Food Borne Disease Protection

Salmonella and *Campylobacter* in Poultry

Among the most successfully and broadly applied commercial vaccines used in animal health are targeted to the poultry industry. An entire range of viral and bacterial vaccines are applied throughout the course of production and have allowed diseases such as Newcastle Virus and Marek's disease, which would normally decimate a flock, to be strictly controlled. These vaccines may be applied in the drinking water in the poultry house, in aerosolized spray cabinets in the hatchery, and recently in mass administration in ovo devices. Poultry is also where we find the most consistently applied programs for food safety vaccines in animal health.

According to the Food-Net; bacterial pathogens with the highest relative incidence for causing bacterial food-borne illness in humans during the period 1996–2003 were campylobacter, salmonella, and shigella (Anonymous, 2005c). Most of the campylobacter and salmonella infections are acquired through the handling and consumption of contaminated poultry products. Although more than 2400 different serotypes of salmonella exist, only *Salmonella enterica* subspecies *enterica* (*S. enteriditis*, *S. oranienburg*, *S. Montevideo*, *S. Newport*, *S. typhimurium*, *S. Anatum*, *S. Derby*, and *S. bredeney*) are responsible for gastrointestinal diseases in humans, and they are grouped as paratyphoid (PT) *Salmonellae. S. enteriditis*, *S. typhimurium*, and *S. Montevideo* are the most frequently isolated in poultry.

Usually an acute, self-limited gastrointestinal illness, characterized by diarrhea, fever, and abdominal cramps is most common presentation of campylobacter and salmonella infection in humans. Poultry infected with salmonella present minimal clinical signs and there are no clinical signs attributable to campylobacter in chickens of any ages. Both salmonella and campylobacter colonize chicken intestinal tract and large numbers of bacteria shed through feces.

Intestinal contamination is the main source of contamination in the processing plant. Campylobacter colonization (detectable levels) occurs at approximately 2–3 weeks of age and once established in a flock it spreads rapidly. The horizontal transmission between chickens has been well documented, the recent reports suggest that vertical transmission may play a role in spread of salmonella and campylobacter in poultry flocks as well (Gast, 2003; Shane and Stern, 2003).

Preharvest, harvest, and postharvest measures are used in an effort to reduce salmonella and campylobacter incidence in poultry. Preharvest measures include use of feed additives (antibiotics, prebiotics, probiotics, synbiotics, and short-chain organic acids), competitive exclusion, and vaccination. Several vaccines are available for *S. typhimurium* and *S. enteriditis* whereas there are no vaccines for campylobacter for chickens.

Salmonella infection is known to elicit strong humoral responses in chickens whereas, little is known about cellular immune responses. However, it is widely accepted that cell-mediated immunity plays a more important role than humoral immunity for tissue clearance of virulent strains while mucosal antibody responses and promyeolcytes seem to be important in intestinal clearance (Gast, 2003). Indeed, recent studies indicate oral inoculation of chickens with *Salmonella typhimurium* results in early expression of chemokines in spleen and liver, followed by increased expression of gamma interferon and increased number of CD4 and CD8 cells (Withanage et al., 2005). These responses correlate with Th-1 responses to systemic infections in other species. Responses to ST infection in the gut are not as clear, while in a one study an increase in proinflammatory cytokine expression in another there was no substantial increase in cytokine responses (Gast, 2003; Withanage et al., 2005). Vaccination has been widely used to control salmonella infections in poultry. Both live and inactivated vaccines have been utilized though the former have been shown to induce stronger and long-lasting immune responses (Gast, 2003; van Immerseel et al., 2005). However, neither vaccine type can induce complete protection against colonization of the intestines and therefore control programs remain and integrated approach of vaccination, proper preventative measures in the processing plant, handling in the transportation chain, and finally by the end consumer.

Currently no vaccines are available for the control of campylobacter in chickens though several experimental approaches have been shown to induce humoral immune responses and some degree of protection against challenge (Stern et al., 1990; Cawthraw et al., 1994; Khoury and Meinersmann, 1995; Noor et al., 1995; Widders et al., 1996, 1998; Rice et al., 1997; Shane and Stern, 2003). However, there is no evidence of complete protection against intestinal colonization in these studies (Stern et al., 1990; Cawthraw et al., 1994; Khoury and Meinersmann, 1995; Noor et al., 1995; Widders et al., 1996, 1998; Rice et al., 1997). One important

aspect of campylobacter colonization is that campylobacter is not usually detected in chickens less than 2–3 weeks of age under commercial broiler production conditions (Jacobs-Reitsma et al., 1995; Evans and Sayers, 2000). However, experimentally it has been shown that chickens less than 2–3 weeks of age are susceptible to campylobacter infection resulting in colonization of the gut suggesting that there is no genetic factors of age-related resistance to infection (Hald et al., 2001; Shane and Stern, 2003). The observed age-related resistance to colonization by campylobacter has recently been attributed to presence of high levels of maternal antibodies (Sahin et al., 2003) in which the decline of maternal antibodies associated with an increase in colonization rate. In addition, maternal antibodies were shown to opsonize campylobacter in in vitro experiments. However, it is well documented that chickens with maternal antibodies can be infected and colonized with campylobacter if higher doses of challenge inoculums' were used (Noor et al., 1995; Hald et al., 2001).

Immune intervention for nondisease causing gut colonizing bacteria is indeed a challenge. One has to consider accessibility of specific immune components into gut content where the bacteria are located. This immediately excludes activity of immune cells in the content though there may be some activity at submucosal level. Although soluble-specific components such as immunoglobulins can be plausible to access to bacteria, their activity in the absence of other components such as complement and phagocytic cells, may not be sufficient to kill or eliminate the bacteria from the gut. One option is to prevent colonization in the first place using immune intervention, and in order to accomplish this, a better understanding of the factors leading to colonization may provide venues to explore vaccine development.

E. coli in Cattle

E. coli is an ubiquitous pathogen of both humans and animals. It is responsible for a wide range of diseases including enteric, septicemic, and urinary track infections. In recent years a significant increase of bloody diarrhea or hemorrhagic colitis caused by a particular strain of *E. coli* (*E. coli* O157:H7) has been observed in most industrialized countries and especially the United States. It has made headlines as hemolytic uremic syndrome, causing death, often in clusters, after consumption of undercooked ground meat, often referred to as "hamburger disease."

The disease manifests in its most common form as severe bloody diarrhea accompanied by abdominal cramps with little or no fever which may resolve in 5–10 days (Anonymous, 2006). In a complication affecting mostly children and the elderly, 2–7% of infections will go to acute renal failure (hemolytic uremic syndrome) and may lead to death (3–5% overall death rate) or long-term complications.

E. coli O157 has an animal reservoir, the primary host being ruminants and specifically cattle. The great majority of cases can be linked back through the handling or consumption of contaminated meat, plants, vegetables, or water. Direct contamination on the farm or in other settings such as petting zoos is responsible for a significant number of cases. The incidence in the United States is estimated at 73,000 cases per annum, including 61 deaths (Anonymous, 2005b, 2006). The strain is highly pathogenic with as little as 1000 bacteria capable of causing the infection.

This makes infection by *E. coli* O157 one of the most frequently reported and severe food-borne illnesses in developed countries. The human disease, its etiology and management has been reviewed recently (Tarr et al., 2005).

While the genus and species *E. coli* is a very important pathogen of all animal species causing mainly enteric diseases such as neonatal diarrhea caused by enterotoxinogenic *E. coli* (ETEC) in calves and piglets, *E. coli* O157 is not pathogenic for cattle. The bacterium colonizes the intestine of the ruminant very efficiently, causing a nonsymptomatic infection. The bacterium is then shed, often intermittently but in high numbers in the feces. Fecal contamination of the meat in the packing plant, bedding, water, fruits, or vegetables on the farm leads to human exposure. The asymptomatic infection is very widespread in many herds across the country. Within a herd, the individual rate is highly heterogeneous from less than 10% to the majority of animals shedding in the environment. Importantly some particular animals shed at very high levels (Matthews et al., 2006).

The genus and species *E. coli* is a very diverse group that comprises approximately 175 O antigen serotypes (e.g., O157). The O antigen is carried by the polysaccharide side chain of the LPS, a component of the bacterial outer membrane. Significant variation is also noted at the chromosomic level (Anonymous, 2005a). More importantly *E. coli*, for the purpose of this discussion are characterized by their virulence factors. Attachment: *E. coli* O157 is part of a group of strains called enteropathogenic *E. coli* (EPEC). Their attachment to the enterocyte causes a lesion that is characterized as effacing because they destroy the cytoskeleton (attaching/effacing *E. coli*). The molecular mechanism has been well described and necessitates at least four major proteins: Esp A, Esp B, Tir, and Intimin. Intimin (a bacterial outer membrane protein) and its receptor

Tir are the attaching molecules. Over 33 virulence factors have been described in this complex process (Deng et al., 2004). An important finding for the understanding of disease transmission, epidemiology, and vaccine studies was the description of preferential adhesion sites in the rectum of the cattle (Naylor et al., 2003). Attachment is a key component of colonization in cattle and the first step of the disease in humans. Toxins: the toxic manifestation of the disease is caused by the secretion of two toxins, called Shiga toxin 1 and 2. The genes for these toxins are carried by bacteriophages. These toxins are also called verocytotoxins and the *E. coli* that secrete them verotoxigenic *E. coli* (STEC or VTEC). They are implicated in the apparition of the hemolytic uremic syndrome in humans (Karch et al., 2005). The resistance of cattle to the effect of these toxins provides an explanation for the absence of disease manifestation in these animals.

Many approaches have been suggested for the development of vaccines using many of the newer technologies as well as more traditional approaches. The target of the vaccination of cattle is the reduction or elimination of infection and excretion, and not disease prevention (as there are no symptoms). This is a particularly difficult target as it must reach a colonization site on the mucosal surface and eliminate or prevent colonization by bacteria that have developed exquisite solutions to parasitize this ecological niche. The most advanced approach is based on the use of *E. coli* secreted antigens that contain several of the proteins involved in the attachment (e.g., Esps and Tir). This approach uses traditional technology but is built on the very precise understanding of the pathogenic mechanisms. It is administered three times by the subcutaneous route. It has led to significant decreases in shedding levels both in challenge models and field trials (Potter et al., 2004). In a more recent test, however, performed under field conditions, the vaccine failed to induce a reduction in prevalence of infection (van Donkersgoed et al., 2005).

Plant (tobacco cell) produced intimin caused a decreased duration of shedding when the vaccine was administered parenterally followed by a booster by the oral route (Judge et al., 2004). Antibodies against intimin passively administered to piglets provided significant protection against a challenge (Dean-Nystrom et al., 2002). A live modified strain of *E. coli* containing a truncated intimin molecule also provided protection against clinical disease in an A/E *E. coli* model in rabbits (Agin et al., 2005). Finally genetically modified toxoids of the shiga toxins will provide both neutralizing antibodies and protection against a toxin challenge in an homologous fashion leading to the conclusions that Stx1 and Stx2 are not cross protective (Wen et al., 2006).

It should also be noted that several other, nonvaccinal approaches have also been proposed to reduce infection at the farm level including nutrition and probiotics. The principal challenges are twofold: first, increase the intrinsic efficacy of the vaccination protocol through optimized formulation or administration regimes, and second, demonstrate the overall efficiency of on farm interventions strategies including infection in reducing the risk for humans. While this has not yet been demonstrated there are many reasons to believe that reduction at the source would provide significant benefits (Matthews et al., 2006).

Considering the highly sporadic as well as the food-borne nature of the disease there is little interest in developing a vaccine for humans. In humans, especially in the light of the increasing levels of antibiotic resistance observed in these strains, improving the treatment tools available, including immunological tools, will be a priority.

Streptococcus suis

Many streptococcal infections have been described in humans. Infection by *S. suis* is a rare zoonotic disease, usually involving specific risk groups consisting of individuals in close occupational contact with infected swine: farmers, slaughterhouse workers, and hunters (of feral swine). Recently, a rare occurrence of a large cluster of patients with a high level of mortality was observed in China (Huang et al., 2005; Normile, 2005). A small number of patients were exposed to the infectious meat (as opposed to the animals or their carcasses). The investigation did not point to a new variant of the bacteria. Thus, the human disease caused by *S. suis* remains a relatively rare but severe zoonotic disease and is not properly speaking a food-borne infection (as opposed to *E. coli* O157, salmonella or listeria). Clinical manifestations are most frequently meningitis (3/4 cases). Sepsis and other very diverse manifestations, including endocarditis, may be observed. Deafness is a very common long-term complication of this streptococcal meningitis (MacInnes and Desrosiers, 1999). Death can occur but the disease is rarely fatal.

The *S. suis* infection in animals is widespread in pig populations across the world. It most frequently colonizes the upper respiratory tract of the swine without causing disease. It can, however, induce diseases either as a primary pathogen (perhaps because of increased virulence of certain strains) or become pathogenic secondarily to another factor: stress, immunodepression, concurrent infections (e.g., viral infections). The disease manifests in many different forms: death, fever, lameness, septicemia, and endocarditis (Martinez et al., 2002).

The disease occurs primarily in swine after they enter the fattening barn (beyond 12 weeks of age). The disease has a very significant impact on the economic performances of the herd. The agent *S. suis* is a gram-positive cocci and part of the broad genus *Streptococcus*. A very important feature of the organism is its significant diversity. At the serotype level, 35 different capsular types have been described. Serotype 2 is the most common isolate but its frequency varies significantly from country to country and between North America and Europe. Serotype 1/2 is the next most frequent isolate (Martinez et al., 2002). At the genetic level, significant diversity is observed between herds and even within herds. Interestingly, the pathogenic strains emerging within a herd seem to separate more distinctly from the isolates obtained in healthy swine (Berthelot-Herault et al., 2005). At the molecular level, differences are also observed in expression of putative virulence factors (Smith et al., 1996).

Despite best efforts to understand, the exact mechanisms of pathogenicity of the virulent strains as well as the ability to predict the virulence of isolate strains based on molecular models remain elusive. Various proteins, such as muramidase-released protein (MRP), extracellular protein factor (EPF), and a hemolysin (suilysine) have been suggested (Martinez et al., 2002). Mutants lacking these genes did not demonstrate attenuation (de Greeff et al., 2002). It has been suggested that the simultaneous presence of the three factors could make strains more virulent. More recently additional proteins have been proposed as virulence factors: fibronectin-binding protein (Gruening et al., 2006), and arginine deiminase system (ADS) (Okwumabua and Chinnapapakkagari, 2005). A 38 kDa protein of unknown function was found reactive with serum from infected animals and demonstrated protection (Llull et al., 2001). The capsular polysaccharides of *S. suis* as with other streptococci may also play an important role (Busque et al., 1997).

It follows that the molecular basis of virulence remains unknown and that antigenic variation exists within the putative virulence molecules identified that vaccines for this disease have not been able to use modern technologies, such as recombinant expression, which require a defined antigen. Essentially two types of vaccines have been made available, live attenuated strains (Wisselink et al., 2002; Haesebrouck et al., 2004) or inactivated whole cell bacterins. Neither has met with significant success. The majority of the market remains occupied by autogenous bacterins. Autogenous bacterins could provide a means to avoid the significant antigenic variation of the strain by providing a vaccine derived from the particular strain infecting the herd. Considering the variability of strains within herds, one should expect to change strains regularly to maintain efficacy. *S. suis* induced disease remains a very significant and costly disease for the swine industry. In addition, it is responsible for an infrequent but severe and potentially deadly zoonosis in humans. The lack of a detailed understanding of the virulence has precluded the development of efficacious modern vaccines.

Cryptosporidiosis in Cattle

Cryptosporidiosis is a disease of humans, livestock, companion animals, wildlife, birds, reptiles, and fish infected with one or more species of the protozoan parasite *Cryptosporidium*. The clinical outcome of the disease varies greatly from species to species and is also dependent on virulence factors on the parasite and the host immune response to them. In immunocompetent humans, the infection can be asymptomatic even though the parasite replicates and is excreted. When an illness develops the outcome ranges from mild enteric symptoms without diarrhea to a profuse watery diarrhea. Additional symptoms can include abdominal cramps, vomiting, low-grade fever, fatigue, anorexia (Ungar, 1990; Mac Kenzie et al., 1994). The disease is self limiting and typically resolves within 2 weeks. Organisms usually infect the lower small intestine, but in immunosuppressed patients, it can extend from the esophagus, throughout the intestinal tract to the rectum. In some cases the appendix, gall bladder, bile ducts, pancreas, and occasionally even the respiratory tract have been infected (Ungar, 1990). In humans, the most frequently found organism, designated *Cryptosporidium parvum* genotype 1 (or human genotype), appears host-specific, infecting, and spreading only among humans. This organism is now recognized as a separate species, *Cryptosporidium hominis* (Morgan-Ryan et al., 2002). Another organism, designated *C. parvum* genotype 2 (or cattle genotype), is zoonotic, capable of infecting and spreading among many mammalian hosts. The main reservoir of *C. parvum* genotype 2 is cattle. Virtually all cattle are exposed to the parasite during the first few months of life. Calves will shed large number of oocysts (up to 10^9/g of feces) for approximately 10 days. An active immune response will develop and control the infection. However, evidence suggests that most infected animals will carry *C. parvum* for life, shedding few oocysts intermittently. Collectively, data suggest that vast numbers of oocysts are passed into the environment and that cattle contribute significantly to these large numbers. Zoonotic transmission may be important in cases of direct exposure to cattle feces (farms, undeveloped countries) or in waterborne outbreaks (developed countries).

Immunocompromised individuals frequently are observed with the cattle genotypes of *Cryptosporidium* (Pieniazek et al., 1999; Morgan et al., 2000). In the United States and Australia, most cases appear to be of human origin: of 14 food and waterborne outbreaks, 10 were of human genotype, 3 of bovine genotype, and 1 with both organisms. However, in Europe the bovine genotype is responsible for more infections than the human genotype (McLauchlin et al., 2000; Alves et al., 2001; Guyot et al., 2001). In the United Kingdom, zoonotic transmission has been considered to be the major route of infections in humans (Hunter et al., 2003).

As the sole mechanism for transmission, oocysts have evolved to be dispersed and survive in harsh environments for long periods of time. The oocysts are unusually resistant to natural stresses and many man-made disinfectants. To control infection in animal populations the current best strategy is to move animals to clean areas. For human populations, disinfection procedures are used.

Because all infections with *Cryptosporidium* are initiated by ingestion or inhalation of the oocysts, measures to prevent or limit the spread of infection must be targeted to eliminate or reduce oocysts in the environment. Despite the fact that more than 200 drugs have been tested for activity against *C. parvum*, in vitro or in vivo, there is still no effective treatment (Rehg, 1993; Fayer and Fetterer, 1995; Woods et al., 1996; Armson et al., 1999). A cattle vaccine against *C. parvum* might reduce the environmental contamination and consequently the frequency of waterborne cryptosporidiosis outbreaks in humans. Since cattle may be exposed to *C. parvum* from their day of birth, before their immune system is mature, an active vaccination is not likely to mediate any significant protection. Thus, vaccination against *C. parvum* is being attempted for the purpose of generating hyperimmune colostrum-containing antibodies that may be effective in passive immunotherapy against cryptosporidiosis in calves. Calves fed hyperimmune colostrums, prepared against oocysts, and challenged had significantly reduced patent periods, oocyst shedding and days of diarrhea compared to calves fed normal colostrums (Fayer and Fetterer, 1995). A number of recombinant *C. parvum* surface or internal antigens have been expressed by DNA-cloning technology. Immune colostrum specific for several recombinant *C. parvum* proteins have demonstrated efficacy in murine and ruminant models against cryptosporidiosis. The most promising candidate proteins for vaccine development are surface (CP15/60, CP15, and P23) and micronemal proteins (TRAP-C1, GP900) of sporozoites. Both CP15/60 and P23 are detected by Western blot analyses of cryptosporidium proteins using fecal antibodies and serum from cryptosporidium-infected humans and animals (Lumb et al., 1988; Mead et al., 1988; Hill et al., 1990; Reperant et al., 1994). CP15/60 is defined by the monoclonal antibody (MAb) 5C3. CP15/60 IgA MAb provided protection against infection when administered orally to suckling mice (Tilley et al., 1991). The comparison of two recombinant forms of CP15/60, one produced in a prokaryotic expression system and the other in a eukaryotic expression system, indicated that the most potent immune response was obtained using the eukaryotic form, possibly due to posttranslational modifications (Sagodira et al., 1999). It has been reported that preparturient cows immunized with DNA encoding CP15/60 in the mammary gland produced sporozoite-specific antibodies in the colostrums (Jenkins et al., 1999). Immune colostrum induced a 50% reduction against *C. parvum* development in mice.

P23 is defined by the MAb C6B6 (Mead et al., 1988). IgG1 (Perryman et al., 1996) and IgA (Enriquez and Riggs, 1998) MAbs reactive with P23 were shown to have significant anticryptosporidial activity in mice. Perryman et al. (1999) reported that late gestation Holstein cows immunized with rC7, an immunodominant epitope of P23, developed specific antibodies. Calves receiving immune colostrum were significantly protected against diarrhea and were shedding significantly fewer oocysts than control calves. Antibodies directed against GP900 were shown to inhibit sporozoite in vitro, suggesting a direct role of the molecule in host–parasite interaction (Barnes et al., 1998). The reported involvement of TRAP-C1 homologs in substrate-dependent locomotion of sporozoite (Sultan et al., 1997), as well as in host cell attachment and invasion (Muller et al., 1993), suggest that TRAP-C1 should be considered as a promising vaccine candidate against cryptosporidiosis.

In summary, use of vaccines as a public health tool in the control of food-borne illnesses is a complex and important field. Reducing bio burdens in food producing species, where the target species normally is carrying, or shedding at an already very low rate, or where the human pathogen is part of the animal's normal host flora, is a significant challenge for current vaccine technologies. In the case of developed market places, the threat of food-borne illness is already at impressively low levels, though public expectations are that they will drop still further. Therefore, it must be understood that for successful control, these programs must be components of fully integrated programs, including husbandry, meat processing, and handling at the retail and customer levels.

OPTIMIZING VACCINATION PROTOCOLS

Over the last decade there have been tremendous advances in our understanding of the immune systems of our major domestic animal species. Nonetheless, we still lag behind the depth of knowledge that exists for the immune systems of mice and men. This has not stopped successful vaccination programs from being developed. Much of vaccinology that is practiced in veterinary medicine, and the animal health industry in general, is empirical. It is driven by the realities that exist in raising production animals or working in veterinary practice, where making a living depends on keeping the animals healthy. It is an industry where vaccines are like insurance policies—protection from events that one hopes never happen, and where tenths of pennies can make or break the economics of a business. When used optimally, vaccines have been shown to prevent disease, reduce the need for pharmaceutical intervention (e.g., reduced antibiotic usage) and improve the health and welfare of animals (Knott et al., 1985; McIlroy et al., 1992).

Then there is the definition of protection. The perception that vaccines provide sterilizing immunity, where the disease agent does not establish an infection, while widely held, is generally unfounded and largely unrealistic. It is debatable if such immunity is even in the animal's best interest as exposure to, and transient infection with, pathogens helps keep the immune response active. Vaccines usually provide protection on one of three levels. First, at the lowest level, protection is simply a reduction of clinical signs associated with the infection. The reduction may be decreased disease severity and/or duration, or simply a delay in the onset of the disease. The infection still becomes established and in most cases the animal will be contagious to other in-contact animals, although there may be a reduction in the level of shedding of the infectious agent. Such immunity is not usually capable of stopping an outbreak from progressing.

Second, vaccines may induce immunity that can prevent clinical signs associated with the infection, where the animal shows no overt signs of being infected. This level of protection may actually be associated with a reduction of shedding of the challenge organism, which can reduce spread during a disease outbreak. Unfortunately, there is no general rule to rely upon in this regard, as reduction in shedding tends to be specific for the strains involved—both of the vaccine and the infection. It must be recognized that vaccine protection that prevents clinical signs of disease being identified can lead to a false assumption that the pathogen is not present in a vaccinated population. In such circumstances, especially where economic pressures exist, there may be a tendency to decrease the use of vaccines with disastrous results.

Third, vaccine protection may prevent the infection from becoming established. While this is what many people think all vaccines do, it is a claim that rarely will be found on product labels. The United States Department of Agriculture (USDA), which regulates vaccines in the US, requires that for this claim to be granted the vaccine must be demonstrated to be able to "prevent all colonization or replication of the challenge organism in vaccinated and challenged animals" and "this must be supported with a very high degree of confidence by convincing data" (DeHaven, 2002).

The USDA recognizes these varying levels of protection in the way they allow label claims. The above three categories are often written on labels as "aids in disease control," "for the prevention of disease," and "for the prevention of infection." The vaccine manufacturer has generated a great deal of data, which has been independently reviewed by a government agency, that become the basis for the label claims. Expecting a vaccine to do something that is unrealistic given the data and a label indication is perhaps the greatest cause of reported "vaccine failures." To paraphrase the old adage, if in doubt always read the label.

While on the topic of the level of protection, it should be noted that vaccines can provide efficacy, or protection, that may come from both direct and indirect effects. The direct effect can be relied upon to provide individual immunity—that is the animal that receives the protective dose of vaccine benefits directly. Additionally there may be indirect protection, or herd immunity, that results from vaccination of sufficient numbers of animals in a given population. Herd immunity protects nonvaccinated animals within a population, whether a flock, herd, or group. It is the result of the reduction of the ability of a disease to transmit through the vaccinated individuals. For such immunity to occur, the vaccine should be capable of reducing the shed of the disease causing agent following infection of a vaccinated animal.

The challenge in developing an optimal vaccination program is in dealing with the great diversity that exists within the animal world, and as such there probably is no single optimal program for all occasions. The multitude of factors that need to be considered in choosing a vaccination program are complex—species/breed differences, and within these the genetic selection that has occurred, some of it for resistance to select diseases; the diverse husbandry practices employed, some dating back centuries, some mandated by governments; and the disparate

prevalence of diseases has resulted in the adoption of tailored vaccination programs. Such programs generally are designed to consider the risks (e.g., disease prevalence and exposure likelihood), husbandry (e.g., animal-to-animal contact, nutrition), and environmental factors (e.g., wildlife vectors, weather) and of course the animals (e.g., age, previous disease experience).

The conditions that influence the tailored vaccination program change rapidly over the life of the animal. Indeed the time period over which protection is required varies greatly. Chickens, unless they are breeding animals, normally go to market by 6 weeks of age, pigs become pork when just 6 months old, and cattle and sheep frequently become someone's dinner by 18 months of age. Even our beloved pets rarely live beyond their teen years. As we touch upon some of the more unique challenges that exist in optimizing vaccination protocols and practical veterinary vaccinology, the following pages are divided up by life-stage.

Prenatal Vaccination

Strengths

The protection that is provided by the mother to the unborn animal is critical in ensuring the delivery of healthy offspring. In livestock, producing new animals is what generates the income for the farm and as a result the use of vaccines during pregnancy has been widely adopted to enhance this protection. In utero, the fetus is protected from the environment and its pathogens. This protection is provided both physically and immunologically by the dam. The physical part is easy to see—fetal membranes and fluids shield the fetus behind a muscular uterine wall inside a multilayered abdomen. The immunological protection likewise is on several levels—innate and acquired immunity of both the dam and fetus—but unlike physical protection, immunological protection may continue beyond the in utero period into early life.

The immunity of the mother may prevent infections from reaching the fetus or may enable the dam to provide immune cells or antibodies to the fetus. Vaccination of the mother is commonly practiced to accomplish both. In species where litters are common, for example, pigs, vaccination of the dam is an effective way to protect the entire litter with a single vaccine dose. Even in single offspring dams, for example, cattle, vaccination is recognized as providing added insurance to getting a healthy newborn. It can also be an effective way for neonatal animals to gain early immunity against the plethora of infectious challenges they face in the first weeks of life. There is evidence that active vaccination of the fetus may occur with some antigens crossing the placenta and stimulating fetal immunity.

Sows, with a gestation period of 113 days, are often vaccinated near the time of breeding and again 2 weeks prior to farrowing. Such vaccinations have proven effective in increasing litter size and growth performance (Descamps et al., 1990). The vaccination in early pregnancy is aimed at protecting the litter by stimulating active immunity in the sow against common pathogens that cause abortion, metritis, or stillbirths, for example, *Leptospira* spp., parvovirus, *Erysipelothrix rhusiopathiae*. These vaccines, typically given by injection, induce an active immune response in the sow, preventing the viremia or bacteremia from occurring and thus protecting the unborn piglets. Vaccinations in late pregnancy are aimed at boosting immunity to maximize the level of passive immunity (transplacental and colostral antibodies) that a dam passes on to her offspring. Typically these vaccinations are targeted at neonatal diseases causing enteric (e.g., rotavirus, *E. coli*) or respiratory problems (e.g., *Pasteurella multocida*, *Bordetella bronchiseptica*). Piglets born of vaccinated sows generally have performed significantly better than those of nonvaccinated sows when evaluated on a variety of parameters such as growth and average daily weight gain (Riising et al., 2002).

Similar vaccination protocols are used in dairy cattle. As with the sows, vaccination during pregnancy prevents abortion and helps ensure the birth of a healthy calf. In turn, the successful birth of a calf also ensures another lactation cycle, which after all is what a dairy is all about.

The late pregnancy vaccinations are expected to generate high levels of circulating antibodies that may be passed onto the newborn animal via colostrum. Colostrum is the first milk that is produced by mammals for their babies. Typically this is produced for 2–4 days and its consumption by the newborn is seen as very important for a variety of reasons. Research has shown that maternal antibodies may be concentrated in the colostrum to levels higher than that found in the dam's circulation (Pfeffer et al., 2005). Through the use of dam vaccination, the specificity and level of these antibodies can be manipulated to tailor protection that is most appropriate for the geographical region or environment where the birth occurs. Maternal antibodies can be directly absorbed by the newborn and enter into circulation providing passive immunity against otherwise fatal infections. There is now good evidence that cells and cytokines of the dam's immune system also pass via colostrum to the newborn. These components of colostrum significantly aid the development of the neonatal immune

TABLE 16.1 In utero transplacental transfer of antibodies

Species	Type of placentation	Number of layers	Ig via placenta	Ig via colostrum
Pig, horse, donkey	Epitheliochorial	6	0	+++
Ruminants	Syndesmochorial	5	0	+++
Dog, cat	Endotheliochorial	4	+	+++
Primates	Hemochorial	3	++	+
Rodents	Hemendothelial	1	+++	+

Source: Tizard (2004).

system (Muneta et al., 2005; Reber et al., 2005). The corollary of this is that colostrum deprived animals typically have numerous health problems and frequent infections.

Some maternal antibody crosses the placenta to protect the unborn animal. The level of this transfer depends on the nature of the placenta. Typically of our domestic species, dogs and cats provide the greatest in utero transplacental transfer of antibodies, while pigs, horses, and cattle provide the greatest colostral antibody transfer (Tizard, 2004) (Table 16.1). Even poultry get the benefits of prenatal vaccination. In ovo vaccination is now common. Vaccines of various types are injected directly into the egg at between 9 and 14 days of age, depending on the organism being used as a vaccine. The whole process is automated enabling many thousands of eggs to be vaccinated in a day. The end result is that at hatching the young birds are protected from select pathogens. Research has shown that in ovo vaccination may be more advantageous than posthatch vaccination (Rautenschlein and Haase, 2005).

Challenges

Of course, there are downsides to prenatal vaccination. Not all vaccines are safe to be given to pregnant animals. The administration of live or adjuvanted vaccines during pregnancy carries the risk of inducing a transient febrile reaction and subsequent abortions or stillbirths that may follow a fever. Typically, live bovine herpesvirus vaccines in naïve cows have been associated with abortions due to fetal infection with the vaccine strain and similarly live porcine reproductive and respiratory virus vaccine has been found to reduce litter size and cause abortions in sows. The choice of which vaccines to use in pregnant animals should, as always, come after reading the label and understanding the risks involved.

The timing of administration can play a large part in influencing the safety and the effectiveness of the vaccine. Vaccination soon after breeding has been shown to reduce the conception rate. This is probably a direct result of the transient febrile reaction decreasing implantation of the embryo. Vaccination in late pregnancy, close to parturition, tends to be less effective. Around the time of parturition, there is a well-described phenomenon of reduced immune system activity (Houdijk et al., 2000). Vaccination may not deliver the expected efficacy if given under these suboptimal conditions.

Even when vaccines work well, inducing strong immune responses in the dam, there may be a downside. Passive antibodies, whether transplacental or colostral, can inhibit active immunization of the newborn. In some cases this blocking effect can last months. Unfortunately, the level of passive immunity that blocks vaccine strains may not be sufficient to protect against virulent pathogens. This "gap" between lack of protection and earliest ability to vaccinate has been well described for canine parvovirus (McGavin, 1985). Vaccination of the dam does not eliminate the problem and can actually shift the problem to a time period when the risk of exposure to disease is greater, for example, young animals taken to market.

Opportunities

As Albert Einstein said "In the middle of difficulty lies opportunity." So it is with prenatal vaccination where every challenge becomes an opportunity and vaccine producers are continually seeking safer, more effective vaccines.

The diversity of approaches to improved safety is enormous but ever increasing regulatory hurdles, rather than true safety issues, make more and more vaccines carry the warning "Not for Use in Pregnant Animals." The true benefits of prenatal vaccination are to enable consistent active immunity to develop in the unborn animal. Many neonatal diseases would disappear, if active immunity was present at birth. The resulting increase in health benefits would be significant. Such vaccines are not readily available at present. In ovo vaccination of chickens being perhaps the exception, although even there not all pathogens can be covered by safe and effective in ovo vaccines.

Likewise improved efficacy would be highly desirable to help overcome the periparturient relaxation of immunity that occurs in dams. Such increased efficacy would result in greater consistency of transplacental and colostral immunity transfer. The development of products that could enhance the transfer of passive immunity to the neonates would be greatly welcomed.

Neonatal and Juvenile Vaccination

Strengths

After leaving the protection of the uterus, the neonate begins dealing with a plethora of new antigens, both environmental and infectious. Unfortunately, most of our domestic species are born with relatively immature immune systems inclined toward a Th2-mediated response (Morein et al., 2002). It is during these early weeks of life after birth that newborn animals are the most vulnerable and this is where vaccines can be most beneficially used. The husbandry practices that we use with many of our animals species often entails mixing of animals from a variety of sources, for example, the combining of 3 week old pigs from perhaps hundreds of litters when they move to the nursery, or mixing of hundreds of puppies at 6 weeks of age when they are transported to the pet shop. The combining of very young animals from diverse disease backgrounds when their immune systems are not yet fully developed and not yet primed by vaccination is a huge challenge for maintaining good health. The need for vaccination before, during, and after such commingling of animals is essential to reduce the suffering that disease outbreaks can cause.

No longer are we trying to vaccinate litters, or trying to vaccinate through the dam. The animal is now an individual, albeit perhaps still part of a larger group. It is possible to directly administer vaccines to the animal in accordance with an assessment of its individual needs. As most animal breeders expect to make money from selling the offspring, each individual animal has a monetary value. This enables a fairly objective view to be taken of risk benefit analysis—the benefits arising from the use of vaccines versus the cost of disease. Most animal breeders have tailored vaccination programs to the needs of their animals, with multiple injections of different vaccines being common. Typically neonatal animals receive multiple vaccinations covering the major diseases that their owners expect they may become exposed to during their lives. A kitten could receive eight different vaccines on two or three separate occasions, although many are given in combination—feline herpesvirus, feline calicivirus, feline panleukopenia, feline leukemia virus, rabies virus, and Chlamydia are common; with feline immunodeficiency virus, *B. bronchiseptica* and *Toxoplasma gondii* also available for cats. Puppy vaccinations often involve combinations containing protection against 11 different disease agents, for example, canine parvovirus, distemper, canine adenovirus types 1 and 2, canine parainfluenza, rabies virus, four different *Leptospira* species and *B. bronchiseptica*. These vaccines are usually given 2 or 3 times at intervals of 3–4 weeks starting at 8 weeks of life.

One consequence of now having to vaccinate the individual animals is that in large numbers the task can prove to be daunting. The labor and logistics of vaccinating 20,000 chickens or 10,000 piglets are quite involved. Fortunately, vaccines are available for mass administrations that are optimal for dealing with large flocks or herds. Several options exist with aerosol spray and drinking water being the most common. The vaccines typically are live agents that are diluted in water containing a stabilizer to prolong the in-use viability of the agent. Aerosol vaccination can be tailored to the particular vaccine by adjusting the droplet size that in turn alters the location within the respiratory tract where the droplet eventually lodges (Gough and Allan, 1973; Gomez and Correa, 1978). While originally developed for poultry vaccination, aerosol vaccination has been used in swine (Nielsen et al., 1990) and cattle (Kita et al., 1982) with the same factors as for poultry needing to be considered—droplet size, type of diluent, environmental conditions (e.g., wind and temperature) and strain, and dose of the vaccine organism.

Drinking water, as a vehicle to mass vaccinate animals, while pioneered for poultry, has been used in other species. The addition of the vaccine to regular tap water can be an effective way to vaccinate provided the chlorine is neutralized by the addition of 0.25% skim milk (Kim and Spradbrow, 1978). Like aerosol vaccination the number of doses required for adequate protection will be contingent on the type of agent in the vaccine and the age of the animal.

Challenges

Vaccination of very young animals poses numerous challenges but none as difficult as that of overcoming the interference of maternal immunity. The maternally derived antibodies that most young are born with, or acquire through colostrum consumption, can be protective but as the level wanes there is a period where it is no longer protective. What proves to be worse for the health of the young animal is that these residual antibodies may block effective immunization.

The traditional solution is to administer multiple doses around the period where the maternally derived protection is waning. As the timing cannot be accurately known even this does not guarantee that there is not a susceptible period. As numerous papers testify to, during the canine parvovirus epidemic of the 1980s, many puppies failed to be protected despite receiving vaccinations at weekly intervals (McGavin, 1985). Similar situations exist in other domesticated species, with the result that many doses of vaccine given to young animals are ineffective, not because of a problem with the vaccine, but with the timing of the delivery.

The use of injections to administer vaccines has proven a very effective delivery method but this too has caused problems. Transmission of disease through the use of contaminated needles or vaccine vials has been documented (Witter and Fadly, 2001; Niskanen and Lindberg, 2003). While good hygiene should prevent such problems, the field conditions under which animal vaccinations frequently occur are often not conducive to maintaining sanitary conditions. The presence of blood, mud, feces, and flies is not unexpected. In meat-producing animals the use of needles to deliver products can lead to another problem—broken needles in meat products. The inability to find a broken needle quite often results in the condemnation of the carcass to keep it out of the food chain. While this is a problem with any product, including medicines, delivered by injection, vaccines represent the most common reason for sticking a needle into a meat-producing animal.

The relative immaturity of the newborn's immune system is another challenge that must be factored into vaccination of the neonatal or juvenile animal. The bias for a Th2 response in the neonate (Morein et al., 2002) is not always the preferred type of immune response for protection against disease. The use of adjuvants that drive Th1 immune responses may be required to confirm effective protection. It has been demonstrated that neonatal calves may be able to develop a cell-mediated response comparable to adults, although antibody responses are markedly lower than seen in adult heifers (Nonnecke et al., 2005). This is in normal, healthy, young animals but there are a variety of situations where the young immune system is even less ready to respond to vaccination.

In colostrum deprived animals the maturation of the immune system may be delayed because of a lack of exposure to specific components in this first milk. Vaccination of colostrum-deprived animals should be undertaken with care to recognize that their responsiveness may be compromised compared to that of animals receiving colostrum. Likewise, stress has been associated with poor immune responsiveness and there is little doubt that the newborn goes through many stresses in the first few weeks of life. There, of course, are the routine environmental stressors such as temperature, air quality, etc., but often more critical for animals is the dietary change including weaning at an early age that is routine in most of our domestic species. Pigs, for example, may be weaned at 2–3 weeks of age, and it has been shown that the composition of their starter diets, in particular the levels of protein, lysine, methionine, and threonine, may be critical in the development of their immune system (YongQing et al., 2001; Nonnecke et al., 2005). The simple event of handling the young animals to enable vaccination has been shown to be stressful and potentially reduces the response to the vaccine. Even a car trip to the veterinarian's office may have the same stress-related effect on the immune system. Unfortunately, when simply looking at a young animal it is not possible to determine its responsiveness to vaccination. It is nearly always a guess, which often results in the administration of multiple doses of vaccine to cover the poor responders.

Opportunities

The largest opportunity to improve vaccination of neonatal and juvenile animals is undoubtedly for vaccines that would consistently work in the face of maternal immunity. The health and financial benefits would be immense if we could remove the need to revaccinate young animals because active immunity was blocked by residual but waning passive immunity. The convenience of knowing that you could take your pup or kitten to the veterinarian once to have them immunized, or the need to only vaccinate a herd of 10,000 piglets once, are immense. Likewise sustained release, or long-acting vaccines could facilitate less handling of the animals and hence less stress. Such long-lasting vaccines would increase the likelihood that the vaccine antigens are present when the animal is able to respond to them.

The ability to test for the responsiveness of an animal to a vaccine before actually administering the vaccine could have huge practical benefits for animal owners, especially livestock producers who have large numbers of animals to vaccinate. Currently laboratory testing for antibody levels is possible, but the cost and time make this relatively impractical. It has proven cheaper to vaccinate and hope for a response than to bleed and test. The ability to determine, perhaps via a simple animal-side test, whether the animal has responded to vaccination would be beneficial.

Considerable progress has been made in avoiding needle delivery of vaccines, and not just through alternative routes such as aerosol and drinking water. In the last 10 years, the development of needle-less injector has been an active area of research. These devices use a variety of approaches but most commonly involve high pressures to force the liquid vaccine directly through the skin without a needle. While most of these injectors are effective to some extent, the challenges of dealing with superficial skin contamination and the problem posed by the presence of a dense hair coat to obtain good skin contact for the injection, have hampered their adoption. It is likely that reliable and highly effective needle-less injection devices will be available within the next few years.

Adult Vaccination

Strengths

Many of the issues that surround vaccination of neonatal and juvenile animals tend to resolve with age. Adulthood generally brings a mature immune system including fully functioning innate immunity. The time of this varies by species but, in general, by 1 year of age most or our domestic species are nearing breeding age and can be considered young adults. As stated earlier, chickens and pigs may well have gone to slaughter before 1 year of age but breeding animals of these species are kept beyond 1 year of age. The value of an adult, having been reared and cared for, perhaps for years, means that the economics of vaccination is generally less of a concern. Multiple vaccinations are often given, considering specific disease risks and environmental factors, as part of a tailored vaccination program.

Adult animals, with their mature immune systems, absence of maternally derived immunity, and adjustment to their environmental stressors, are normally the best candidates for vaccination. Even in these near ideal candidates for vaccination, the number of doses that are required for efficacy will depend on the nature of the vaccine. Vaccines fall broadly into one of two categories—live or killed.

Live vaccines typically replicate in the host and hence deliver a large antigenic mass to the immune system resulting in rapid and strong immunity. Live vaccines have several advantages. Formulated without specific immune system stimulants, they generally cause less injection site reactions. Even when not being injected they have the advantage that most retain the infectivity of the wild-type pathogen enabling effective delivery by routes such as aerosol or orally. One potential negative is that, because they replicate, there is the risk that in an immunocompromised individual they may induce some signs of the disease they were meant to prevent.

Killed vaccines might be better termed nonreplicating to cover vaccines that never were alive, for example, subunit-containing vaccines. Most vaccines in this category are made from the culture of live organisms that are inactivated, or killed, using one of a variety of chemicals, with formaldehyde the commonest. The inactivated organisms on there own will often only stimulate a weak or transient immune response. While there are numerous causes of this phenomenon, the common explanations are that inactivation alters the conformation and hence presentation of some antigen epitopes and the inactivated antigens do not signal quite the same danger to the animal's immune system. The "danger signal" model of immunity moves away from the self versus nonself based view and considers the idea that the immune system is more concerned about organisms that damage the animal rather than just being foreign (Gallucci and Matzinger, 2001). To overcome this shortcoming, the addition of an adjuvant is classically done to stimulate a greater immune response, or to drive a particular immune response, for example, Th2 versus Th1. Killed vaccines are safe, in that, without live agents in the final product, they cannot be the source of an infection. However, the presence of the adjuvant often results in greater injection site reactions than is seen with live vaccines. Injection site reactions can range from merely discomforting to quite painful, but in livestock they often end up as imperfections in the meat resulting in trim losses on the slaughter line. The route of vaccination is often dictated by the nature of the injection site reaction. In beef cattle most vaccines are given subcutaneously to avoid reactions damaging the meat. In show animals, for example, horses, intramuscular injections are preferred to avoid any blemishes that subcutaneous injections may cause.

The typical adult will fall into one of two categories with respect to vaccination—naïve or preexposed. The true naïve adult will not have a problem with maternally derived antibodies blocking effective vaccination and normally responds well to vaccinations. In fact the responsiveness to vaccination is much more predictable (strength of protection engendered) and reliable (percentage of animals responding) in these naïve adult animals. This is critical as the adult animal tends to be more adventurous, often traveling and having greater contact with other animals. This is particularly true of the companion animals' species where dogs, cats, and horses may go to shows, boarding facilities, and sporting events. At these venues their opportunity to interact with animals from a

diverse range of geographies, and consequently disease backgrounds, is enormous. Even as our livestock species grow older they will have greater exposure risks—stock movement is common and introduced animals whether for breeding or to add production capacity frequently come from markets where mixing of animals is commonplace and disease transmission is prevalent. The onset and duration of immunity that occurs after vaccination of naïve animals will generally be representative of a primary immune response. Such responses tend to be slower in reaching protective levels and the memory may be shorter following a single vaccine dose.

The preexposed adult may have already experienced the disease or have a prior vaccination history. Often these two events will be indistinguishable without an accurate history of the animal. Fortunately when it comes to vaccination it does not matter, both recovery from infection and effective previous vaccination will have engendered an immune memory provided the exposure was not too long ago. The duration of immunity that follows exposure of the immune system to a disease agent, even a vaccine strain, depends on the translation of at least part of the initial response into a memory response. The presence of specific memory T cells enables an amnestic response regardless of the source of the agent inducing the original response. This phenomenon is leveraged in adult vaccination programs to decrease the frequency of revaccination. Traditionally, dog and cats were revaccinated on an annual basis throughout their lifetimes, although it was anticipated that routine vaccines were likely to provide far greater than 1 year of protection. Recent work has proven that under field conditions there is evidence of immunity that can persist for 48 months in some animals (Mouzin et al., 2004a, 2004b). Evidence in horses and cattle would indicate that the duration of immunity following vaccination may be only as long as 1 year but varies with the disease agent (Hannant et al., 1988; Peters et al., 2004). The vaccine manufacturer normally provides guidance as to the duration of immunity that may be anticipated following successful vaccination of animals. Depending on the individual circumstances the duration of immunity may be longer or shorter than the label indicates, especially in environments where exposure to the disease agent occurs. This results in natural boosting of immunity and essentially lifelong immunity.

Challenges

Like their younger counterparts, there are a variety of problems that may be associated with vaccination, for example, injection site reactions and mild transient signs of disease, which are a concern to owners. There are some issues however that tend to be seen more commonly in adults. The reason may be easily understood by remembering that the longer an animal lives the more vaccination events it is likely to have lived through. While this is good with respect to developing immunity, there may be downsides.

Transient lameness may occur following vaccination when the dose is administered into a leg or neck muscle and may be more noticeable in adults simply because of the greater weight of the animals compared to their neonatal or juvenile counterparts. Prior exposure to vaccines may induce a hypersensitivity to components, such as bovine serum albumin, used in manufacturing the product with the result that larger injection site reactions may occur. Other reactions such as arthropathy, vasculitis, neurological dysfunction, and thrombocytopenia have been associated with repeated vaccine exposure (Schattner, 2005). Fibrosarcomas in cats have been linked to vaccine reactions and usually have fatal outcomes (Hershey et al., 2000). Nonetheless the incidence of postvaccinal reactions is relatively rare. In one study, the reaction rate in over 1.2 million dogs receiving 3.4 million doses of vaccine was found to be less than 1 in 250 dogs (Moore et al., 2005).

The use of vaccines during periods of lactation has been found occasionally to cause transient decreases in milk production (Scott et al., 2001). The milk drop appears to be associated with a febrile response that in particular follows the administration of live viral vaccines. In cattle, the milk production loss typically is small but readily noticeable by diligent dairy staff.

Adult animals are often subject to stressful conditions that younger animals are spared. Whether it is the stress of lactation, or the stress of performance in racing or pulling wagons, the result is the same—potential down-regulation of the immune system and reduced responsiveness to vaccination.

Opportunities

The move in companion animals toward longer duration of immunity is a trend that is likely to expand into vaccines for livestock. The labor costs of handling mature livestock are considerable and yet the cost of a disease outbreak can financially devastate a producer. Several promising areas of vaccine research raise the likelihood of longer duration of immunity for all animal species.

Vaccine researchers are tapping into the trends in human health to improve the effectiveness of animal vaccines. The use of DNA vaccines with specific cytotoxic lymphocyte antigens and CpG motifs has

been found to induce more potent memory responses (Kennedy et al., 2005). Another promising area of research involves TLRs. These receptors are a family of transmembrane proteins that can interact with a variety of antigens from microbial organisms. Once activated by the interaction, the TLRs can induce an intracellular cascade resulting in select gene expression associated with the immune system. The discovery of TLR agonists or ligands may result in new classes of adjuvants that are more specific and yet safer.

The incorporation in vaccines of interleukins, or genes coding for them, has been a popular area of veterinary research. The intent is that coadministration of antigens with cytokines will result in enhanced immunity. Such products, should they come to market, are likely to also benefit neonatal animals as cytokines may help the maturation of the immune system.

In summary, there is no magic solution to optimizing vaccination programs for animals. A solid understanding of the animal's innate and environmental risk factors as well as the variables such as stress will enable the development of tailored vaccination schedules that best meets the needs of the animal. While no vaccine will be 100% effective under all circumstances, careful consideration of what and when to use, can certainly enhance the chances of successfully protecting animals. Finally, if all else fails, read the label and follow the manufacturer's recommendations. They are based on extensive research and are provided to help optimize the effectiveness of vaccines.

STRATEGIZING THE USE OF ANIMAL VACCINES FOR PROTECTING THE PUBLIC

Health, Modeling, and National Economies

The direct and indirect impacts of infectious diseases, particularly highly contagious diseases, on human and animal health may become rapidly massive and erode a national economy within a few hours or days. These effects may be exponential in nature if the disease is zoonotic and trade sensitive. For example, the recent international crisis of outbreaks of high pathogenicity of the Avian influenza H5N1 (Schudel and Lombard, 2006) reduced trade (Hall, 2004) and negatively impacted the economies of several nations across the globe from Southeast Asia to Western Europe (McQuiston et al., 2005; Vallat and Mallet, 2006) in addition to human morbidity and mortality and serious social disruption (Gust et al., 2001). Other diseases and especially trans-boundary diseases including Nipah virus, West Nile virus, severe acute respiratory syndrome (SARS) (von Overbeck, 2003), classical swine fever, porcine reproductive and respiratory syndrome (PRRS) (Garner et al., 2001), rinderpest, peste des petits ruminants (PPR), Rift Valley fever (RVF), brucellosis, and bovine tuberculosis have been identified as having profound effects on international trade and national economies if introduced into countries free of these diseases (Domenech et al., 2006). Modeling analyses of the immunization against tuberculosis, HIV, Chlamydia trachomatis, and malaria with effective vaccines predicts significant health and economic benefits (Bishai et al., 2001; Bishai and Mercer, 2001; Frick et al., 2004; Maire et al., 2006).

The classic example of a highly contagious animal disease severely impacting international trade, causing social disruption, and having profound repercussions on national and global economies is foot and mouth disease (FMD) (McCauley et al., 1977; Krystynak and Charlebois, 1987; Perry et al., 1999; Paarlberg et al., 2002; Randolph et al., 2002; Belton, 2004; Vallat and Mallet, 2006), which unfortunately occurred in the United Kingdom in 2002 (Samuel and Knowles, 2001; Thompson et al., 2002). The losses attributed to FMD to agriculture and the food chain in the United Kingdom amounted to about £3.1 billion. FMD is an ongoing crisis in several countries and continuously poses a serious threat to FMD-free countries. Based upon the significant risks of an accidental or intentional introduction of zoonotic and nonzoonotic diseases, newer strategies are being developed as countermeasures.

Use of Models for Preemptive Vaccination and Identification of Emerging Disease Vaccine Targets

In response to the growing global crises associated with known, emerging, and unknown infectious diseases of man and animals, more robust disease models and surveillance systems are now being developed to assess the risks and identify potential targets for vaccine research and development; however, more comprehensive interoperable datasets, middleware, and improved micro- and macrolevel models will be required to make the system more efficient and effective (Gust et al., 2001). Several models indicate that vaccination strategies for FMD and respiratory pathogens are justified (Bates et al., 2003a, 2003b, 2003c; Pourbohloul et al., 2005). Even with more sophisticated FMD predictive modeling methods (Perez et al., 2005, 2006; Branscum et al., 2007; Shiilegdamba et al., 2008), the accompanying implementable governmental policies will need to be in place to take tactical and

strategic advantage of newer FMD surveillance and vaccine technologies (Marshall and Roger, 2004; Kobayashi et al., 2007a, 2007b), or the control and eradication programs may be prolonged (Whiting, 2003; Perez et al., 2004). Additionally, for purposes of biopreparedness, predicting which vaccines and what quantity of vaccine should be stockpiled becomes a daunting task (Rossides, 2002); however, modeling approaches have been developed to facilitate the decision-making process given the uncertainties and complexities of naturally occurring much less intentional infectious disease outbreaks (Medema et al., 2004).

Reduction and Control of Zoonoses through Strategic Application of Animal Vaccines

In reviewing data from several sources, Lutticken et al. (2007) found that with the increasing demand for food, the enlarging scale of world food production, the augmented transportation of animals and food products, and simultaneous contact of animals with the environment, several microorganisms have established themselves in farmed animals, which although may be relatively harmless to animals are pathogenic to man. These investigators propose options for reducing the risk of transferring zoonotic agents from animals (particularly farm animals) to man by specifically applying veterinary vaccines against viral and bacterial diseases (Lutticken et al., 2007). Other investigations documented that avian influenza, West Nile virus, *Bartonella henselae*, rabies and anthrax vaccines which protect animals reduce or prevent transmission of zoonoses to humans (Capua, 2007; Lutticken et al., 2007; Marano et al., 2007; Miguens, 2007). Vaccination of vector/reservoir species, when efficacious vaccines are available, offers will offer significant advantages to combating zoonotic human disease (Zinsstag and Weiss, 2001; Marano et al., 2007). In summary, when appropriate biopreparedness, management strategies and contingency plans of the future (Westergaard, 2008) are linked with (1) protective DIVA vaccines (Clavijo et al., 2004; Selke et al., 2007) against zoonoses, (2) effective predictive modeling (Branscum et al., 2007), and (3) deployable implementation policies (Kobayashi et al., 2007b), control and prevention of serious zoonotic diseases of man and animals will become more achievable at local, state, and national levels.

Misinformation about Vaccines

Martin G. Myers[1,2] *and Diego Pineda*[2]

[2]National Network for Immunization Information, Galveston, TX, USA

OUTLINE

ABSTRACT

Erroneous information about vaccine safety (misinformation) has existed since the dawn of vaccines and its dissemination is permitted by the freedom to express an opinion—no matter how incorrect.

Because of the increasing number and timing of vaccines, they are easy scapegoats for adverse events which occur coincident with vaccine administration, particularly those outcomes that are incompletely understood. In addition, vaccine-preventable disease activity has been greatly reduced by immunizations, causing parents to fear what they perceive might be complications of vaccines more than the actual diseases that the vaccines prevent.

It may require years to collect the data necessary to meet the rigorous standards that permit scientists to emphatically reject a vaccine safety concern. During the time needed to collect the evidence, however, those claims can evolve into misinformation.

Misinformers may be unintentional (they are uninformed) or intentional, in which case many have profit incentives. The most effective misinformers, however, are parents who truly believe that their child has been injured by vaccines.

Misinformation about vaccines can—and is—aggressively disseminated. Presented as fact by prominent individuals, it is often featured in publications, expounded on by the news media, discussed on popular TV and radio talk shows, and made the subject of TV dramas and docudramas. Because these compelling stories often feature prominent people, it is little wonder that other parents become confused. Unfortunately, there are barriers in responding to misinformation including innumeracy on the part of the public and poor communication skills on the part of vaccine spokespersons.

Confused parents may delay or refuse immunizations for their child. Many parents have many misperceptions about disease risks and vaccine safety, both those parents who permit their child to be immunized and those who do not. Health professionals can also become confused and some have helped perpetuate misinformation about vaccine safety.

The consequences of misinformation about vaccine safety can be declines in immunization acceptance and coverage followed by disease outbreaks with global consequences.

Countering misinformation about vaccines has become an urgent priority to assure the continued success of immunization programs. Fortunately, parents continue to seek information as well as the means to validate what they find. They also are seeking to identify trusted health providers to give them more information and guidance.

INTRODUCTION

In the 20th century, infectious diseases in the United States and other developed countries began to be better controlled as a consequence of clean water, pest control, and especially because of vaccines (Table 17.1). National immunization programs were successful because of effective childhood vaccines and a broad societal consensus that rare serious side effects—such as vaccine-associated poliomyelitis—were tragic but were tolerable for the benefit of the general public health. Of course, serious vaccine misadventures during the past century led to the vaccine industry being one of the most closely regulated of all US industries (Parkman, 2002).

While the immunization programs have been remarkably successful, they have had to deal with many challenges some of which are consequences of misinformation about vaccines and vaccine safety (Gust et al., 2004, 2005). For example, there have been recent measles outbreaks in the UK (Jansen et al., 2003; Ashmore et al., 2007), the Netherlands (Lernout et al., 2007), Germany (van Treeck, 2006; Bernard et al., 2007; Steart-Freedman and Kovalsky, 2007), and Switzerland (Richard and Masserey Spicker, 2007), attributable to inadequate rates of immunization coverage, at least in part related to the impact of misinformation about the safety of measles-containing vaccines. Similarly, recent outbreaks of mumps in the US seem likely to have been imported from the epidemic in the UK (Centers for Disease Control and Prevention, 2006a), also related to decreased vaccine coverage due to the measles misinformation.

Seventy seven percent of US children 19–35 months of age are fully immunized with all the universally recommended vaccines (Centers for Disease Control and Prevention, 2007)—of course, that also means that 33% of children are under-immunized. In 2001, it was estimated that 3 children per 1000 had never received any vaccines (Smith et al., 2004); thus many others must be incompletely immunized. Under-vaccinated children are consequences of limited health-care access as well as financial and other barriers to immunization, although some are also a consequence of confusion about the importance of vaccines and misperceptions about vaccine safety (Gust et al., 2004). In contrast to under-immunized children, unvaccinated children's families tend to oppose immunization, cluster in communities, and their parents tend not to consider the advice of physicians or other health professionals (Smith et al., 2004; Salmon et al., 1999). Many parents are uninformed about the risks of vaccine-preventable diseases as well as misinformed about the safety of vaccines (Gust et al., 2004).

People opposed to immunization have been present since immunizations began. Cotton Mather's home was bombed (fortunately the bomb did not detonate) for preaching support for variolation, having convinced Zabediel Boylston, a physician, to variolate people in Boston in 1721 (Best et al., 2004). Admittedly, variolation was a practice with severe side effects, including 2% of patients dying, but the risk was less

TABLE 17.1 Vaccines and vaccine-preventable diseases—a remarkable outcome

Diseases	Number of cases before vaccine was widely used[1]	Year vaccine recommended for routine childhood vaccination	Number of cases	
			2005	2006
Smallpox	48,164	Early 1900s	0	0
Diphtheria	175,885	Mid-1940s	0	0
Pertussis	147,271	Mid-1940s	25,616[a]	15,632[a]
Tetanus	1314	Mid-1940s	27	41
Paralytic poliomyelitis	16,316	1955	0[c]	0
Measles	503,282	1963	66	58
Mumps	152,209	1967	314	6584
Rubella	47,745	1969	11	11
Congenital rubella	823		1	1
Invasive *H. influenzae*, type b[b]	20,000	1985	9	29
Invasive *S. pneumoniae*[b]	17,240	2000	1495	1861
Hepatitis A (acute)	26,796	1995	4488	3579
Hepatitis B (acute)	26,107	1986	5119	4713
Varicella	About 4,000,000	1995	32,242	48,445
Deaths	105		3	ND[d]

[c] In 2005, there was one case of imported, vaccine-associated paralytic poliomyelitis.
[d] ND, no data are available for 2006 yet.

than the mortality of smallpox in the unimmunized that developed smallpox (14.9%). Initial concerns about the safety of variolation led Benjamin Franklin to decide to not have his 4-year-old son, Franky, immunized by variolation, with tragic consequences:

> In 1736 I lost one of my sons, a fine boy of 4 years old, by the Small Pox… I long regretted bitterly and I still regret that I had not given it to him by inoculation; This I mention for the sake of parents, who omit that operation on the supposition that they should never forgive themselves if a child died under it; my example showing that the regret may be the same either way, and that therefore the safer should be chosen (Hastings Weld, 1859).

MISSING INFORMATION

Missing Community Fear

How can communities knowingly put their children at risk from vaccine-preventable diseases? Of course, communities do not realize that their children may be at risk. In the absence of the vaccine-preventable diseases, parents do not recognize that their communities remain at risk of these infections and that these diseases can be introduced and quickly spread within communities. This loss of societal fear represents one of the extraordinary ironies of the success of immunization programs. Except for smallpox, the vaccine-preventable diseases are still present. Tetanus spores persist in soil and, with global air travel, diseases like measles, mumps, rubella, diphtheria, and poliomyelitis remain just a plane ride away.

Decades ago, when thousands of children (and adults) in the United States contracted these diseases, parents feared these diseases. Successful immunization programs, however, have remarkably lowered disease rates for many of these illnesses. Presently, most parents (and many physicians) have never seen a child with paralytic poliomyelitis, asphyxiated by a diphtheric membrane, or brain damaged by measles, congenital rubella, or *Haemophilus influenzae*, type b (Hib). Some parents even believe that some of the vaccine preventable diseases are "not so bad" (Benin et al., 2006).

Although antivaccine opinions have been around for a long time, the majority of parents have maintained a collective consensus—largely driven by fear of the vaccine-preventable diseases—that vaccines and vaccine mandates are essential to the public health and the safety of children in a given community. In the

absence of disease visibility the collective consensus has begun to erode.

The challenge for vaccine policy makers is to communicate that the risks of disease introductions are real—even if they are largely unpredictable.

Missing Data or "The Data are Insufficient to Accept or Reject the Hypothesis"

The timing of immunizations—beginning shortly after birth and then repetitively during the first 2 years of life with continuing immunizations throughout childhood—occurs at the ages when developmental and other problems are being recognized for the first time. Thus, the timing of vaccination—plus their widespread use—make vaccines the perfect "scapegoats" to be blamed for causing diseases of unknown or poorly understood causes.

When a vaccine concern is first suggested—particularly when the association is to a disease about which there is little understanding about etiology—there are often little or no data available to permit an honest scientist to state categorically that "vaccines do not cause that particular disease." And then, as data accumulate, the lack of a demonstrated association does not assure coincidence, requiring multiple studies before scientific consensus is reached that the data "favor rejection of the hypothesized association."

Compounding the issue of the time it takes to collect the needed data is the fact that many well-educated and intelligent people are innumerate—that is, they are unable to process information about risk assessments and measurements (Paulos, 1988). In addition, many suffer from availability bias (Poland and Jacobson, 2001). That is, they make intuitive judgments using readily available information. They base their estimates of how likely an event is based upon how easily they can imagine an example as well as its emotional impact.

Finally, when trying to communicate the complexities of demonstrating coincidence to an innumerate public, vaccinologists and public health officials often "speak in tongues"— using technical jargon as well as using expressions that have very different technical meanings than when they are used in everyday conversational English (Table 17.2). For example, when discussing vaccine safety, the vaccinologist uses the term "adverse event" to describe something that occurred temporally related to vaccine administration whereas many misconstrue that term to mean a "vaccine side effect." For instance, fever is a common side effect of many vaccines, but febrile adverse events after vaccine receipt are not always caused by the vaccine. Similarly, when some serious condition is recognized at about the time vaccines have been administered, the temporal association is difficult for parents to grasp as likely having been coincidental; particularly when public health officials only reassure with expressions such as "the data favor rejection of the theory."

The Uniformed as Misinformer

The uninformed or incompletely informed person may unintentionally disseminate misinformation. Parents rely on many sources for health information (Gellin et al., 2000; Paulussen et al., 2006) including family and friends but, unfortunately, many of these sources may also be uninformed misinformers.

MISSING INFORMATION CAN EVOLVE INTO MISINFORMATION

Once evidence favors rejection of a vaccine safety hypotheses—such as has occurred with thimerosal- or measles-containing vaccines and autism (Institute of Medicine, 2004)—assertions about that vaccine safety concern are misinformation. The evolution of a vaccine safety concern into misinformation is complex but seems to follow a pattern which includes both unintentional and intentional misinformers (Table 17.3).

Consistently, there is a period of scientific uncertainty; a period of missing information where the scientist has difficulty being emphatic that the vaccine and the adverse event are unrelated, even if (s)he believes that the association is coincidental. People respond differently during these periods. Some parents do not immunize their children, perhaps believing that public health and health provider information was "one-sided" or "poor" (Smith et al., 2004); other parents express distrust of the medical community and perhaps a conspiracy by those advocating vaccines (Mills et al., 2005); while the majority, fortunately, trust that their physician or nurse will know what to do (Gellin et al., 2000).

A person's perception of risk is based upon their experiences and knowledge. Someone who thinks that their child—or someone else's child with whom they can empathize—had an adverse outcome because of a vaccine would likely think that vaccines are riskier than a person who has not. Conversely, a parent whose child has had a vaccine-preventable disease—or a physician who has treated that disease—will likely advocate for vaccines.

People respond better to some types of perceived risk than others (Reynolds, 2002). For example, natural

TABLE 17.2 Technical and conversational expressions that may confuse the public

Expression/word	Technical meaning	Conversational meaning
Vaccine adverse event	Something that occurred at about the same time as vaccination, which may or may not be caused by the vaccine	Something caused by the vaccine (vaccine reaction or side effect)
Bias	Systematic error that could lead to the wrong conclusion	Not having an open mind
Controversy	There are different but plausible interpretations of the same data within the scientific community	There is a difference in opinion
The patient " denies xyz"	The patient says she does not have them	The patient reacts defensively to an accusation
Epidemiology	The study of how disease is distributed in a population and of the factors that influence that distribution	Number crunching
Favors rejection of the hypothesis	The data suggest that the hypothesis should be rejected (but you can not prove a negative)	They still do not know
The finding would not go away	We could not find an alternative explanation	They are fudging the data
Inadequate to accept or reject the hypothesis	The data do not allow a definitive statement	They do not know
Naive	The person or animal has not previously been exposed to a particular infection, drug, or vaccine	Unsophisticated, lacking experience, or training
Paralysis	Loss of the ability to move a body part usually as a result of nerve damage	Inability to act, helpless inactivity
Plausible	Theoretically possible	Appearing worthy of belief, factual
Positive	The results of the study concur with the hypothesis; having a value greater than zero	Good
Power	The likelihood of a study finding an effect, if there was one; or, the number of times a number is multiplied by itself	Energy, strength, control
Probably a small risk	The association is likely real but very infrequent; or, uncertainty	Likely that it is a risk
Relative risk	The ratio of two rates of risks, often used to compare risks	The risks are related
Safe	Remote or insignificant risk	No risk or zero risk
Significant	This may not be a chance difference	Important
Not significant	Likely due to chance	Not important
Uncertainty	When the available scientific information is not sufficient to prove a relationship or is not sufficient to favor rejection of a relationship	They do not know

Source: Adapted from Myers and Pineda (2008) with permission of the publisher.

risks (such as infectious diseases) are better tolerated than man made risks (such as vaccine side effects) and risks that affect adults are better tolerated than risks affecting children. Risks that are perceived to have unclear benefits are less tolerated than risks where the benefits are clearly understood. For example, some parents believe that the risk of contracting measles could be lower than the risk of their child possibly experiencing a serious side effect being suggested by other parents who are convinced that their child was harmed following immunization. If they think that there is little benefit from immunizing their child, they may conclude that there is no reason to take the risk of a possible adverse event, even if public health officials try to reassure them. If they are confused as to the risks, they may fail to immunize their child.

Stories about bad things happening to children after a vaccination circulate widely on the internet, are discussed on radio and TV, and described in magazines and newspapers. Despite the fact that serious vaccine safety risks are rare, perceived health risks are the center of attraction to the media, make effective sound bites, and may be egregiously inaccurate (Pribble et al., 2006).

TABLE 17.3 The evolution of vaccine safety concerns into misinformation

A vaccine safety concern is suggested—usually by case reports of possible temporal associations of adverse events with vaccine administration or by an increase of reports of possible adverse events following vaccine administration.
- In the absence of any data making an association, and despite reassurances from the public health authorities, the media may declare that there "may be a problem."[a]
- Some parents become frightened.

Vaccinologists respond that there are insufficient data to be able to state that the vaccine caused the adverse event or that it was just coincidental in time.
- This creates a sense of uncertainty which in turn causes some parents to become confused.

Public health officials compare the possible risk from the adverse event with the known risk of the disease, based on whatever available data there are.
- They make a recommendation.
- Some parents perceive a "cover-up."

The media reports the scientific "uncertainty."
- Parents who are convinced their child was harmed by vaccines want to warn other parents.
- The media often describe a controversy (difference of opinion) between public health officials and parents. True scientific controversy is rarely reported.
- Pseudoscience is promulgated; it is discounted by scientists but is often widely reported by the media.
- Intentional misinformers seek publicity.

Many parents become confused about vaccine benefits and risks.
- Parents see no disease, and reason "why take a risk?"

As data are collected, scientists reach a consensus that the data "favor rejection of the hypothesis."
- Misinformers deny the data.
- Misinformers attempt to discredit the scientists.
- Those who are convinced, make up ad hoc hypotheses.

If community immunity has declined, outbreaks of disease may occur.

Ultimately—perhaps decades later—a cause for the coincidental disease is described.

[a] For example a BBC news headline reported (BBC News Online, 1998, http://news.bbc.co.uk/2/low/uk_news/60510.stm) "child vaccine linked to autism" following the initial case reports by Wakefield et al. (1998) about measles-containing vaccine and some cases of autism.

Media reports about the vaccines-autism theories, for example, continue to be published frequently. Although scientists say "the data suggest no association" (or, that "the data favor rejection of the theory"), parents want to hear a trusted source say "that vaccine does not cause that." In contrast, some who believe that their child (or one that they know) was harmed by vaccine(s) insist that the theory has been established. Unfortunately, media reports often cite both opinions with equal credibility and emphasis; generating uncertainty among parents, affecting their perceptions of risk, and their decision to vaccinate their child (Dannetun et al., 2005).

IMMUNIZATION MANDATES

States require vaccines because they have a responsibility to protect both individuals and the entire population of their state. All states have immunization laws. However, other countries that also have very high levels of immunization coverage—such as Canada and Mexico—do not (WHO, 2007a).

School immunization laws were first established to control outbreaks of smallpox and in recent decades have been widely used to increase vaccine coverage and reduce outbreaks of vaccine-preventable diseases. Immunization requirements are set by states and currently all states have school immunization laws—although there are differences in what may be required in different states (see www.immunizationinfo.org for individual states' requirements and exemptions).

Measles vaccine was licensed in the US in 1963; there was a rapid decline in the incidence of measles from about 438,000 cases/year (1960–1964) to about 42,700/year (1967–1971) in the United States (Centers for Disease Control and Prevention, 1995) (Fig. 17.1A). Both national and local epidemics continued to occur, however (Fig. 17.1A, B).

The constitutional basis for "a community to protect itself against an epidemic of disease" by immunization was established in 1903 (Parmet et al., 2005). This provided a means for states to expand immunization coverage. In the late 1960s and the 1970s immunization laws for school entry were enacted in many states largely on the demands of parents, because of continuing measles epidemics. For example, in Iowa, the creation of immunization requirements for school entry in 1977 (Iowa Administrative Code, 1977) was largely a response of parents to the recurring measles epidemics with the attendant mortality, cases of encephalitis, and overall morbidity (Myers, 1977, unpublished observations); the impact on measles activity was rapid (Fig. 17.1B) with cases dropping from 4333 in 1977 to none in 1981 through 1985 (Iowa Department of Health, 2007).

Parents who oppose vaccines for their children actively seek means to avoid immunizations, including home schooling and lobbying legislators for easier exemptions from immunization laws. Some parents oppose immunization mandates as a violation of their civil liberties. Both groups of parents try to recruit other parents to their "cause."

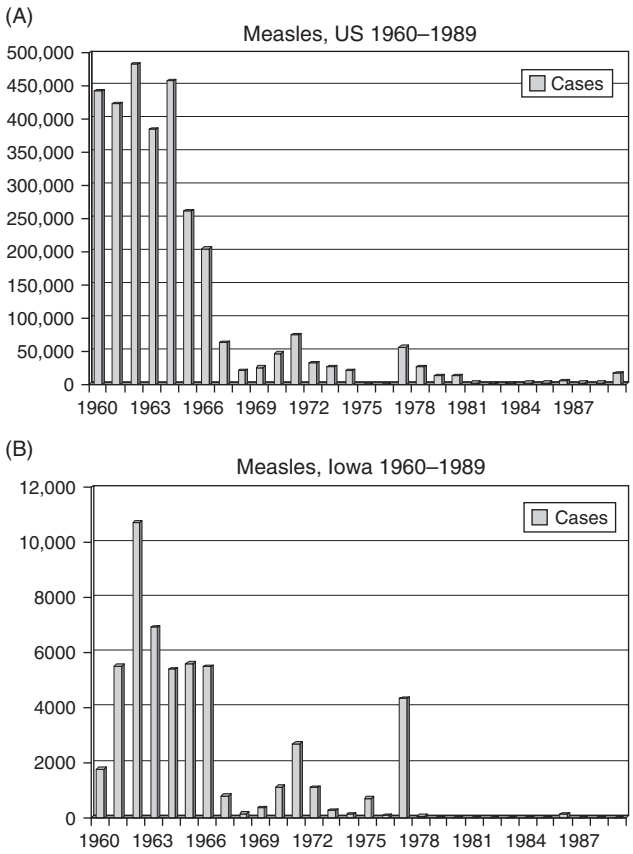

FIGURE 17.1 Measles in (A) the United States (Centers for Disease Control and Prevention, 1995) and (B) Iowa (Iowa Department of Health, 2007, www.idph.state.ia.us/adper/pdf/cade/decades/pdf) 1960–1989. Measles vaccine was licensed in 1963. Mandatory immunization laws were enacted widely by states in the late 1960s and 1970s. Iowa enacted its immunization law in 1977 (Iowa Administrative Code, 1977).

All US states permit exemptions for children who have medical contraindications to immunization. However, most states also permit religious or philosophical exemptions. States permitting easy exemptions have many more unvaccinated children than do states that do not permit philosophical exemptions and unvaccinated children tend to cluster in communities (Smith et al., 2004; Salmon et al., 1999). Children who received exemptions were found to be 35 times more likely to contract measles and were more likely to spread measles to others (Salmon et al., 1999; Parker et al., 2006).

Washington State had school entry immunization exemption rates exceeding 5% in 2005–2006, six counties exceeding 10%, a substantial increase over 1999 (Bardi, 2007). Texas reported a school district with 19.05% conscientious exemptions for the school year 2003–2004, the first year after enactment of the exemption (Immunization Branch, Texas Department of State Health Services, 2003–2004, http://www.dshs.state.tx.us/immunize/coverage/conscientious.shtm).

MISINFORMERS

Misinformation comes from many sources. Some who are uniformed or misinformed unwittingly misinform. Others are parents who honestly believe that their child was harmed by vaccines and they want to warn other parents. Still others are antivaccine activists many of whom may gain by disseminating and popularizing misinformation. For example, profits may come from contributions to organizations, book sales, movie rights, political support, tort precedents, court testimonies, speech making, inches of news space, or minutes of news time.

Conflicts of Interest

Many organizations, government agencies, and universities require their employees (and their immediate families) to divulge potential or perceived financial and other conflicts of interest. Because of the nature of what vaccine researchers do, it is not surprising that some hold patents for their intellectual property, that they may be asked to consult for vaccine companies, or that a portion of their salary may come from grants or contracts with vaccine companies. While it is hard to imagine how an individual could otherwise become a vaccine expert, these types of relationships when active do in fact represent perceived—and at times real—conflicts of interest.

Misinformers make much ado about vaccinologists' real and perceived conflicts of interest. But they are aware of these conflicts of interest because the vaccinologists divulge these associations.

Misinformers may also have conflicts of interest, some obvious others less so. They have no obligation to divulge their own or their families' conflicts of interest. Book authors do not need to divulge their book sales income; investigative reporters (or their spouses) do not need to expose their retirement portfolios; pseudoscientists do not need to divulge their funding sources nor the income they receive from court testimony; and politicians only divulge conflicts of interest that are required by law.

False Experts or "Experts" who Lack Expertise

No credible expert vaccinologist would claim to be expert in *all* the fields that relate to vaccine safety. For example, the IOM Committee on Immunization Safety included experts in pediatrics, neurology, immunology, internal medicine, infectious diseases, genetics,

epidemiology, biostatistics, risk perception and communication, decision analysis, public health, nursing, and ethics (Institute of Medicine, 2004).

Some who claim to be experts make claims outside their field of expertise. Such is the case of Dr. Mark Geier:

> Dr. Geier's expertise, training, and experience is [sic] in genetics and obstetrics. He is however a professional witness in areas for which he has no training, expertise, and experience (U.S. Court of Federal Claims, 2003).

Another example would be "…Dr. Eric Ryndland who is considered one of the nations foremost experts on autism…" according to the reporter (Gillen, 2007). He[1] has no publications listed on the National Library of Medicine's Pub Med. It is unclear what, therefore, the reporter utilized to form her opinion of him as an "expert" in her article "To vaccinate or not to vaccinate."

Journalists who have Written Articles or Books about Vaccine Safety

Although many journalists do a credible job writing about scientific and medical issues in ways that makes this information understandable and informative to the general public, they are usually specialized medical or science reporters at large news organizations. Good science journalists let the experts speak through their articles instead of purporting themselves to be experts.

Often times, however, stories—particularly published by smaller news organization and local TV stations—have not been checked for the reliability of the facts and present "controversies" that pit parents or others with an opinion against scientific experts, as if opinions and facts had similar value.

Others simply misinform. Media exposure and "controversies," of course, sell books and attract readers. For example, the journalist David Kirby—with apparently no scientific background or expertise in any field relating to vaccine safety or developmental disorders—wrote a book, *Evidence of Harm*, about thimerosal and autism which misinterprets scientific evidence and quotes out of context, attempting to imply a cover-up by respected scientists. Nevertheless, this book received an award for investigative reporting (Investigative Reporters and Editors, 2006, http://www.ire.org/history/pr/2005ireawards.html). Kirby is a frequent speaker at events for antivaccine and antithimerosal activists.

Dan Olmsted, the author of *The Age of Autism*, once a regular columnist for United Press International (UPI), reported on his "research" that autism is less frequent among unvaccinated Amish children in Pennsylvania in contrast to other children. For a time, his articles attracted media attention despite the lack of any scientific content. His research methods included discussing his theories with a man who sells water purifiers in Amish communities (Olmstead, 2005).

Politicians who Claim to be Experts

Many politicians bring together groups with differing interests and expertise—such as parents with opinions and scientists with expertise—in order to collect information and to understand the issues. However, there is little in a politician's training—including those with advanced education including a medical degree—that would qualify them as experts. Of course, politicians often seek support by taking on the causes of different interest groups.

Between 1999 and 2004 the Committee on Government Reform of the US House of Representatives held more than 10 hearings about vaccines, thimerosal, and autism. Rep. Dan Burton chaired this Committee from 1997 to 2002; his claim to expertise being that he is the grandfather of a child whom he believes has autism as a consequence of vaccines. When the IOM Vaccine Safety Committee said in 2004 that the body of scientific evidence favored rejection of a causal relationship between thimerosal-containing vaccines and autism (Institute of Medicine, 2004), Rep. Burton said in a press release:

> Unfortunately, I believe the findings announced in the May 18th IOM report are heavily biased, and unrepresentative of all the available scientific and medical research (Burton, 2004).

Politicians, lawyers, journalists, and others such as parents with an opinion contribute in a very positive way to the public discussion of immunization policy and vaccine safety but they are not authoritative scientific experts. Nonetheless, they are often quoted as if they were.

DISSEMINATION OF MISINFORMATION

Unfortunately, misinformers can disseminate misinformation easily, especially employing the internet and other media.

More than two-thirds of US adults use the internet (Fox, 2005) and 80% of them use the Internet to

[1] Neither this spelling, nor Rindland, nor Rynland.

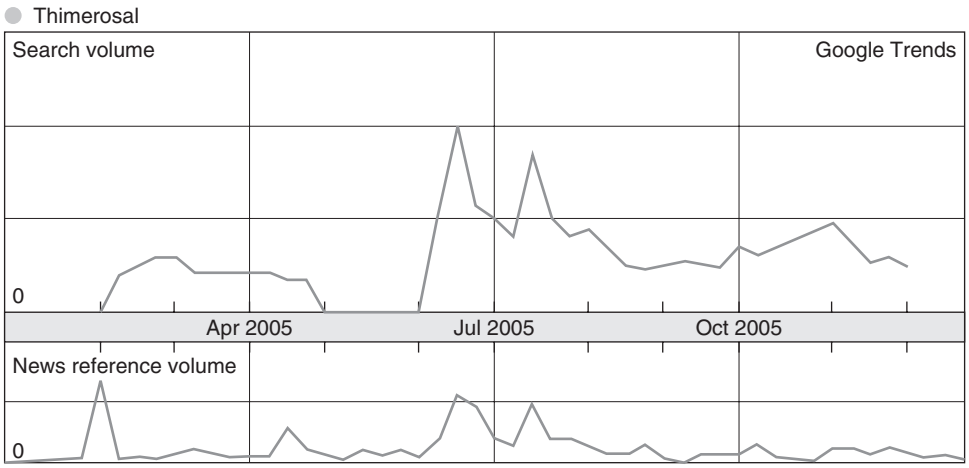

FIGURE 17.2 Thimerosal misinformation events in March and June, 2005 were associated with increased news and search volume for thimerosal. "News reference volume" relates to news stories containing the search word that were accessed on Google News©. "Search volume" describes the volume of internet searches made using that search term.

find health information, including information about vaccines and immunization (Fox, 2006). There are disparities of access to the internet as well as the quality of internet access but those who access the internet (Fox, 2005) appear to have similar demographics to those who are antivaccine (Smith et al., 2004). Those who seek information online usually start at a search engine and do not often check on the source of the information (Fox, 2006). Internet search engines do not distinguish information from misinformation and most people are unable to distinguish reliable from unreliable information. In addition, one-third or more of streaming video on www.YouTube.com were critical of immunizations, with those videos higher rated than video clips favorable to immunizations (Keelan et al., 2007).

An example of how people use the internet in response to misinformation was shown by surges in search engine queries that included the word "thimerosal" following extensive publicity surrounding two misinformation "events": the initial release of the book "Evidence of Harm" by David Kirby (St. Martin's Press) in March, and the publication of the article "Deadly Immunity" by Robert Kennedy Jr. in Rolling Stone and Salon.com in mid-June, 2005. Google Trends© demonstrated both increased news volume and search engine searches for thimerosal in March (book release) and mid-June (article published) (Fig. 17.2) (Myers and Pineda, 2007).

The mainstream media reaches and influences all segments of society. For example, health stories must attract viewers because these account for more than 10% of air time in nightly TV news broadcasts. Unfortunately, these stories are usually unrelated to public health priorities, they may be inaccurate, and provide misinformers with exposure. These reports may contain erroneous information (Pribble et al., 2006).

Unfortunately journalists may feel compelled to present a balance between opinions, reporting "controversies" (or "debates") between the scientific community and misinformers, giving misinformers extensive media exposure and possibly credibility in the minds of the public. For example, on reporting the findings from a large comprehensive study that did *not* suggest any causal association between increasing exposure to mercury in thimerosal—neither prenatal or early in life exposure—and subsequent neuropsychological outcomes at 7–10 years of age (Thompson et al., 2007), Time Magazine in October, 2007 (Time Magazine, 2007), headlined an article "the vaccine debate goes on" and opened the article "Latest Findings. Thimerosal, a mercury-based vaccine preservative, has long been associated with neurological disabilities like autism." The article continued by outlining Centers for Disease Control and Prevention and their "critics" positions.

MISINFORMATION CONTENT

Misinformation content often consists of many of the following:

Pseudoscience

Pseudoscience ("false knowledge") is often presented to the media as "science" by misinformers. It is usually ambiguous, employs hard to comprehend methods,

may not be quantifiable, and the results can usually not be duplicated. In many cases, these reports are not subjected to peer review. Often, data may be represented to show one outcome when another is the case. Other times the methods that are used may be likely to give a predetermined outcome. Only data purporting to support the author's claims are presented while conflicting data are ignored or dismissed.

The peer review mechanism employed by most respected journals is intended to ensure that only carefully conducted science is published; but sometimes poorly run studies slip by the most careful editor. Because of the vetting process, however, most pseudoscientific claims about vaccine safety are not published in respected journals but are often published in obscure journals or in the "alternative medicine" press.

A number of studies implying a link between vaccines and neurodevelopmental disorders have been published by Mark Geier and his son David Geier. They often utilize data from the Vaccine Adverse Event Reporting System (VAERS) to try to establish causality (Geier and Geier, 2004). VAERS data cannot be used to establish causality. The purpose of VAERS is to tabulate possible adverse events in order to look for "signals" that should be explored systematically (Varricchio et al., 2004). In addition, the Geiers' reports also often failed to describe methods, important statistical figures were not defined accurately, and data sets overlapped (American Academy of Pediatrics, 2003, http://www.aap.org/profed/thimaut-may03.htm).

In addition to pseudoscience, misinformers often misquote legitimate research claiming that studies support their views, when in fact the original data do not. For example, the November 14, 2005 issue of the New York Times included a full-page advertisement by the group Generation Rescue thanking the researchers who did "groundbreaking research on the connection between mercury and autism" (The New York Times, 2005, http://www.generationrescue.org/images/051114.gif). The ad listed 19 citations of articles—including one by the Geiers. None of the 19 articles shows that mercury causes autism. Although some of them did look for a possible link between mercury and autism, others were about autism in general with no mention of mercury. One of the papers cited was by Andrew Wakefield, about MMR (which does not contain thimerosal) and autism.

Invalid Assumptions

Some invalid assumptions often underlying misinformation claims are that illness in a vaccinated person proves that the vaccine does not work, temporal associations establish causation, and epidemiologic studies are not real science.

Logical Fallacies

Misinformers often use logical fallacies in their arguments. For example, the post hoc argument is common; that is, the temporal association of an adverse event is assumed to infer causality. It is especially seen online, where people report that a vaccine harmed a child because certain symptoms appeared a few days or weeks after vaccination. Also, VAERS reports are purported to be descriptions of vaccine side effects. Often they also make an *argument from ignorance*—claiming that a statement is true only because it has not been proven false, or that it is false only because it has not been proven true.

The ad hominem fallacy—attacking the person—takes many forms in discussions of vaccine safety, alleging cover-ups and conspiracy theories by which misinformers try to discredit those who do not agree with them. Indeed ad hominem arguments are recognized to be a frequent attribute of antivaccination Web sites (Davies et al., 2002) as well as media coverage about antivaccination topics (Leask and Chapman, 1998). Attacks of this type on members of the Institute of Medicine Vaccine Safety Committee and other reputable scientists were so serious that Senator Enzi (2007) filed an investigative report with the US Senate Committee of Health, Education, Labor and Pensions in 2007 refuting the charges. Similarly, the *guilt by association* fallacy claims that a theory or an argument must be false simply because of who else supports the argument.

Misinformers often use the ad misericordiam fallacy to frighten other parents, by featuring anecdotes about children that they claim have been killed or maimed by vaccines (Davies et al., 2002; Wolfe et al., 2002).

Ad hoc Hypotheses

When misinformers find themselves in the position of believing something that becomes unsupportable based on the data, they will often resort to making an ad hoc hypothesis. Attorneys litigating vaccine injury claims do this not infrequently. When multiple studies found no causal association between measles- or thimerosal-containing vaccines with the subsequent development of autism, a new hypothesis was generated that together measles-containing vaccine and the preservative thimerosal in other vaccines cause autism (Office of Special Masters, 2007).

THE CONSEQUENCES OF MISINFORMATION

Outbreaks of vaccine-preventable diseases often begin among the unimmunized and underimmunized and then spread to the fully immunized in the community (Salmon et al., 1999; Parker et al., 2006)—a portion of whom remain susceptible because no vaccine is 100% effective. Sustained transmission of infections within communities occurs when a sufficiently large proportion of the population is susceptible, the proportion differing among the different vaccine preventable communicable diseases (Fine, 2004). Immunization coverage is often utilized as a surrogate marker for the proportion who is immune.

Following periods of intense misinformation, decreases in immunization coverage may occur and disease outbreaks may occur. For example, because of the concerns about whole-cell pertussis vaccine possibly being associated with severe neurologic developmental problems, immunization rates in Great Britain in 1978 had fallen from 80 to 30%. Epidemic pertussis soon followed: between 1977 and 1979 there were 102,500 cases of whooping cough with 36 deaths (Cherry et al., 1988).

In Japan, because of concerns about the whole-cell pertussis vaccine's safety and claims that it was no longer necessary to immunize because pertussis was not present in the community, the age for immunization was changed and immunization coverage for infants fell from about 85% in 1974 to 13.6% in 1976 (Cherry et al., 1988). In 1979, Japan reported 13,105 cases of pertussis with 41 deaths. In the early 1980s Japan re-introduced acellular pertussis-containing vaccines with a reduction in the number of cases (Gangarosa et al., 1998). Similarly, after discontinuing pertussis vaccine, rates of whooping cough returned to the levels seen in the prevaccine era in Sweden. Of 2282 who were hospitalized for whooping cough in 1981–1983, 4% had brain injury from the illness (Cherry et al., 1988).

The specific contribution that misinformation played on these pertussis outbreaks is hard to define because it is not clear when missing information about whole-cell pertussis vaccine safety evolved into misinformation. However, countries whose immunization programs were disrupted by whole-cell pertussis antivaccine movements (Sweden, Japan, the UK, Ireland, Italy, Australia, the former West Germany, and the Russian Federation) experienced ten to 100 times higher pertussis incidence than did countries in which the antivaccine movement had a limited impact on pertussis vaccine coverage (Hungary, the former East Germany, Poland, and the US) (Gangarosa et al., 1998).

Two decades later, another vaccine scare began in the UK. In 1998, Wakefield and others published a series of case reports suggesting that some children who had received measles-containing vaccine suffered bowel injury, permitting absorption of substances that caused brain injury and thus autism (Wakefield et al., 1998). Although Wakefield's report did not provide any evidence of a link between measles vaccine and autism, media coverage was extensive, giving his hypothesis credibility in the eyes of many in the public; the headline in London's *Daily Telegraph* read, "Vaccination may trigger disease linked to autism" (Daily Telegraph, 1998, http://www.telegraph.co.uk/htmlContent.jhtml?html=/archive/1998/02/27/nmmr27.html). Many national and international news outlets carried the same story. Both the initial report and subsequent claims of evidence for measles virus in children with autism have now been dismissed (D'Souza et al., 2006; Doja and Roberts, 2006; Murch et al., 2004; Horton, 2004) but many frightened parents, not surprisingly, feared the vaccine more than the diseases. In the following years MMR vaccination rates fell from 93 to 79% by 2003, with measles (Gust et al., 2005) and mumps (Centers for Disease Control and Prevention, 2006b; WHO, 2007b) (Fig. 17.3) outbreaks as a consequence. The outbreak of mumps in 11 states in 2006 and the epidemic in the UK in 2005 were both caused by mumps virus, genotype G (Centers for Disease Control and Prevention, 2006a), suggesting they may have been epidemiologically related.

Misinformation confuses many. For example, in an unpublished random digit dial telephone survey, almost half the parents with children less than 6 years of age reported that they believed vaccines can cause

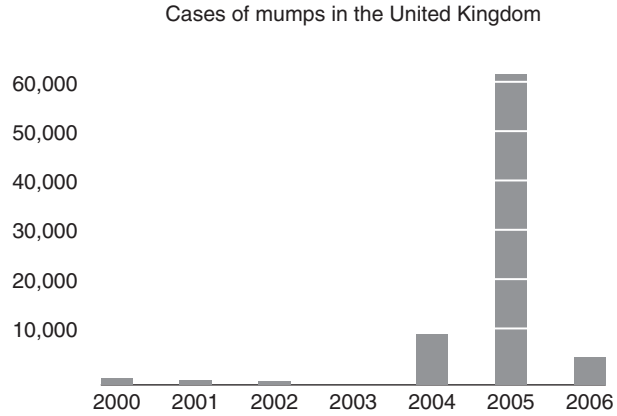

FIGURE 17.3 In 2005, there were more than 63,500 cases of Mumps in the United Kingdom (WHO, 2007b) (Adapted from Myers and Pineda (2008) with permission of the publisher.)

autism (APCO insight, 2006). Misinformation can also confuse health providers, including school personnel overseeing immunization programs (Salmon et al., 2004). In 2006, a 23-month-old asthmatic child with influenza A pneumonia was admitted to a hospital in Texas requiring ventilator support. Two weeks previously she had been denied influenza immunization because the provider believed the child should only receive influenza vaccine without thimerosal preservative, which the practice did not have in stock (Patel, 2006, personal communications).

Misinformation impacts parental decision-making. For example, 13 of 33 mothers interviewed postpartum were vaccine hesitant or outright rejected vaccine for their newborns (Benin et al., 2006). A couple in Tennessee, confused about vaccine safety because of what a friend had told them, decided to delay their daughter's vaccinations. The girl developed Hib meningitis (Snyder, 2000).

Misinformation can have serious consequences for individual families as well as for communities.

VACCINE MISINFORMATION IS A GLOBAL PROBLEM

Misinformation about vaccine safety is a problem that affects developing as well as developed countries. False allegations in Nigeria that oral polio vaccine could cause sterility—thought to be intended to limit the Muslim population size—or that it could cause AIDS, resulted in a resurgence of wild-type polio viruses transmission, cases of polio, and the spread of wild-type virus into 19 previously polio-free countries (Centers for Disease Control and Prevention, 2005–2006). Similar rumors have plagued the introduction of other vaccine programs in other countries. For example, the introduction of a maternal and infant tetanus immunization program necessitated Egypt to train community guides to dispel these types of rumors—and one immunizer had to immunize herself to prove the vaccine safe (U.S. Fund for UNICEF, 2004, www.who.int/entity/immunization_monitoring/diseases/06_fall_2004.pdf).

In contrast to developed countries, antivaccine activities in developing countries focus on national immunization days, religious and political arguments against vaccines, and concerns about "western plots," especially that vaccines could cause involuntary contraception or sterilization (Eastern and Southern Africa Regional Office, United Nations Childrens Fund, 2001).

Part of the difficulty of dealing with misinformation about vaccines in developing countries is resistance to change (Regional Office for South Asia, United Nations Childrens Fund, 2005, http://www.unicef.org/rosa/Immunisation_report_17May_05(final_editing_text).pdf) as well as the recognition that some vaccines and immunization practices have in fact in the past been unsafe (Simonsen et al., 1999). Because the foundations of an effective immunization program are safe and effective vaccines which are delivered in a safe manner, the WHO has put in place systems to try to ensure the safety of the vaccines used in all national programs (Duclso, 2004; Clements et al., 2004).

To measure the impact of a vaccine and to be able to evaluate adverse events following immunization require surveillance of vaccine coverage and disease activity as well as the monitoring of adverse events. Many developing countries have not integrated these components into their national immunization programs (Duclso, 2004). Countries that do have these tools in place, such as the US, still have difficulty dispelling concerns about vaccine-associated anecdotes; in the absence of such an infrastructure, it is little wonder that health officials have difficulty reassuring the public about coincidental associations.

The historical impact of antivaccination rumors on the introduction of immunization programs have led to the development of strategic communication plans for national immunization programs that include the assumption that misinformation and negative reactions will occur as part of the introduction of new vaccines (Regional Office for South Asia, United Nations Childrens Fund, 2005, http://www.unicef.org/rosa/Immunisation_report_17May_05(final_editing_text).pdf).

FIGHTING WITH THE BOOGEYMAN: COUNTERING MISINFORMATION ABOUT VACCINE SAFETY

The vast majority of parents would not opt out of any vaccine and they also understand that school immunization laws protect their children (Gellin et al., 2000). However, there are also many parents who have great misperceptions about the risk and severity of vaccine preventable diseases as well as about the safety of vaccines (Mills et al., 2005; Dannetun et al., 2005; APCO insight, 2006; Salmon et al., 2004; Freed et al., 2004; Fredrickson et al., 2004). Misperceptions about disease risks and vaccine safety are similar among parents who refuse vaccines for their child and among those parents who permit their child to be immunized, although the proportions of parents with misperceptions are greater among those who withhold some or all vaccines from their children (Gust et al., 2004, 2005).

Parental refusal (either refusal or delay) of vaccine for their child is not uncommon (Benin et al., 2006; Fredrickson et al., 2004; Diekma and Committee on Bioethics, 2005; Flanagan-Klygis et al., 2005), most physicians who care for children have to deal with this problem at least once a year—the rate of refusal is estimated to be 7.2/1000 children less than 18 years of age (Fredrickson et al., 2004). Fear of pain, fear of serious side effects, plus the belief that the diseases are not harmful are common reasons for vaccine refusal. These are also common concerns among parents who do immunize their children.

Misinformation about vaccine safety comes in many forms and from many sources. Fortunately, most parents still obtain information about immunizations from trusted health professionals (Gellin et al., 2000). Unfortunately, some health professionals may be uninformed, some themselves may be confused by misinformation, and some (particularly alternative medicine providers) may be "anti-vaccine."

Parents are actively seeking more information (Gust et al., 2004). The most important intervention for countering misinformation may be that a trusted provider addresses the parents' lack of knowledge about the diseases as well as their concerns about vaccine safety. But this approach is limited by the time available to busy clinicians: discussions about vaccines comprising about 15s during the average visit (Davis et al., 2004).

We have observed increasing use of the NNii Website www.immunizationinfo.org over time—from 17,677 visitors per month in October 2005, to 32,553 in October, 2007 (Myers and Pineda, 2007). The entrance pages to the Web site are usually the Homepage or, if accessed by search engine, often directly to specific vaccines/diseases featured in the section "Vaccines and the Diseases they Prevent." The next most popular section is Immunization Issues, consisting of essays about topical issues on vaccine safety (many suggested by viewers). We also have observed that during times of increased media activity surrounding misinformation events (Fig. 17.2), there is a corresponding surge in readership of archived essays on related topics (see Fig. 17.4A on our Web site. At about the same time, many visitors follow links to information about assessing the reliability of information found on the internet (Fig. 17.4B) (Myers and Pineda, 2007).

A large proportion of parents—whether vaccine hesitant or not—have been confused by misinformation publicized about vaccine safety. Although some parents have made up their mind to not immunize their children—and disregard data that do not support their views (Meszaros et al., 1996)—the majority of parents desire more information. They have many information resources available; unfortunately, they may frequently locate misinformation. However, in addition to seeking information, they also seem to want to confirm the reliability of what they found.

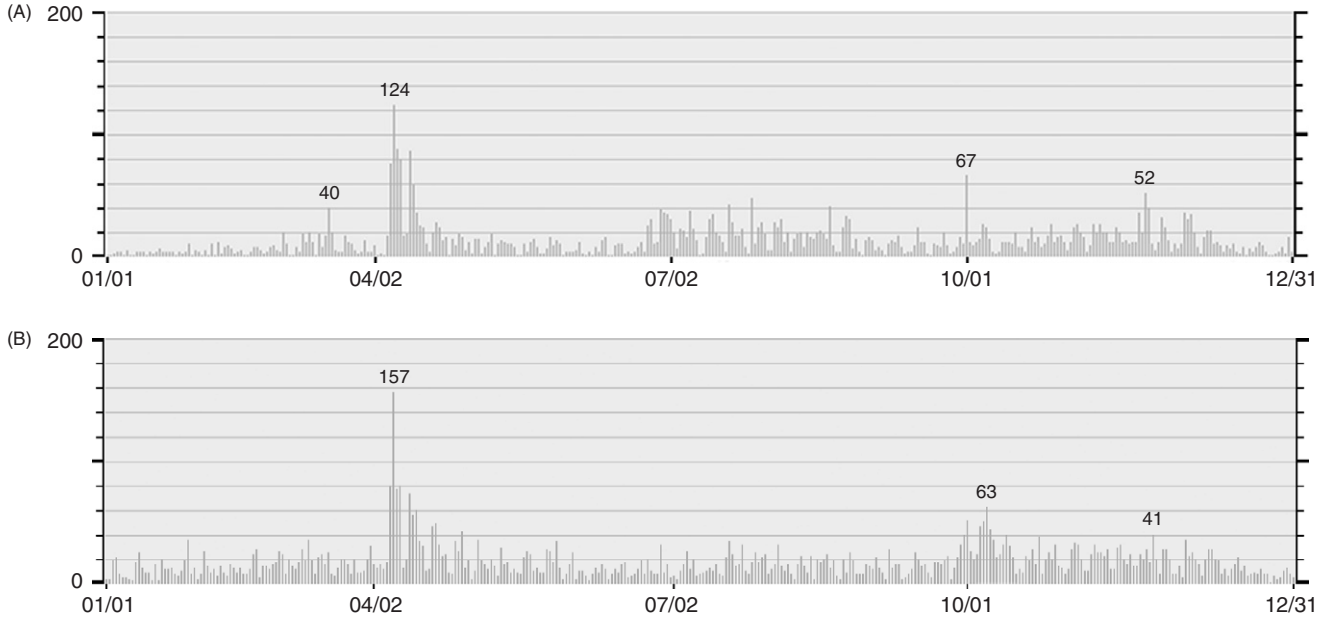

FIGURE 17.4 Search activity at www.immunizationinfo.org coincident with increased media activity surrounding thimerosal-containing vaccines. (A) Daily pageviews of archived essays about thimerosal-containing vaccines. (B) Daily pageviews of archived essays about misinformation about vaccine safety, viewed largely by hyper links (Myers and Pineda, 2008). A pageview is a request for a page, enumerated by www.urchin.org.

Parents need education about the risks and severities of the vaccine-preventable diseases; most do not recognize that they are uninformed.

There seem to be a number of favorable factors to counter misinformation: Most parents want to establish trusting relationships with health professionals; they are seeking more information; they are willing to utilize guidance; and many seek to validate information they locate. These openings would seem to provide the most effective means to sustain and expand confidence in immunization programs in the face of burgeoning misinformation about vaccines and vaccine safety.

In considering the introduction of new vaccines—including vaccines for biothreats and emerging infectious diseases—as well as vaccines developed employing new technologies and new delivery strategies, it will be important to employ communication plans for all the target populations, analogous to those being utilized for the introduction of new vaccines in developing countries (Regional Office for South Asia, United Nations Childrens Fund, 2005, http://www.unicef.org/rosa/Immunisation_report_17May_05(final_editing_text).pdf).

CHAPTER

18

Vaccines for Military Application

Andrew W. Artenstein[1,2]

[1]Department of Medicine and Center for Biodefense and Emerging Pathogens, Memorial Hospital of Rhode Island, Pawtucket, RI, USA

[2]The Warren Alpert Medical School of Brown University, Providence, RI, USA

OUTLINE

ABSTRACT

Vaccines have long been used by military forces in order to prevent communicable diseases and thereby fulfill their primary mission: to preserve the fighting force. A tradition that began with the mass vaccination of the Continental Army against smallpox during the War of the American Revolution in the late 18th century continues today with routine and deployment-based vaccination of military forces against potential pathogens of nature and biological weapon threats. As the role of militaries has expanded in recent years to include humanitarian and peacekeeping missions, military applications of vaccines against infectious diseases have concomitantly broadened to include civilian populations worldwide. In many cases involving infectious diseases of military significance, the military has either directly, through the work of force researchers, or indirectly, through investments and resource provision, promoted the development of vaccines. This pattern is expected to persist as new threats are recognized and military forces accept additional challenges.

INTRODUCTION

Military imperatives necessitate force readiness; disease prevention is a critical component of this doctrine. While the ratio of disease-associated deaths to battlefield-associated deaths in U.S. military deployments has progressively decreased over the past century, disease still accounts for the majority of morbidity in military venues (Murray and Horvath, 2007). It is widely recognized that for many diseases of potential military significance, prevention is best accomplished through the deployment of vaccines. Vaccines, considered by many to top the historical list of the ten greatest public health achievements of the 20th century (Centers for Disease Control and Prevention, 1999), have therefore been a cornerstone of military preventive medicine since before the first systematic study of their utility by Edward Jenner in the late 18th century.

Throughout history, the military has been a major force in both the development and the use of vaccines against infectious diseases (Artenstein et al., 2005). The U.S. military, for example, has contributed directly and significantly to numerous vaccines throughout modern history (Table 18.1). In some instances military exigencies have stimulated vaccine research on infectious diseases of mission-specific importance; in others, the military has functioned as a high-volume consumer of routine immunizations.

Aside from their traditional involvement in combat operations, modern military forces have additional roles in global geopolitics including duties as peacekeepers, police, humanitarian relief workers, and disaster assistance personnel (Ryals and Baker, 1996; Baker and Ryals, 1999). These diverse roles beyond their traditional combat duties potentially expose military personnel to a wide array of environments over a broad range of geographic settings throughout the world. Such duties may alter the primary mission from force preservation to the protection and treatment of civilians, notably women and children (Sharp et al., 2001). This evolving role of global militaries since the latter part of the 20th century potentially predisposes forces to an expanded array of pathogens. Vaccines in these settings are used to prevent routine childhood diseases among troops and civilians and for health maintenance of civilians at risk. Military personnel are also at high risk to encounter such infectious diseases during recruit training, a setting in which numerous young adults reside in confined living conditions for extended periods of time and are subjected to intense physical, emotional, and immunologic stressors, increasing their risk of communicable diseases, especially those transmitted by respiratory routes (Benenson, 1984).

Some of the pathogens that threaten military forces cause common infectious diseases that are prevalent in developing nations lacking widespread routine childhood vaccination programs; others are endemic to only select regions of the world and tend to cause sporadic infections or outbreaks in deployed military personnel; while others may cause outbreaks of common diseases when occurring in enclosed populations. To guard against the plethora of infectious diseases that may assail a military in any of its many expanded modern functions, and to fulfill their supplementary roles as humanitarian relief workers in civilian emergencies, a variety of vaccines is widely deployed. Table 18.2 provides a general listing of the current vaccines, not differentiated based on individual service branches, used by the U.S. military under various conditions. As extensive coverage of the individual pathogens and their associated vaccines is provided in other chapters of this text, the present chapter summarizes vaccines as applied to a variety of transmissible diseases of military importance.

HISTORY REDUX: SMALLPOX

For historical reasons smallpox is an appropriate departure point for a discussion of vaccine applications in the military as this disease led to the precedent-setting mass deployment of immunization in troops more than 20 years before the term "vaccination" was first proposed. Smallpox has the dubious distinction of being the greatest historical disease scourge of mankind. Although it was commonly observed from ancient times through the 18th century that survivors of smallpox were protected against further episodes of the disease (Moloo and Artenstein, in press), the history of vaccination from a scientific standpoint is traditionally dated from the 1798 publication of Edward Jenner's landmark experiments with cowpox in which he inoculated a neighbor's boy with purulent material from a milkmaid's hand lesion in Berkeley, England, thus protecting the child against a smallpox challenge (Parish, 1965). However, long before Jenner's human experiments other forms of inoculation were used throughout the world to protect against smallpox.

Variolation, derived from the Latin word "variola" meaning "mark on the skin" (Parish, 1965), describes the technique in which material from the pustules of smallpox-afflicted persons is inoculated into the arm of a healthy person through multiple scratches or

TABLE 18.1 U.S. military contributions to vaccines against infectious diseases (as defined in text)

Disease/agent	Dates	Military relevance	Military contribution	Key personnel
Smallpox	1777	Highly contagious scourge of troops	First large scale inoculation of an army	Gen. George Washington, Dr. Benjamin Rush
Yellow fever	1900	Epidemic disease associated with high mortality in American-occupied areas	Demonstrated that the etiologic agent was a filterable virus transmitted by *A. aegypti* mosquitoes, leading to disease control through vector eradication and eventually, through vaccination	Maj. Walter Reed, Maj. James Carroll, Aristide Agramonte, Jesse Lazaer, Col. William Gorgas
Typhoid	1909	Communicable cause of outbreaks among deployed troops	Development of killed typhoid vaccine that became mandatory for all Army and Navy personnel in 1911 and greatly reduced the morbidity and mortality of typhoid among military personnel	Maj. Frederick F. Russell
Pneumococcus	1945	Prominent respiratory pathogen among troops	Tested first multivalent polysaccharide vaccine at the Army Air Base, Sioux Falls, S.D. (under auspices of the Armed Forces Epidemiological Board), reduced incidence of pneumonia and the pneumococcal carrier state	Dr. Colin MacLeod, Dr. Michael Heidelberger, Lt. Richard Hodges
Hepatitis A	1945; 1985–1990	Cause of major outbreaks among troops in setting of military conflict	1945, demonstrated that passive immunization with pooled normal human immunoglobulin could prevent or attenuate disease; 1980s–1990, investigated safety and immunogenicity of inactivated vaccines and directed a pivotal efficacy study of inactivated HAV vaccine in ~40,000 Thai children	Col. Charles Hoke, Lt. Col. Bruce Innis, Dr. Len Binn, Dr. Stanley Lemon
Adenovirus	1952–1969	Major cause of acute respiratory disease in recruits, disruptions in training, economic losses	Isolated causative agent, later named adenovirus, at Ft. Leonard Wood; described epidemiology and clinical spectrum of adenovirus infections; developed killed bivalent vaccine; recognition of SV40 contamination; developed oral, attenuated, multivalent vaccine	Dr. Maurice Hilleman, Col. Edward Buescher, Maj. Franklin Top, Col. Phillip Russell
Influenza	1957	Epidemic and pandemic disease impede military readiness and fighting force	Described antigenic drift and shift; developed surveillance system for epidemic disease	Dr. Maurice Hilleman
Rubella	1961	Consequences of disease in pregnancy affects military families	Isolated the causative virus after noting interference with enteroviral growth in African green monkey kidney cell cultures; led to development of a safe and effective vaccine using this virologic technique	Cpt. Paul Parkman, Cpt. Malcolm Artenstein, Lt. Col. Edward Buescher

punctures. The method was introduced into early 18th century Europe via travelers returning from Istanbul and brought to England in 1721 by Lady Mary Wortley Montague, the wife of the British ambassador to the Ottoman court (Barquet and Domingo, 1997). After her daughter was inoculated under the public scrutiny of physicians of the royal court, variolation caught the interest of the royal family, thus gaining

widespread acceptance in England; the practice ultimately disseminated throughout Europe by the 1740s (Barquet and Domingo, 1997).

Despite an observed mortality rate of 2–3% related to variolation, the procedure still offered better odds than the 15–30% mortality from naturally acquired smallpox. In 1721, Reverend Cotton Mather successfully advocated for its use to abort a smallpox epidemic in Boston (Moloo and Artenstein, in press). Variolation subsequently gained the support of American thought leaders such as Benjamin Franklin and became widespread in the colonies. In 1777, with his army decimated by smallpox and inoculated British troops holding a significant tactical advantage, General George Washington, in consultation with one of colonial America's preeminent physicians and statesman, Dr. Benjamin Rush of Philadelphia, adopted the bold and unprecedented plan to inoculate all susceptible members of the Continental Army, a strategy that is believed to have tipped the balance in favor of the Americans (Artenstein et al., 2005) and to have represented the first large-scale inoculation of a military force.

Jenner published *An Inquiry into the Causes and Effects of the Variolae Vaccinae, a disease discovered in some of the western counties of England, particularly Gloucestershire and Known by the Name of Cow Pox* at his own expense in 1798. In it he coined the term "vaccination" (from the Latin word vacca, for cow) to describe the procedure and distinguish it from variolation (Barquet and Domingo, 1997). The work, though initially met with considerable skepticism, was subsequently confirmed by others and led to the dissemination of vaccination against smallpox in the Western world by the early part of the 19th century (Moloo and Artenstein, in press). The U.S. War Department ordered mandatory vaccination with Jenner's cowpox product, in lieu of variolation, beginning in 1812 (Grabenstein et al., 2006). Smallpox vaccination with vaccinia products distantly related to Jenner's continued to be routinely administered to new recruits until early 1990, nearly 20 years after the cessation of routine civilian use of the vaccine, when it had become clear that the risk outweighed any potential benefits (Redfield et al., 1987).

Smallpox was eradicated as a cause of natural human disease after an intensive global campaign by the World Health Organization and sponsoring countries; the last naturally acquired case occurred in 1977. However, in December 2002 after more than a 12-year hiatus, the U.S. government reinitiated large-scale military vaccination using live vaccinia in response to the perceived threat of bioterrorism involving smallpox. The military program vaccinated over 730,000 individuals as of early 2005; their data reveal that most adverse events occurred at rates below historically anticipated levels (Poland et al., 2005). The relative dearth of "expected" vaccine complications in the recent U.S. vaccination programs was perhaps due to a combination of factors including more rigorous screening for vaccine contraindications than during the previous era of routine vaccine use.

Despite the low incidence of "expected" serious toxicities associated with smallpox vaccination in the military program, a number of unexpected, serious cardiac complications of the use of live vaccinia were noted. Cardiac complications of smallpox vaccines had been reported, albeit infrequently, during the previous era of routine use. Through the 1960s and 1970s, data from Finland and Australia demonstrated rates of myopericarditis as high as 1 per 10,000 vaccinees (Karjalainen et al., 1983); up to 3% of Swedish recruits in the 1960s were found to have nonspecific, asymptomatic T-wave changes on electrocardiogram following smallpox vaccination (Ahlborg et al., 1969).

The major cardiac complications of smallpox vaccination observed in the recent U.S. programs were of

two varieties: cardiac ischemic events or myopericarditis (Poland et al., 2005). While a causal relationship of ischemic cardiac events to traditional vaccinia virus vaccination has not been clearly established, their temporal association resulted in a series of government recommendations regarding cardiac screening, new vaccine contraindications, and surveillance for cardiac events that may impact future clinical studies involving newer smallpox vaccine approaches. Additionally, the military program identified 86 cases of myopericarditis during its first two years (Poland et al., 2005), a rate of approximately 1.2 per 10,000, similar to rates observed in Finnish conscripts described 24 years ago (Karjalainen et al., 1983). These rates were clearly higher than age-matched, nonvaccinated individuals, and since cases presented in close temporal association to vaccination, the appropriate conclusion was that smallpox vaccination using live vaccinia virus is associated with an increased risk of myopericarditis.

Currently, smallpox vaccine is given to select U.S. military units that will potentially deploy to areas considered to be at "high risk" due to the threat of biological weapons exposures (Grabenstein et al., 2006). Other developed nations, such as Canada and Great Britain, have not adopted policies of vaccinating large groups of military personnel against smallpox.

VACCINES USED ROUTINELY AND IN RECRUIT TRAINING SETTINGS

Routine childhood immunizations, including those against tetanus, diphtheria, pertussis, measles, mumps, rubella, varicella, and polio are consistently applied to service members early in recruit training to ensure complete penetrance of immune protection against these preventable pathogens. As most young adults have received basic immunizing doses in childhood, these vaccines are generally given either as booster doses to sustain immunity or are given based on the results of serologic screening; subsequent doses are given at intervals as recommended by the Advisory Committee on Immunization Practices (ACIP) (Grabenstein et al., 2006).

Tetanus

Wound-associated tetanus, an enormous disease burden and major cause of battlefield-related mortality throughout history, was effectively controlled by passive immunization of the wounded during World War I and virtually eliminated as a significant risk with the advent of active immunization using formalin-inactivated toxin, tetanus toxoid, in the 1930s (Benenson, 1984). Only 16 cases of tetanus were reported among all U.S. forces serving in World War II following the first large-scale deployment of tetanus toxoid, and most of these occurred in incompletely immunized individuals (Benenson, 1984). Recently, the tetanus, diphtheria, and acellular pertussis combined vaccine product has been widely adopted by the military for use in primary immunization series or for booster doses for service members in recruit settings (Grabenstein et al., 2006). The military deployment of tetanus, diphtheria, and pertussis vaccines may be most beneficial in humanitarian operations in developing countries where routine vaccination is either unavailable or inconsistently applied.

Measles, Mumps, Rubella, Varicella

Classic viral respiratory diseases of childhood, measles, mumps, rubella, and varicella, represented major causes of nonbattlefield morbidity throughout military history (Ottolini and Burnett, 2005). During World War II alone, these infectious diseases accounted for hundreds of thousands of hospital admissions and training days lost to illness among U.S. armed forces (Grabenstein et al., 2006). The practical and economic impact of these viral respiratory diseases in military settings was noted as recently as the 1970s (Meiklejohn, 1983).

Live-virus vaccines against measles (Katz et al., 1960), mumps (Hilleman et al., 1968), and rubella (Meyer and Parkman, 1971) were developed in the 1960s and licensed by the end of the decade. Rubella vaccine, developed shortly after the isolation of the causative agent by military researchers (Fig. 18.1) (Parkman et al., 1962), and measles vaccine were relatively rapidly adopted for routine use in military trainees; mumps vaccine was not uniformly used until 1991, based on the infrequent occurrence of outbreaks of this disease in recruit settings (Grabenstein et al., 2006). Because recent serosurveys have documented that more than 85% of basic trainees are immune to these viruses by virtue of childhood immunization, serologic testing and vaccination of only the nonimmune has become standard (Clardy, 1993; Smoak et al., 1994; Grabenstein et al., 2006). These products, as with other routine childhood vaccines, may be most useful in civilian populations during military humanitarian duties. Varicella vaccine, developed in the 1970s by Takahashi but not licensed in the U.S. until 1995 (Moloo and Artenstein, in press), is also currently used as indicated by the results of individual serologic screening (Burnham et al., 1998).

Hepatitis A

Epidemic jaundice, now known to be due to the hepatitis A virus, has long accompanied armies at war, from Napoleon's campaigns in Russia and North Africa to the U.S. Civil War to World War II and the Korean conflict (Dooley, 2005). Hepatitis A outbreaks among combat forces in North Africa and Italy during World War II accounted for more days of training and force strength lost than any other cause of disease and may have delayed the D-day landing by one month (Dooley, 2005). While investigations clearly showed the infection to be directly related to poor sanitation and hygiene, risk was inherent to military operations because of the unsanitary nature of combat theaters and associated exposures.

Initial forays into the prevention of hepatitis A involved passive immunization with pooled gamma globulin (Dooley, 2005). The short-term efficacy of such an approach was shown by Stokes, Gellis and others in a series of clinical trials, some of which were performed in military populations (Gellis et al., 1945; Stokes and Neefe, 1945). Passive immunization remained the main mode of protection against hepatitis A until viral isolation and propagation in nonhuman primate cell lines in the mid-1980s led to a prototype, formalin-inactivated vaccine (Dooley, 2005). Innis et al. (1994) performed a pivotal clinical trial of hepatitis A vaccine in the early 1990s involving more than 40,000 school children in rural Thailand and demonstrated vaccine safety with efficacy of 94%. Inactivated vaccines were licensed in 1995 and were immediately adopted as a component of the vaccine regimen for recruits and other military personnel (Grabenstein et al., 2006).

Hepatitis B

Hepatitis B, "serum" hepatitis, gained initial notoriety in a military setting as the etiology of a 1942 epidemic among U.S. soldiers who received contaminated lots of yellow fever vaccine manufactured with tainted human albumin (Dooley, 2005). More than 300,000 individuals were likely infected; 50,000 developed jaundice (Norman et al., 1993). First-generation, plasma-derived, hepatitis B subunit vaccines were licensed in 1981. The recombinant subunit hepatitis B vaccine supplanted the plasma-derived product in 1986 and has been applied to military cohorts based upon occupational (e.g., medical personnel) or geographic (e.g., Korean assignment) risk. As hepatitis B vaccination has become routine in childhood, penetrance of immunity is becoming widespread among service members.

Influenza

Influenza, a highly transmissible acute respiratory virus infection, tends to amplify in certain settings, especially crowded, enclosed environments.

In military training camps and aboard naval troop vessels (Earhart et al., 2001), environments in which young adults of varying susceptibility backgrounds and exposure histories are intermixing under cramped conditions, the opportunities for epidemic spread are pronounced. The largest influenza pandemic in recorded history, that of 1918, is believed to have ignited in U.S. training camps and to have disseminated via movement of global military forces in the context of World War I (Taubenberger and Morens, 2006). During the 1918 pandemic, it is estimated that between 50 and 100 million people perished worldwide (Taubenberger and Morens, 2006), including 1.5% of the entire American military force (Grabenstein et al., 2006).

Excessive morbidity and mortality related to seasonal epidemics of influenza and the threat of recurrent pandemic disease have significant impact on military forces and their state of readiness. The Armed Forces Epidemiological Board (AFEB), an advisory group of civilian physicians and scientists, was established in 1941, initially as a response to the influenza threat; the AFEB charter was subsequently expanded to respond to a variety of infectious disease threats (Woodward, 1990). Influenza vaccination among select U.S. military forces began during World War II and became widespread and routinely used by the early 1950s (Grabenstein et al., 2006). Annual immunization is currently deployed to protect against seasonal influenza outbreaks in military settings.

Adenovirus

Acute respiratory disease (ARD) caused by a variety of pathogens has consistently been a leading cause of morbidity among military recruits probably as a result of the crowded living conditions and physical stressors inherent to training camps (Gray et al., 1999). In 1954, Hilleman (Fig. 18.2) and others isolated the virus responsible for the majority of ARD and primary atypical pneumonia in noncombat military settings (Hilleman and Werner, 1954); the agent was later named "adenovirus" based upon the isolation of biologically related organisms from the tonsils and adenoids of children (Enders et al., 1956).

Adenoviruses were noted to have an enormous impact on troop health in recruit environments: attack rates as high as 80% existed in some camps with up to 20% requiring hospitalization; these numbers translated into hundreds of weekly admissions at some of the larger recruiting centers in the U.S. in the mid-20th century (Dudding et al., 1973). Because of the impact on troops and their training, medical resources, and

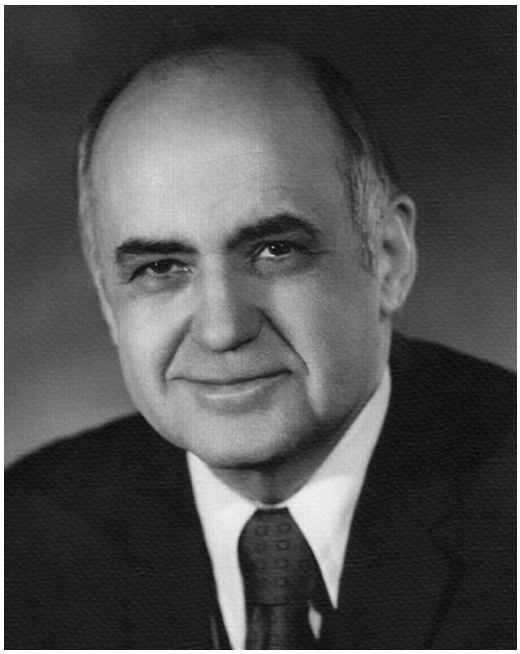

FIGURE 18.2 Maurice Hilleman. (*Source*: Courtesy of the Hilleman family. Used with permission.)

overall economic costs to the military, vaccine development was a high priority. Once it became clear that two serotypes of adenovirus, types 4 and 7, accounted for the majority of ARD in recruits, a formalin-inactivated bivalent vaccine for adenovirus was developed within three years of the initial description of the infectious agent (Hilleman, 1999). Pivotal, large, clinical efficacy trials were performed at multiple large recruit centers; the vaccine proved to be greater than 90% effective and was licensed in 1958 (Hilleman, 1999; Artenstein et al., 2005). Manufacturing problems, however, were identified early and included partial loss of antigenicity in large-scale production and seed lot contamination by Simian virus 40, an oncogenic virus that also contaminated oral and inactivated poliovirus vaccines during the same time period; the license for the parenteral product was revoked in 1963 (Gaydos and Gaydos, 2004).

Second generation, live adenovirus vaccines targeting types 4 and 7 virus, given as enteric-coated capsules, were developed in the mid-1960s under the leadership of Colonel Edward Buescher (Fig. 18.1) and extensively studied at military facilities (Pierce et al., 1968). Through induction of an asymptomatic gastrointestinal infection that is unassociated with the transmission of vaccine virus to close contacts, the vaccines stimulate serum neutralizing antibody in more than 95% of recipients (Top et al., 1971a). The products, either given singly or in combination, resulted in a 50% decrease in hospitalization rates due to ARD

in recruits and a greater than 95% reduction in illness due to type 7 adenovirus (Top et al., 1971b). Beginning in 1971 both vaccines were routinely administered to military recruits within hours of their arrival at basic training. A cost-benefit analysis of the U.S. military's adenovirus vaccination program demonstrated a favorable ratio, even accounting for the one-time costs related to vaccine development (Collis et al., 1973).

As a result of adenovirus vaccine use during the period from 1971 to 1996, there were essentially no outbreaks of ARD reported in U.S. military units related to either of the adenovirus serotypes used in the vaccines. However, the sole manufacturer of the vaccines ceased production in 1996; thus a program of reduced vaccine use was instituted prior to the depletion of stocks in 1999 (Gaydos and Gaydos, 2004). The unavailability of adenovirus vaccines has resulted in a recrudescence of ARD due to these agents. Recent surveillance data in sentinel military populations reveal that 55% of throat cultures obtained from recruits with ARD from 1996 to 1998 yielded adenoviruses, primarily types 4 and 7 (Gray et al., 1999). Unvaccinated personnel with ARD were significantly more likely to be infected with adenovirus than their vaccinated counterparts. Outbreaks of adenovirus infection causing ARD have been reported from a variety of military centers since the cessation of routine vaccination and have generally resulted from a large pool of susceptible hosts; nearly 90% of new recruits were seronegative to either type 4 or 7 adenovirus in one study (Gray et al., 1999). Recognizing the benefit of adenovirus vaccine, the U.S. government has taken steps to reinstitute the program by contracting with industry to develop and produce the product for the future.

Meningococcal Disease

Epidemic meningococcal meningitis has been a well-described complication of troop mobilizations in training camps and combat theaters since the latter part of the 19th century. The U.S. forces experienced outbreaks during World War I, prompting the formation of the Armed Forces Epidemiological Board Commission on Meningococcal Meningitis in 1941 to accelerate scientific study and control of the disease (Woodward, 1990). From 1941 to 1943, the Commission documented over 5,000 domestic cases among U.S. Army personnel (Woodward, 1990). The epidemiology in this population clearly showed that the incidence of meningococcal disease was inversely associated with duration of military service; the greatest risk for recruits was during their first three months of military service (Artenstein et al., 2005).

Although sulfa drugs, discovered in 1937, were effective as therapy and prophylaxis for meningococcal disease, reports of sulfa-resistant organisms began to emerge by 1945. By the early 1960s, the majority of clinical isolates of meningococci was resistant to sulfa agents (Artenstein and Gold, 1970), findings confirmed by epidemics of meningococcal disease at multiple military facilities during that time frame (Alexander et al., 1968). The rapid emergence of sulfa-resistance and later rifampin-resistance led the field to focus efforts on vaccine development in the belief that a meningococcal vaccine represented the best hope for long-term control of the problem in military populations.

In 1969, Dr. Malcolm Artenstein (Fig. 18.1), the Chief of the Department of Bacteriology at the Walter Reed Army Institute of Research (WRAIR) and his associates, Emil Gotschlich and Irving Goldschneider, published a series of five classic papers that described in detail the human immunologic response to *Neisseria meningitidis* (Goldschneider et al., 1969a, 1969b; Gotschlich et al., 1969a, 1969b, 1969c). In this work they demonstrated the protective role of serum bactericidal antibody against systemic disease (Goldschneider et al., 1969a); identified the group-specific polysaccharide as the key antigenic determinant (Goldschneider et al., 1969b); and described novel methods for the preparation of high molecular weight group A and C polysaccharides as immunogens (Gotschlich et al., 1969a). In preclinical studies they proved the safety of such preparations in animals and proceeded to show immunogenicity in humans in a phase I clinical trial, with high concentrations of group-specific bactericidal antibody induced after a single, intradermal injection and significant reduction of the nasopharyngeal carriage rates of group C meningococcus (Gotschlich et al., 1969b, 1969c).

Armed with their basic science and preclinical findings, the WRAIR investigators initiated a large clinical trial of a group C meningococcal polysaccharide vaccine. Because there was no method for predicting the location of epidemics, the study involved multiple recruit training centers; and, because of the known rapid acquisition of the carrier state among newly arrived recruits, informed consent and vaccination had to be accomplished within days of arrival (Artenstein et al., 1970). In the pivotal efficacy study 13,763 men at 5 different military posts were vaccinated with a group C polysaccharide, and more than 53,000 served as unimmunized controls. The vaccine proved safe, reduced the acquisition rate of group C meningococcus (although not that of other meningococcal groups), and significantly reduced the rate of systemic meningococcal disease caused by group C

organisms during an eight-week period (Artenstein et al., 1970). The results of a second, large field trial, with sample sizes similar to the first, confirmed the protective effect (Gold and Artenstein, 1971).

Based on the aforementioned data, the military began administering meningococcal C polysaccharide vaccine to all recruits in late 1970, resulting in the virtual elimination of meningococcal C disease as a major military health problem (Granoff et al., 2004). The current, tetravalent (groups A, C, Y, and W135) vaccine, licensed in 1981, is indicated for military recruits, asplenics, individuals with terminal complement deficiencies, travelers to areas where meningococcal disease is hyperendemic or epidemic, and subgroups of college students (Granoff et al., 2004). Military personnel deployed to meningococcal-endemic areas such as sub-Saharan Africa receive the vaccine. In the United Kingdom and several other countries, group C meningococcal polysaccharide conjugated to carrier proteins such as tetanus toxoid or diphtheria toxin derivatives has been used with remarkable success in reducing the burden of disease in children, a group in whom polysaccharides are traditionally poorly immunogenic (Granoff et al., 2004). The U.S. military is currently transitioning to the routine use of meningococcal conjugate vaccines for its forces (Grabenstein et al., 2006). The development of a vaccine targeting serogroup B meningococci, the cause of a significant minority of epidemic disease worldwide, remains elusive (Granoff et al., 2004).

VACCINES USEFUL FOR SPECIFIC DEPLOYMENTS AND ALERT FORCES

Selected vaccines have military applications based on deployments or potential deployments of troops to areas with extant vaccine-preventable endemic risks or in members of specialized military forces that are involved in alert settings, such as rapid response or special operations personnel. Similarly, the perceived and ubiquitous threat of biological weapons in military settings extends the repertoire of vaccine-preventable diseases that must be considered in military planning.

Yellow Fever

Yellow fever, currently endemic to sub-Saharan Africa and spotty areas in South America, caused epidemic disease along the eastern seaboard of the U.S. and Central America until the early part of the 20th century. "Yellow Jack" halted Napoleon's armies in New Orleans in 1801 and led to the French abandonment of the Panama Canal Zone in 1889 (Artenstein, et al., 2005). The disease was rampant in Cuba, the island acquired by the U.S. in the Spanish-American War, generating U.S. government–sponsored research into the epidemiology, microbiology, and prevention of yellow fever led by Major Walter Reed. Reed and his group of young army preventive medicine officers elucidated the epidemiology and transmission characteristics of the pathogen; their work directly led to the successful vector control efforts by Major William Gorgas both in Cuba and the Canal Zone, eventually eliminating yellow fever from the latter and allowing the completion of the Panama Canal.

The seminal investigations of Reed and colleagues led to the identification of the viral etiology of yellow fever and, in the 1930s, to the successful attenuation of the virus by serial passage in chick embryos by Max Theiler and colleagues at the Rockefeller Institute (Theiler and Smith, 1937). The resultant live, attenuated strain, 17D, was shown to induce long-term immunity in Rhesus macaques and human volunteers and continues to be used more than 60 years later to protect military forces deploying to yellow fever–endemic regions (Artenstein, et al., 2005; Grabenstein et al., 2006).

Japanese Encephalitis

Japanese encephalitis virus (JE), a mosquito-borne flavivirus that is endemic throughout the continent of Asia, represents a significant risk for deployed troops who are bitten by infected insects as an incidental branch of the viral life cycle (Hoke, 2005). More than 300 cases, 6% of them fatal, were identified in an outbreak among U.S. military personnel assigned to the Korean peninsula in 1950 (Lincoln and Siverson, 1952). Military research in the 1960s confirmed persistent risk in areas of active or planned operations, thus laying the theoretical and epidemiological foundations for vaccine development.

Although vaccine development by the U.S. military and Japanese public health authorities was undertaken to satisfy military exigencies, the ultimate product benefited mostly Asian children who were at the greatest risk from JE (Hoke, 2005). The pivotal vaccine study in the late 1980s enrolled approximately 66,000 subjects in rural Thailand and demonstrated 91% efficacy (Hoke et al., 1988), resulting in licensure by the U.S. Food and Drug Administration in 1992. The JE vaccine, now in transition to a cell culture–based production method, is given to military forces either deploying or on alert to regions with endemic disease.

Rabies

Military forces deployed worldwide are potentially at risk for bites from rabies-infected animals, and preventive approaches to manage the risks are required (Hoke, 2005). Preexposure immunization of forces may be useful in troops assigned to remote or forward areas with ongoing risks of animal exposures (Grabenstein et al., 2006).

Typhoid

Typhoid was a well-recognized scourge of military forces throughout modern history; U.S. troops training for entry into the Spanish-American War experienced multiple large outbreaks of disease as a result of unsanitary conditions at the camps (Grabenstein et al., 2006). Early generations of killed typhoid vaccines, developed by Sir Almroth Wright, were used with equivocal success to protect British troops deployed in the Boer War in 1899 (Benenson, 1984). Major Frederick Russell of the U.S. Army Medical School adapted the British vaccine for subcutaneous use and orchestrated field trials of the new product; mandatory vaccination of American military forces was instituted in 1911 and continued through the Vietnam era, and in concert with improvements in sanitation, significantly limited the impact of typhoid on deployed forces (Grabenstein et al., 2006). Late in the 20th century, whole-cell vaccines were supplanted by subunit and live attenuated typhoid vaccines, and these products are currently applied to military forces in high-risk deployment settings.

Tick-Borne Encephalitis

Virologically similar to JE, tick-borne encephalitis (TBE) is endemic to most areas of Europe and throughout much of Asia; most reported cases derive from Russia (Barrett, et al., 2004). TBE has the potential to be a significant disease threat in military deployments to endemic regions. During the U.S. military involvement in Bosnia-Herzegovinia in the mid-1990s it was estimated that as many as 1% of U.S. forces operating in the region may be at risk for infection, prompting the use of TBE vaccine in 4000 soldiers under an investigational new drug (IND) status (Craig et al., 1999).

Anthrax

Anthrax continues to occupy a position atop the category A agent bioterrorism threat list because of its potential for large-scale morbidity and mortality when used as an aerosolized weapon (Artenstein, 2007). "Proof of principle" of this agent's significance as both a military and civilian threat was amply demonstrated in two events: the unintentional release of weaponized spores in Sverdlovsk in 1979 and the intentional anthrax attacks in the U.S. in 2001 that killed 5, sickened 17 others, and terrorized millions of people around the world (Inglesby et al., 2002).

Due to its obvious military significance, anthrax has historically been mission-relevant for military medical research, resulting in many important scientific contributions deriving from this quarter (Christopher et al., 2005). The current anthrax vaccine, licensed in 1970, is a subunit product that employs protective antigen (PA), one of three protein exotoxins secreted by germinating bacteria in vivo, as the immunogen; vaccine-induced anti-PA antibodies are known to be highly protective in animal models of inhalational disease and human trials involving largely cutaneous anthrax (Inglesby et al., 2002). Approximately 150,000 American military forces were vaccinated during the Persian Gulf War in anticipation of the use of biological weapons by the Iraqi regime (Berezuk and McCarty, 1992; Grabenstein et al., 2006). Beginning in the late 1990s and accelerating since the events of 9/11, the U.S. military embarked on an expanded program of anthrax vaccination in certain deployable forces; to date over 1.5 million individuals felt to be at potential risk because of assignment location have received in excess of 5 million doses of anthrax vaccine in this program (Grabenstein et al., 2006). Numerous cohort studies and data reviews in the aftermath of the expanded use of anthrax vaccine by the military have failed to reveal a causal relationship between anthrax vaccine and chronic comorbid medical conditions (Sever et al., 2004; Grabenstein et al., 2006).

Alphaviruses

In addition to JE and yellow fever, a number of other vector-borne viral pathogens pose risk to military forces either as environmental threats related to specific geographic deployments or as potential agents of biological warfare. The alphaviruses, while antigenically and molecularly distinct from one another, share a mosquito-borne transmission pattern and cause similar clinical syndromes: viral encephalitis, seen with Venezuelan equine encephalitis (VEE), Eastern equine encephalitis (EEE), and Western equine encephalitis (WEE); or febrile rash with serositis in Chikungunya, Ross River virus, and O'nyong nyong (Pittman and Plotkin, 2004). The U.S. military has developed IND vaccine products targeting the

viral encephalitides and Chikungunya. These vaccines have been limited in their scope of use largely to at-risk laboratory personnel and have shown promise in reducing laboratory-acquired infections with these agents (Pittman and Plotkin, 2004; Hoke, 2005). Because the use of these vaccines has only been implemented on a small scale, safety has not been assessed on a broad scale. Immunologic interference related to the co-administration of these vaccines has also been noted (Pittman and Plotkin, 2004).

Viral Hemorrhagic Fevers

These agents, deriving from multiple families of RNA viruses, are generally arthropod- or rodent-borne infections that result in clinical syndromes involving systemic symptoms, disseminated hemorrhagic manifestations, and vascular collapse (Thomas et al., 2005). Hemorrhagic fever viruses are considered to be high-priority threat agents for bioterrorism (Borio et al., 2002) and are threats of nature based upon incursions into their geographic and ecologic niches by military forces (Thomas et al., 2005; Grabenstein et al., 2006). The U.S. military has developed safe and immunogenic vaccines against Rift Valley fever and Argentine hemorrhagic fever (AHF) caused by the Junin arenavirus (Pittman and Plotkin, 2004). The latter live product has been found to be 95% effective in preventing disease in endemic settings in formal phase II testing in humans (Maiztegui et al., 1998); it is currently used to protect civilians in Argentina.

Viral hemorrhagic fevers of significant military importance but for which vaccines remain largely elusive and in active development include dengue, hantaviruses, and disease caused by the filoviruses Marburg and Ebola. Novel strategies, based on advances in molecular biology and genetics, are being applied to these pathogens; much of the research is being driven by or involves collaboration with military scientists, a testament to the relevance of these pathogens to the military's mission (Thomas et al., 2005).

CONCLUSIONS

The development of safe and effective vaccines targeting diseases related to other biological weapons, such as plague and tularemia in addition to improved anthrax and smallpox vaccines, is a high priority and of obvious military application. Similarly, based upon the sheer global burden of disease, malaria continues to pose a significant threat to military forces deployed in many parts of the world. While a vaccine solution to this enormous public health problem remains elusive, substantial resources are engaged to achieve this goal. Military medical research has been a leader in the development of malaria vaccines to date and will likely be a major consumer of future effective products for both combat and humanitarian operations (Ockenhouse et al., 2005).

HIV-1 also represents a global threat to militaries. As with other sexually transmitted and blood-borne pathogens, HIV-1 may represent a direct threat to military forces in sporadic fashion (Artenstein et al., 1995; Brodine et al., 1995). However, the most significant threat posed by the worldwide HIV epidemic to deployed military forces is its deleterious impact on global security and the stability of governments, especially those in developing nations. The destabilizing influence of the HIV-1 epidemic serves to create or exacerbate humanitarian crises that subsequently involve military forces in expanded roles. Thus, an effective vaccine against HIV-1 may have important military application.

A variety of infectious threats continually face military forces as occupational hazards related either to the epidemiology of deployments, wartime vulnerabilities, or based upon the epidemiology of troop encampments and training environments. While many such threats have been controlled or prevented with vaccines, others remain. Vigorous research continues toward the goal of developing safe and effective products against these incompletely addressed pathogens.

OUTLINE

ABSTRACT

Molecular evolution studies suggest that dengue virus (DENV) evolved 1000 years ago and entered a sustained human–mosquito cycle between 125 and 320 years ago. While it is unlikely that DENV would be used as a biothreat agent, DENV has emerged since World War II as the most important mosquito-borne *viral* pathogen infecting an estimated 100 million persons each year. Infection with any of the four DENV serotypes (DENV-1, 2, 3, and 4) can be inapparent, result in classic dengue fever with high fever, headache, eye pain and muscle ache, or progress at the time of defervescence to dengue hemorrhagic fever (DHF) characterized by hemorrhagic manifestations and plasma leakage that can lead to shock and death. The immunopathological mechanisms by which DENV causes the clinical features of DHF are intricate and include aberrant humoral and cellular immune responses. Previous DENV infections may predispose to more severe disease by the induction of enhancing antibody and cross-reactive T cells. Treatment is supportive relying upon careful fluid management which can be lifesaving. Prevention currently depends on vector control which has been largely unsuccessful. Several dengue vaccine candidates have advanced to clinical trials to include classically and molecularly attenuated live virus vaccines, chimeric vaccines using dengue and yellow fever virus backbones, and DNA vaccines. Whole virus inactivated and recombinant subunit vaccine candidates should soon enter into clinical testing. Live attenuated DENV vaccines offer the most promise in terms of broad, long-lasting protection, and although they are economical to produce, they may carry the risks of enhanced reactogenicity in recipients with preexisting flavivirus antibodies, adverse events among the immunocompromised, vaccine virus transmission by vector mosquitoes, and the risk of adventitious agents. Chimeric vaccine approaches use the same gene sequence for the nonstructural proteins for each of the four DENV serotypes avoiding the need for attenuating mutations in the structural genes and potentially reducing interference in the replication of the four virus vaccine components within the multivalent vaccine recipient. DNA vaccines, in combination with other approaches, may increase the complexity and effectiveness of the immune response. Whole inactivated virus approaches have been used successfully for other viral diseases, reduce interference issues in multivalent vaccines, and have protected nonhuman primates from viremia following challenge with wild-type virus. Recombinant subunit vaccines have also protected nonhuman primates from viremia and offer a more focused approach in an attempt to tailor antibody and cell-mediated immure responses. While pathogenesis studies seek to dissect immune responses in an attempt to avoid vaccine-related disease enhancement, these risks, which apply to all vaccine approaches, may need to be evaluated empirically.

INTRODUCTION

Despite the fact that approximately 2.5 billion people live in regions where dengue virus (DENV) transmission by mosquito is possible, and despite the resurgence of dengue disease over the last 25 years, dengue remains classified as a neglected tropical disease by the World Health Organization. This neglect may be compounded by the low likelihood that DENV would be used as an agent of bioterrorism. Nevertheless, the disease burden created by DENV is significant, especially among children living in endemic regions of Southeast Asia, the Indian subcontinent, and Central and South America. Because the vast majority of DENV infections are asymptomatic, many would consider these infections unimportant. However, previous infection with DENV or the presence of maternally derived DENV antibodies is the most recognized risk factor for the progression to serious dengue disease. Therefore, all DENV infections are significant, whether they are inapparent or result in dengue fever (DF) or the more severe dengue hemorrhagic fever (DHF). Although vector control is currently the most effective measure to reduce the impact of DENV, its effectiveness is dependent on the intensity and sustainability of such programs, which are tenuous at best. Recent advances in our understanding of dengue pathogenesis and in vaccine development show promise to deliver effective and long-lasting dengue control.

HISTORY OF DENGUE DISEASE

Epidemics of DF-like illness have been identified in the medical literature as far back as 992 CE or 1014 years ago. A Chinese "encyclopedia of disease symptoms and remedies" described an illness called "water poison" associated with flying insects and water that included rash, fever, eye pain, arthralgias, myalgias, and hemorrhagic manifestations (Nobuchi, 1979; Gubler, 1997). If this was truly a description of a dengue epidemic then recent molecular evolution studies of DENV suggest that this was one of the first. According to Twiddy et al. (2003), DENV may have evolved approximately 1000 years ago, transferred from solely a monkey–mosquito sylvatic cycle to a sustained human–mosquito cycle between 125 and

320 years ago, and diversified into the four DENV serotypes only in the last 100 years. While the name "dengue" probably comes from Africa (see below), the virus itself most likely originated in Asia as all four DENV serotypes have been identified in sylvatic cycles in Asia while only DENV serotype 2 (DENV-2) has been identified in forest cycles in Africa (Gubler, 1997).

More commonly cited as the first clinical description of dengue was that provided by Dr. Benjamin Rush, a signer of the United States Declaration of Independence and Surgeon in Charge of Hospitals during the American Revolutionary War under General George Washington (Rush, 1789). Following the epidemic of fever in Philadelphia in the summer of 1780, Dr. Rush provided the following description:

> This fever generally came on with rigor, but seldom with a regular chilly fit.…The pains which accompanied this fever were exquisitely severe in the head, back, and limbs. The pains in the head were sometimes in the back parts of it, and at other times they occupied only the eyeballs.…A few complained of their flesh being sore to the touch, in every part of the body. From these circumstances, the disease was sometimes believed to be a rheumatism. But its more general name among all classes of people was, the *Break-bone fever*.

Dr. Rush did not use the term "dengue" but rather "bilious remitting fever" and "break-bone fever" and was probably describing febrile illnesses with multiple etiologies. Donald Carey agrees that Rush was, for the most part, describing what is currently referred to as DF (illness associated with DENV infection). However, the disease referred to as dengue throughout most of the 19th century more closely resembled the clinical syndrome now associated with chikungunya virus infection (Carey, 1971) (see Chapter 32 for Chikungunya). The term dengue was first used in Cuba in 1928 meaning "affected." The Spanish term may have been based on the Swahili term "dinga" or "dyenga" meaning "a sudden cramp-like seizure" used during chikungunya-like epidemics on the East Coast of Africa in 1823 (Rigau-Perez, 1998). The term dengue and the virus (chikungunya) may have traveled to the Caribbean as a part of the slave trade. With infrequent epidemics the terms "break-bone fever" and "dengue" were confused. Toward the end of the 19th century, the term dengue was increasingly applied to Rush's break-bone fever including outbreaks in Australia reported in 1898 (Hare, 1898). The disease previously known as dengue became chikungunya meaning "that which bends up" following outbreaks in East Africa in 1952 with the isolation of that alphavirus (Robinson, 1955).

In 1906, US Army physicians Ashburn and Craig, working in the Philippines, demonstrated that dengue was caused by an "ultramicroscopic nonfilterable agent" or virus by injecting healthy volunteers with filtered serum from febrile dengue patients using syringe and mosquitoes (Ashburn and Craig, 1907). This dispelled earlier contentions that dengue was caused by a bacteria or parasite. This was only the second human viral pathogen described following the yellow fever virus (YFV) described by Reed et al. (1901). Their work also confirmed the work of Graham (1903) at the Syrian Protestant College in Beruit (now American University) that DENV was transmitted by mosquito vectors. With controlled experimental infections and careful clinical descriptions the clinical label of dengue became fixed.

The Japanese and United States accelerated dengue research during World War II leading to DENV isolation by intracranial injection of mice with patient serum. Dr. Hotta and Dr. Kumura isolated DENV-1 from specimens collected between 1942 and 1945 (Hotta, 1952) and Dr. Sabin and Dr. Schlesinger isolated DENV-1 and DENV-2 from specimens collected in Hawaii/India and New Guinea, respectively, in 1944 (Sabin and Schlesinger, 1945; Sabin, 1952). In 1956, a DHF epidemic occurred in Manila resulting in the identification and naming of DENV-3 and DENV-4 viruses by Dr. Hammon (Hammon et al., 1960).

ETIOLOGIC AGENT

DENV is a member of the *Flavivirus* genus of the virus family Flaviviridae. The virus is a spherical particle containing a single-strand, positive-sense RNA genome about 11 kb in length. The genome of the virus contains a single open reading frame which is expressed as a large polyprotein subsequently processed by virus-encoded and host cell proteases into three structural and at least seven nonstructural (NS) proteins. The termini of the genome contain untranslated regions (UTRs) that are important for viral replication. The 5′ UTR is relatively short (approximately 100 nucleotides) and has a type I cap structure (m^7GpppA), while the 3′ UTR (approximately 450 nucleotides) contains a number of conserved RNA structures and lacks a terminal poly(A) tract. The overall genome organization is 5′UTR-C-prM-E-NS1-NS2A-NS2B-NS3-NS4A-NS4B-NS5-3′UTR (C, capsid; prM, membrane precursor; and E, envelope). The infectious virion is approximately 50 nm in diameter and has a relatively smooth surface consisting of a compact arrangement of 180 copies of the E glycoprotein on the virus lipid envelope (Fig. 19.1). Immunity to the virus is mediated primarily by neutralizing

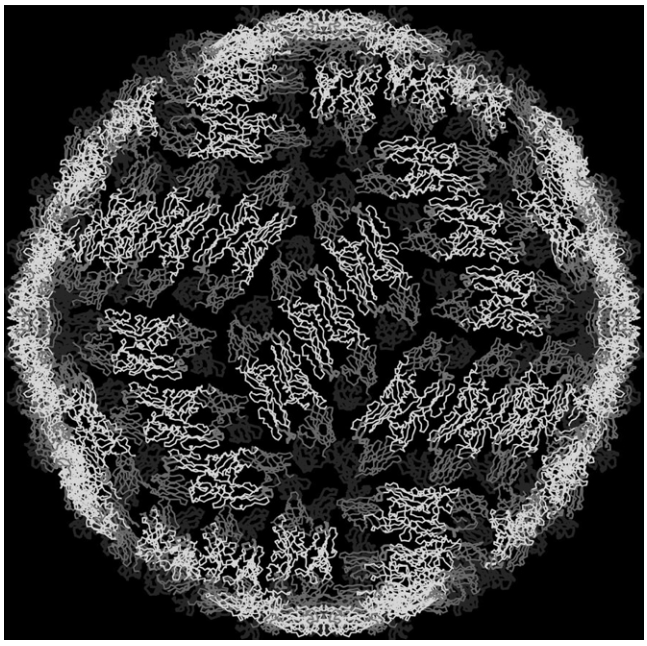

FIGURE 19.1 Arrangement of the E proteins on the surface of the mature virus (Kuhn et al., 2002). The virus surface is covered with 30 protein "rafts," each containing three anti-parallel dimers of E protein. Each monomer is colored as follows: red, domain I (central region); yellow, domain II (dimerization and fusion region); blue, domain III; green (receptor-binding region) (see color plate section).

antibodies to the E glycoprotein which also defines each of the four DENV serotypes (DENV-1, DENV-2, DENV-3, and DENV-4).

Recent crystallographic and cryo-electron microscopic techniques have greatly advanced the understanding of the E glycoprotein structure and its organization on the surface of the virus (Modis et al., 2005; Mukhopadhyay et al., 2005). The molecular conformation of E protein is highly dependent on the pH of the environment: at relatively alkaline pH, the E protein molecules are arranged in a dimeric conformation and lay flat along the virus surface in a herringbone pattern, giving the virus its characteristically smooth appearance; at the relatively acidic pH of the endosomal compartment, the E protein molecules shift to a trimeric conformation and protrude from the virus surface during the process of viral and endosomal membrane fusion which facilitates release of the viral genome into the cell cytoplasm. It is the inherent flexibility of the E protein structure which allows for these considerable conformational changes required during virus maturation and infection. Recent studies have demonstrated that glycosylation sites on neighboring E proteins are bound by a single carbohydrate recognition site of DC-SIGN, a proposed receptor of DENV (Pokidysheva et al., 2006). As the sole protein exposed on the virus surface, the E glycoprotein must function to bind cellular receptors, interact with host cell membranes, direct viral assembly and budding, as well as display antigenic determinants that elicit immune responses.

The primary antigen of DENV is the E glycoprotein, although antibody responses directed toward prM and NS1 have been identified. The E glycoprotein monomer can be divided into three structural/functional domains, I, II, and III (Fig. 19.1). Recent crystallographic studies have suggested that epitopes located among each of the three domains may impart different functionality to the elicited immune response (Modis et al., 2005). Serotype-specific, neutralizing antibodies are generally elicited by epitopes on the surface of domain III, which has also been implicated in cell–surface receptor binding. Although antibodies against epitopes in domain I are generally nonneutralizing, antibodies that recognize epitopes in domain II, which contains the fusion peptide region, have been shown to neutralize virus, probably by inhibition of membrane fusion. Therefore, it is possible that neutralization of DENV can occur not only at the level of virus attachment, but also at the level of membrane fusion and viral entry, as first demonstrated for West Nile virus (Gollins and Porterfield, 1986).

PROTECTIVE IMMUNE RESPONSE

Antibody-Mediated Protection

Humoral immunity is thought to play both a protective and a permissive role in DENV infection. Early studies in mice found that antibody, but not cell-mediated immunity, was critical to the recovery from acute DENV infection (Chaturvedi et al., 1977, 1978). In addition, epidemiologic data suggests that maternal antibody protects infants from DENV infection for the first few months of life (Halstead et al., 2002). Solid protection against a second infection with a homotypic DENV has been demonstrated for as long as 18 months after primary infection but is believed to be much longer, perhaps even lifelong (Sabin, 1952). The evidence for long-lasting homotypic immunity is derived primarily from in vitro studies that detected neutralizing antibody in the sera of persons infected with DENV more than four decades earlier (Halstead, 1974; Papaevangelou and Halstead, 1977; Okuno et al., 1983). Sabin (1952) suggested that short-lived heterotypic immunity may exist resulting in milder illness up to 9 months following primary infection. Animal studies in nonhuman primates have also found little evidence of long-lived cross protection between

heterologous DENV (Halstead et al., 1973a; Whitehead et al., 1970; Scherer et al., 1972).

The kinetics of antibody production following primary and secondary DENV infections are quite different (Russell et al., 1967, 1969; Innis et al., 1989). In primary DENV infection, IgM antibodies appear first, generally between the 4th and the 7th day of illness, peak within 2 weeks, and then decay to undetectable levels within 6 months after infection (Innis et al., 1989; Vaughn et al., 1997). In contrast to the high levels of IgM antibody that are present early after primary infection, only low levels of IgG antibodies against DENV are detected during the acute phase of illness. IgM antibody levels greatly exceed IgG levels for 2–4 weeks following primary infection. Both IgG and IgM antibodies have the ability to neutralize virus and to inhibit the hemagglutination (HI) of gander red blood cells but only IgG antibody has complement fixation (CF) activity. Secondary DENV infection produces an anamnestic response as the result of common antigens shared by DENV. Characteristic of an anamnestic response, IgG is the primary antibody produced; IgM antibody is markedly reduced. High levels of IgG antibody are detected early and rise dramatically in contrast to IgM antibody levels, which are elevated only modestly. Secondary infection is associated with high neutralizing, HI, and CF antibody titers that have broad cross-reactivity and are comprised almost entirely of IgG. For this reason, the hemagglutination-inhibition titer has been used to classifying DENV infections as primary or secondary, and a patient with an HI titer of $\geq$1:2560 in an acute specimen is defined as having a secondary flavivirus infection (Anonymous, 1997).

Different methods of detecting dengue antibody vary in their specificity and their sensitivity over time. HI antibodies are usually cross-reactive, even in primary DENV infections, for months to years (Whitehead et al., 1970; Scherer et al., 1978; Scott et al., 1976; Vaughn et al., 1997). The HI serotype specificity response is variable over years; becoming monotypic in some patients, remaining heterotypic in some patients, and disappearing altogether in others (Hammon et al., 1966; Scott et al., 1976; Papaevangelou and Halstead, 1977). For this reason, the absence of HI antibody is an unreliable criterion for defining a dengue-naive individual. Of the methods used to measure dengue antibody, the neutralizing antibody test exhibits the greatest dengue serotype specificity (Scherer et al., 1978, Russell et al., 1967). Neutralizing antibody titers to homologous virus following primary infection are usually below 1:1000 and cross-reactions tend to be low titered. In addition, neutralizing antibody titer to homologous virus can increase progressively over a period of at least 6 months. Neutralizing antibody produced following secondary infection is broadly cross-reactive and can remain so for years (Russell et al., 1967; Papaevangelou and Halstead, 1977). The specificity may narrow over time but this is variable among individuals (Innis, 1997). Despite the induction of heterologous antibody with secondary infection, DENV have been shown to demonstrate the phenomenon of original antigenic sin (Halstead et al., 1983). During secondary DENV infection, Halstead demonstrated that neutralizing antibody responses were detected against both homotypic and heterotypic viruses but the highest titers were detected to the original infecting DENV serotype. In general, the presence of neutralizing antibody to more than one DENV serotype in late convalescent serum indicates a history of multiple prior DENV infections, or at least prior flavivirus infection, and only the absence of neutralizing antibody to all four DENV serotypes is evidence that no previous DENV infection has occurred.

Inhibition of virus attachment and virus-mediated membrane fusion are thought to be the mechanisms of DENV neutralization (Gollins and Porterfield, 1986; Roehrig et al., 1998). The DENV E protein is considered to be the major antigen participating in antibody-mediated neutralization of virus. In primary DENV infection in humans, the E protein elicits the first immune responses and the ones with the longest duration (Churdboonchart et al., 1991). Monoclonal antibody (MAb) studies have corroborated the E protein as a target for neutralizing antibodies (He et al., 1995; Kaufman et al., 1987, 1989). MAb against DENV-2 E and prM proteins protected mice against challenge with both heterologous and homologous DENV. Neutralization activity correlated well with protective ability for E monoclonal antibodies. Although prM monoclonal antibodies were also protective, their protective ability did not correlate as well with neutralizing activity. Antibodies to the NS proteins can also be detected following primary and secondary DENV infection. NS1, NS3, and NS5 are detected following primary infection and antibodies to C, prM, NS1, NS3, NS4A, and NS5 can be detected in the convalescent sera of patients with secondary DENV infection (Kuno et al., 1990; Churdboonchart et al., 1991; Huang et al., 1999). Although NS1 antibodies do not have neutralizing activity, NS1 MAbs were able to partially protect passively immunized mice from intracerebral challenge with DENV-2 virus (Henchal et al., 1988). In these experiments solid protection equivalent to that conferred by polyclonal neutralizing antibody was achieved with one pair of DENV-2 NS1 MAbs given as a combination. NS1 is a soluble, complement-fixing antigen that is expressed on the surface of

DENV-infected cells. Studies have suggested that NS1 antibody may be protective by promoting complement-mediated lysis of infected cells (Schlesinger et al., 1986, 1987; Falgout et al., 1990). What role, if any, antibody to the other NS proteins plays in the immune response to DENV has not been clarified.

Cell-Mediated Immunity

Although virus-specific cytotoxic T lymphocytes (CTL) have been reported to be important in the recovery from certain viral infections such as influenza (Wells et al., 1981; Yap et al., 1978), the role of CTL in recovery from DENV infection is less defined and has not been studied to the same extent as the antibody response. Both $CD4^+$ $CD8^-$ and $CD4^-$ $CD8^+$ DENV-reactive memory T cells are generated after primary DENV infection. In a study of volunteers who developed DF in response to infection with a candidate live dengue vaccine, activation of $CD4^+$ T cells occurred during the presence of viremia and activation of $CD8^+$ T cells followed $CD4^+$ T cell activation (Kurane et al., 1995). Activation of T cells preceded the disappearance of viremia and T cell activation gradually subsided once viremia ended, suggesting that T cell activation contributed to the control of DENV infection. The presence of DENV-specific $CD4^+$ $CD8^-$ T lymphocytes has been detected in peripheral blood mononuclear cells (PBMC) collected from persons naturally infected with DENV or immunized with live attenuated candidate dengue vaccines (Kurane et al., 1989a, 1989b; Dharakul et al., 1994). The proliferative responses of $CD4^+$ $CD8^-$ T lymphocytes in bulk culture after primary infection are both serotype-specific and serotype-cross-reactive memory responses, however when examined at the clonal level, the responses are mainly dengue serotype-cross-reactive (Kurane et al., 1991a). DENV-specific $CD4^+$ T lymphocyte clones were established from a volunteer who had been immunized with yellow fever vaccine 2 years prior to being infected with DENV-3.

Although $CD4^+$ $CD8^-$ T lymphocytes from this volunteer were primarily serotype-specific in bulk culture, at the clonal level there were serotype-cross-reactive and flavivirus-cross-reactive responses. DENV-specific $CD4^+$ T cell clones established from other DENV recipients also demonstrated a heterogenous response (Kurane and Ennis, 1994b), indicating that both serotype-specific and serotype-cross-reactive $CD4^+$ memory CTL are present in most individuals after primary DENV infection. Activated $CD4^+$ $CD8^-$ T lymphocytes produce a predominantly Th-1 response consisting of high titers of IFN-γ and IL-2, and are effective at lysing DENV-infected cells expressing the MHC class II phenotype (Kurane et al., 1990). $CD4^+$ T cells can efficiently lyse both target cells expressing DENV antigen as well as uninfected bystander cells, perhaps contributing to the hepatocyte damage observed during acute dengue illness (Gagnon et al., 1999). In addition, the expression of IFN-γ by activated $CD4^+$ $CD8^-$ T lymphocytes may also contribute to the pathogenesis of DHF/DSS (see below).

Although cytolytic responses to DENV have been detected in $CD4^+$ T cell populations, $CD8^+$ cytotoxic T cells are thought to contribute the majority of the cytolytic activity (Mathew et al., 1996). Following primary DENV infection, $CD8^+$ T lymphocytes exhibit significant serotype-specific proliferation with a variable level of serotype-cross-reactivity (Gwinn et al., 2003; Mathew et al., 1996; Dharakul et al., 1994; Bukowski et al., 1989). Although proliferative responses are generated to one or more heterologous DENV, the most significant proliferative and cytolytic responses are nearly always directed toward the homologous serotype. The cross-reactivity among DENV memory T cells is contributed to by the relatively high degree of sequence homology between the viruses. Studies of T cell clones from DENV-infected individuals have identified clones that not only recognize DENV, but also recognize other flaviviruses such as YFV, West Nile virus, Kunjin virus, and Japanese encephalitis virus (JEV) (Spaulding et al., 1999; Mathew et al., 1998; Kurane et al., 1991a). The NS3 protein is highly conserved across the flaviviruses and NS3 has been identified as an important target of $CD4^+$ and $CD8^+$ T cells (Zivna et al., 2002; Spaulding et al., 1999; Mathew et al., 1998). NS3 was found to be the most frequently recognized viral antigen by the T cells of Vietnamese adults experiencing a secondary DENV infection (Simmons et al., 2005). These studies have demonstrated that most DENV NS3-specific T cells are serotype-cross-reactive. The E protein, capsid protein, and NS proteins other than NS3 have also been identified as targets of $CD4^+$ and $CD8^+$ T cells from DENV-infected individuals (Bukowski et al., 1989; Simmons et al., 2005; Mathew et al., 1996; Green et al., 1997; Livingston et al., 1994; Gagnon et al., 1996).

T cell activation appears to contribute to the resolution of DENV infection and IFN-γ receptor-dependent immune responses have been demonstrated to mediate early DENV clearance in a mouse model, although IFNα/β receptor pathways were more crucial in limiting initial DENV replication (Shresta et al., 2004b). Although activation of T cells may contribute to the control of DENV infection it may also contribute to the immunopathogenesis of DHF/DSS. Markers of

T cell activation such as sIL-2R, sCD4, sCD8, IL-2, CD69, and IFN-γ have been measured during acute DENV infection with wild-type or vaccine candidate viruses (Kurane et al., 1991b, 1995; Green et al., 1999a). A significant increase in the percentage of $CD8^+$ and NK cells expressing CD69 during the febrile period of illness was found in children with DHF compared to those with DF or other nondengue viral illnesses. Evidence of marked T cell activation, including higher levels of sIL2-R, sCD4, IL-2, and IFN-γ, were found in the sera of Thai children with DF or DHF compared with sera from healthy Thai children. In addition, higher levels of sCD8 were found in the sera of DHF patients, but not patients with DF, suggesting greater T cell activation in DHF. Hospitalized children suffering from acute secondary DENV infection had higher circulating numbers of NS3-specific $CD8^+$ T cells than did normal DENV-immune individuals. During acute infection, these $CD8^+$ T cells exhibited a huge proliferative response balanced by massive apoptosis (Mongkolsapaya et al., 2003). The clones that proliferated demonstrated a relatively lower affinity for the DENV causing the secondary infection and a higher affinity for serotypes that were presumed to be from a prior DENV infection. These $CD8^+$ T cells may be less effective at clearing DENV encountered in secondary infection. In addition, patients infected with DENV-1 or DENV-4 mounted IFN-γ responses to DENV-2 peptides that were equivalent in strength to those of patients infected with DENV-2. This suggests that, in contrast to primary infection, serotype-cross-reactive rather than serotype-specific T cells dominate the acute response during secondary infection. The role of T cell activation in producing the clinical signs and symptoms of DHF/DSS is discussed below and schematized in Fig. 19.2.

EPIDEMIOLOGY

Significance as Public Health Problem

More than 2.5 billion persons in 100 countries are at risk for dengue by virtue of living in areas with the

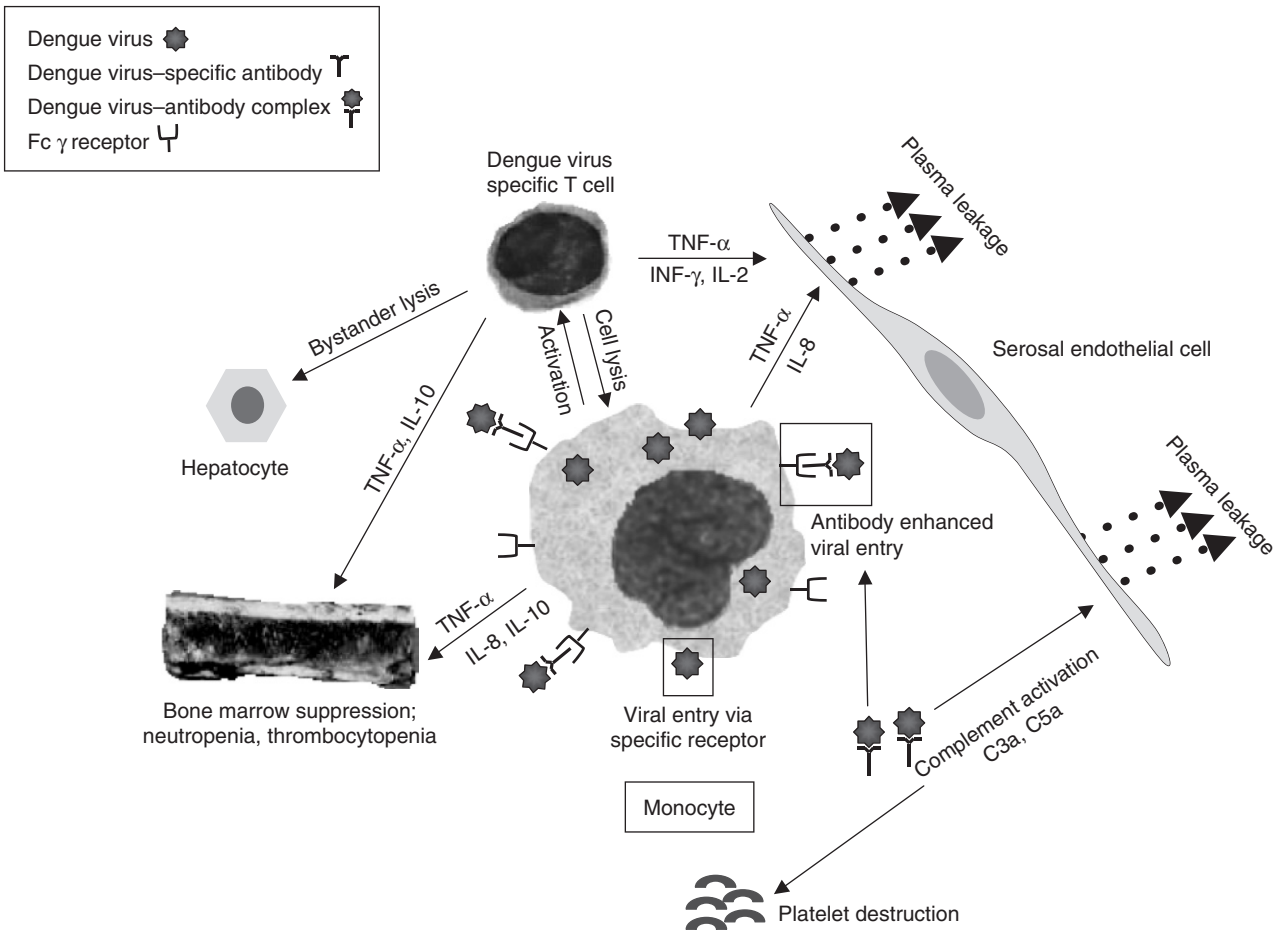

FIGURE 19.2 The immunopathogenesis of dengue hemorrhagic fever (DHF). See text for explanation.

necessary vector mosquitoes (primarily *Aedes agypti*, *A. albopictus*, and *A. polynesiensis*) and a tropical or subtropical climate (Fig. 19.3). It has been estimated that DENV infects 100 million people each year. Most infections are subclinical or result in self-limited febrile illness though up to 500,000 cases of DHF occur each year and more than 60,000 deaths due to dengue have been reported to date (Thomas et al., 2003; Gubler, 1998). DHF, a severe form of DENV infection, has been widely recognized since DENV infection was associated with Philippine hemorrhagic fever and Thai hemorrhagic fever in the 1950s (Hammon et al., 1960; Halstead et al., 1963). However, the literature documents dengue outbreaks with hemorrhagic manifestations including epistaxis, hematemesis, and gingival bleeding occurring as early as the late 1890s in North Queensland (Hare, 1898). DHF was reported sporadically from the Americas (Honduras, Jamaica, Puerto Rico, Curacao) in the late 1960s and 1970s (Anonymous, 1990). The Cuban DHF outbreak in 1981 marked the start of severe dengue disease in the Americas (Kouri et al., 1989).

Dengue epidemics can be intense both in terms of clinical attack rates when large numbers of nonimmune individuals are exposed (e.g., 20,000 cases among US forces on Saipan during World War II over a 3-month period) and morbidity and mortality (e.g., 344,203 reported cases, 10,312 severe cases, and 158 deaths in the Cuba outbreak of 1981 (Pinheiro and Corber, 1997) or 711,919 cases of DF and 2229 cases of DHF in Brazil in 2002). While dramatic outbreaks have occurred in Central and South America, India, Southeast Asia, and the Pacific Islands, there have been few reports of dengue for Africa (Thomas et al., 2003). In fact, no dengue cases were reported to the WHO between 1998 and 2001 (Anonymous, 2001) though there are rare reports of clinical disease (Durand et al., 2000). This may be due to limited circulation of DENV, under reporting (limited surveillance and laboratory capabilities) or reduced virus virulence in genetically African populations (Halstead et al., 2001). Many of the reported dengue outbreaks in Africa are among foreigners (Thomas et al., 2003).

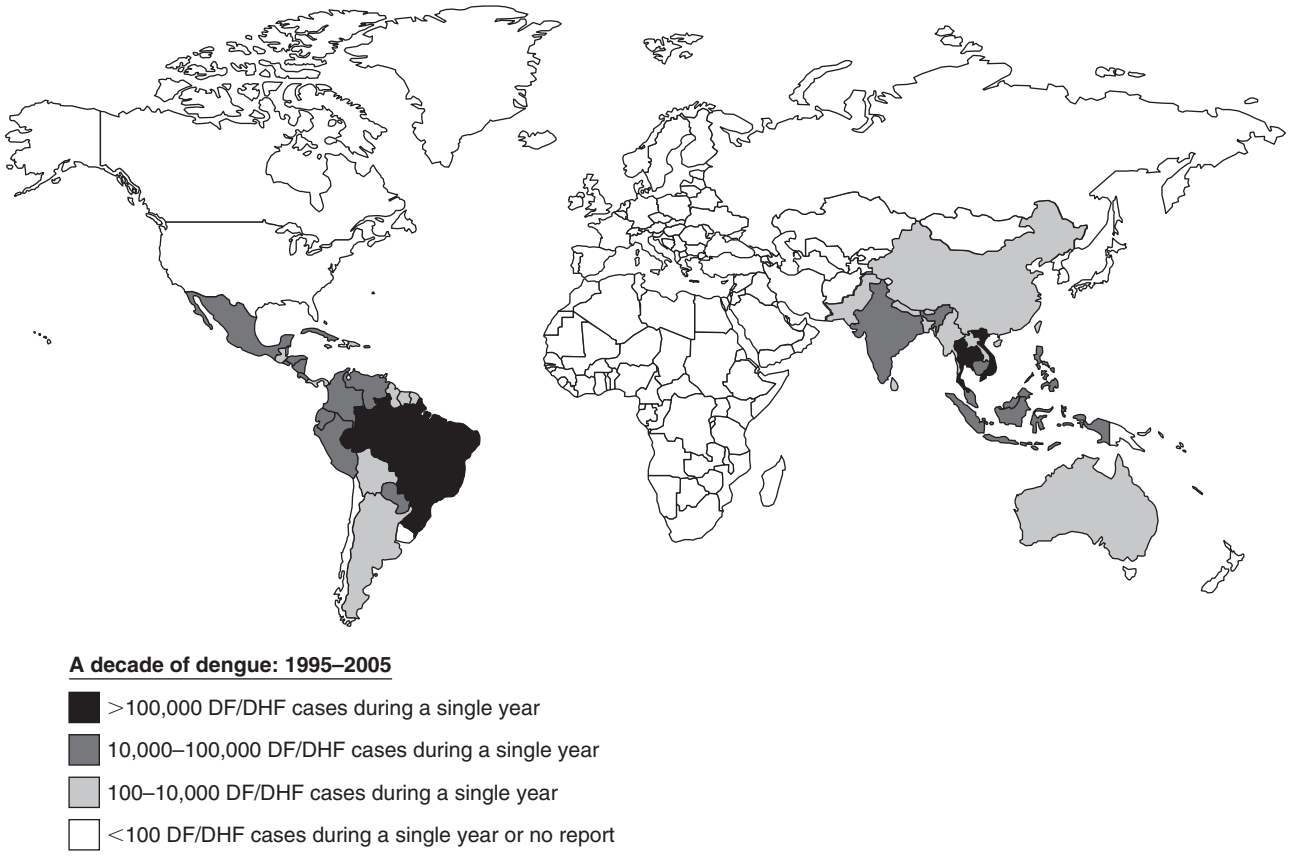

FIGURE 19.3 Countries reporting dengue fever (DF) and dengue hemorrhagic fever (DHF) from 1995 through 2005. Source of information: WHO DengueNet (www.who.int/csr/disease/dengue/denguenet) and PAHO (www.paho.org/english/ad/dpc/cd/dengue.htm).

When dengue first enters a community it affects all age groups. In hyperendemic areas where all four DENV serotypes circulate, adults become immune and dengue becomes a disease of children. In the past, dengue was considered to be an urban disease where large numbers of susceptibles could sustain transmission. However, with modern intensity and rapidity of transportation, incidence rates in more rural areas equal those in urban centers (Cummings et al., 2004). A person infected with DENV can travel to any population center worldwide with dengue vectors during the asymptomatic incubation period.

Potential as Biothreat Agent

Viruses causing viral hemorrhagic fevers (VHFs) have been classified by both the CDC and NIAID as Category A priority pathogens. Although DENV can cause hemorrhagic fever, it has relatively low potential for use as a biothreat agent due to its very low incidence of person-to-person spread and inability to be transmitted by the aerosol route. Initially the NIAID listed DENV as a Category A pathogen, but recommended in its 2003 Research Agenda for Category B and C Priority Pathogens that DENV be transferred from Category A to Category C (http://biodefense.niaid.nih.gov). However, according to the 2006 Progress Report of the NIAID Biodefense Research Agenda for Category A Agents, DENV is still included as a Category A pathogen. Currently, the CDC does not include DENV on the Bioterrorism Agents/Diseases list (http://www.bt.cdc.gov/agent/agentlist-category.asp). In its 2002 Consensus Statement, the Working Group on Civilian Biodefense excluded DENV from the list of hemorrhagic fever viruses that pose serious risk as biological weapons because it is not transmissible by small-particle aerosol, and primary DENV infection rarely causes hemorrhagic fever (Borio et al., 2002).

CLINICAL DISEASE

Infection with DENV may result in a spectrum of outcomes ranging from clinically inapparent infection to life-threatening hemorrhagic fever accompanied by vascular compromise and shock (Guzman et al., 2000; Anonymous, 1997; Burke et al., 1988; Endy et al., 2002). The WHO has provided case definitions for the major clinical syndromes caused by DENV: classic DF, DHF, and dengue shock syndrome (DSS) (Anonymous, 1997). All four serotypes of DENV can cause the full clinical spectrum of illness; it is primarily the degree of vascular leak that differentiate these syndromes.

Classic Dengue Fever

Most symptomatic cases of dengue present as classic DF, the clinic course and presentation of which has been well described in both experimental and natural infection studies (Simmons, 1931; Eram et al., 1979; Siler et al., 1926; Sabin, 1952; Liu et al., 1989; Halstead et al., 1969). The incubation period of dengue can range from 3 to 14 days but is generally 4–7 days. Dengue presents with a sudden onset of fever accompanied by headache; pain in the eyes, muscles, back, and joints; flushing of the face; anorexia; abdominal pain; nausea; occasionally vomiting; and rash. The epithet *break-bone fever* was given to dengue due to the back, limb, and joint pains that can be so severe as to be incapacitating. The fever that accompanies dengue generally does not exceed 40°C and typically has a duration 3–5 days, but may last a week or longer. Clinicians have described a two-peaked fever pattern in some dengue patients: the saddle-backed curve (Simmons, 1931; Siler et al., 1926). In these instances, fever begins with the onset of symptoms and may subside on the 3rd or 4th day only to return 1–3 days later. The saddle-backed fever pattern was noted in 40–85% of patients infected experimentally with a DENV. Rash is a common physical finding in dengue with a reported incidence in some studies of greater than 80%, however it is often evanescent and polymorphic in its appearance (Siler et al., 1926; Sabin, 1952; Halstead et al., 1969, 1970; Liu et al., 1989; Lai et al., 2004). The rash is most commonly seen on the trunk, inside of the arms and thighs, and the plantar and palmar surfaces. It may present as macular, maculopapular, morbilliform, scarlatiniform, or petechial in character. Intense pruritus and desquamation of the rash have been reported. DENV infection tends to present as a milder illness in younger children compared with older children and adults who more typically manifest the symptoms of classic DF described above (Halstead et al., 1969, 1970; Innis, 1995). In young children, DENV infection is often subclinical or a mild undifferentiated febrile illness. Respiratory symptoms, including cough; pharyngeal injection; sore throat; and rhinitis are frequently present in children with primary or secondary DENV infection (Halstead et al., 1969). Hepatomegaly may be present in children, especially in those with the more severe DHF or DSS (Eram et al., 1979; Nimmannitya, 1987; Nimmannitya et al., 1969; Kalayanarooj et al., 1997; Wichmann et al., 2004). Common laboratory

abnormalities reported with DENV infection include leukopenia, thrombocytopenia, and elevation in serum transaminases (Siler et al., 1926; Sabin, 1952; Kuo et al., 1992; Kalayanarooj et al., 1997; Simmons, 1931; Souza et al., 2004). These laboratory abnormalities are transient. Leukopenia is most marked during the febrile period and is thought to be due to bone marrow suppression by the virus (La Russa and Innis, 1995). Full recovery from DF can be expected, however it may be prolonged with many patients complaining of weakness and depression for many weeks following recovery from the acute phase illness.

Dengue Hemorrhagic Fever/Shock Syndrome

DHF is a more severe form of DENV infection that is characterized by fever, thrombocytopenia, hemorrhagic manifestations, and evidence of altered vascular permeability with leakage of intravascular fluid into interstitial spaces (vascular leak syndrome) (Carlos et al., 2005; Nimmannitya, 1987; Kalayanarooj et al., 1997; Gubler, 1998; Hayes et al., 1988). DHF is primarily a disease of children less than 15 years of age in hyperendemic areas (Anonymous, 1997; Eram et al., 1979). The presence of plasma leakage and thrombocytopenia is the critical feature that distinguishes DHF from DF. The hemorrhagic manifestations of DHF include capillary fragility; petechiae, ecchymoses, or purpura; bleeding from the mucosa, gastrointestinal tract, or other site; and hematemesis or melena. Capillary fragility can be documented by a positive tourniquet test. This test is performed by inflating the blood pressure cuff midway between the diastolic and systolic blood pressure for 5 min and then counting the number of petechiae in a defined area. Twenty or more petechiae in a 2.5 cm^2 area is considered a positive test. The WHO has classified DHF into four severity grades (Table 19.1) where Grades III and IV are designated DSS (Anonymous, 1997). The clinical course of DHF resembles classical DF in its initial presentation of abrupt onset of high fever and other nonspecific constitutional signs of a few days duration. Shortly before, during, or after the time of defervescence, the patient's condition suddenly deteriorates with the advent of hemorrhagic manifestations and symptoms of hypovolemia due to plasma leakage. Hepatomegaly may become evident in a high percentage of children, particularly those in Thailand where up to 98% of children diagnosed with DHF were reported to have liver enlargement (Nimmannitya, 1987; Eram et al., 1979; Wichmann et al., 2004). In the study by Nimmannitya, liver enlargement was not necessarily accompanied by elevated transaminases as 74% of pediatric dengue cases in that study had normal ALT levels despite clinical hepatomegaly. However, mild-to-moderate elevations in both AST and ALT have been commonly reported in dengue patients, with more severe enzyme elevations observed in DHF and DSS cases (Nguyen et al., 1997; Souza et al., 2004). Increased vascular permeability allows the loss of plasma into the interstitial spaces. Pleural effusion, especially right-sided, is nearly always present in DHF patients (Nimmannitya, 1987; Pramulijo and Harun, 1991; Venkata Sai et al., 2005; Kalayanarooj et al., 1997). Ascites is also common, with a reported incidence of more than 50% in DHF patients examined by ultrasound (Venkata Sai et al., 2005; Pramulijo and Harun, 1991). Hemoconcentration occurs as a result of plasma leakage and an increase in the hematocrit of $\geq$20% over the course of illness or recovery is a diagnostic criterion for DHF. Hypovolemic shock ensues with sufficient leakage of plasma into the interstitial spaces. In mild cases of DHF (Grades I and II), the degree of plasma leakage is such that there is little effect on the blood pressure. In Grades III and IV, the shock is profound; the patient is often restless and irritable with cool, clammy extremities and a rapid, weak pulse. The course of shock is short but life-threatening; patients usually succumb or recover within 24 h of the onset of shock. The tourniquet test may be negative in patients who present in frank shock but will generally turn positive once the patient is hemodynamically stable (Innis, 1995).

Fulminant liver failure and neurological manifestations have been described in patients with dengue (Subramanian et al., 2005; Lawn et al., 2003; Nimmannitya et al., 1987; Patey et al., 1993; Solomon et al., 2000). There have been case reports of children and adults with confirmed DENV infection whose clinical presentation included fever, jaundice, altered sensorium, and liver transaminase levels in the thousands. Histological examination of the liver has shown marked steatosis, hepatitis with necrosis, and Councilman bodies in some of these cases. Reye's syndrome associated with dengue has also been reported (Kho et al., 1981; Alvarez and Ramirez Ronda, 1985). Encephalopathy, convulsions, meningismus, coma, and transverse myelitis have been reported neurological complications of DENV infection, although they are infrequent in occurrence and difficult to distinguish from co-morbidities that include DENV infection (Solomon et al., 2000).

Early diagnosis of dengue can be difficult as the symptom complex produced by DENV infection is similar to that of many other infectious diseases. In addition, the diagnosis of dengue can be definitively proven only by recovery of the virus or viral antigen

TABLE 19.1 Dengue hemorrhagic fever case definition adapted from WHO (1)

	Platelet count	Hemorrhagic manifestations	Plasma leakage[1]	Circulatory compromise
Dengue fever	Variable	Variable, includes petechiae, epistaxis	Absent	No
Dengue hemorrhagic fever				
Grade 1	< 100,000/mm^3	Positive tourniquet test and/or easy bruising	Present	No
Grade II	< 100,000/mm^3	Spontaneous bleeding in addition to manifestations of grade I	Present	No
Dengue shock syndrome				
Grade III	< 100,000/mm^3	May be hemorrhage	Present	Rapid, weak pulse and narrow pulse pressure or hypotension, with the presence of cold, clammy skin and restlessness
Grade IV	< 100,000/mm^3	May be hemorrhage	Present	Profound shock with undetectable blood pressure

[1]Objective evidence of plasma leakage includes fluctuation in the hematocrit ≥ 20% during the course of illness or clinical signs such as pleural effusion, ascites, or hypoproteinemia.

from blood or tissue of a patient, or by serological confirmation. The combination of a positive tourniquet test, depressed total white cell count, depressed absolute neutrophil count, and elevated AST level were found to be predictive in discerning DF from other febrile illnesses in children (Kalayanarooj et al., 1997). Even when dengue is suspected, it is difficult to predict which patients will deteriorate to DHF/DSS. Frequency of abdominal pain, restlessness, epistaxis, thrombocytopenia, and increased hematocrit have been found to be higher in those children hospitalized with DHF compared with those hospitalized with DF (Carlos et al., 2005; Eram et al., 1979; Hayes et al., 1988; Cohen and Halstead, 1966). Individual risk factors that may predispose to severe disease include underlying chronic disease, age, and race (Bravo et al., 1987; Guzman et al., 2002).

TREATMENT

Typical DF is a self-limited illness that can be managed at home. However, DF is often managed in hospital as prior to defervescence, DF and DHF are indistinguishable and the onset of shock with DHF can be rapid. If managed at home, patients or their parents should be instructed on the early signs and symptoms of plasma leakage, and have a means of quick transport to the hospital. Antipyretics may be useful to reduce the risk of febrile convulsions in young children. Acetaminophen, dosed according to age, is preferred over salicylates which may increase the risk of bleeding complications (Anonymous, 1997).

The successful management of DHF relies upon a high index of suspicion to promptly recognize the onset of plasma leakage followed by frequent assessment of intravascular volume status with monitoring for hemorrhagic complications. A rise in hematocrit with concomitant drop in platelet count may precede the onset of clinically apparent shock. A treatment algorithm developed at the Bangkok Children's Hospital (now the Queen Sirikit Institute of Child Health) outlines the importance of and approach to careful fluid management (Vaughn and Green, 2000). Careful and rapid replacement of plasma losses can reverse or prevent shock and prevent complications due to shock and electrolyte imbalances such as disseminated intravascular coagulation. Over hydration must be avoided. Colloid solutions (e.g., Dextran 70) appear to restore cardiac index and blood pressure and normalize hematocrit more rapidly than crystalloids (e.g., Ringer's lactate) (Dung et al., 1999; Soni et al., 2001; Khongphatthanayothin et al., 2003). Drug interventions have yet to be shown to improve outcomes over careful fluid management (Tassniyom et al., 1993; Leyssen et al., 2000; Atrasheuskaya et al., 2003).

A lack of improvement may indicate inadequate fluid resuscitation, internal bleeding, or iatrogenic

fluid overload. Fresh whole-blood transfusions may be required or fluid restriction and treatment with furosemide. Fresh frozen plasma or platelets may also be considered in cases where disseminated intravascular coagulation (DIC) or other coagulaopathies complicate the clinical course (Anonymous, 1997; Mairuhu et al., 2003). The Queen Sirikit Institute of Child Health has seen a steady decline in case fatality rates, from 10% in 1970 to 2% in 1984 to 0.2% in 1990 (Nimmannitya, 1997). Mortality is usually linked to delayed provision of supportive treatment and/or premorbid chronic illness (Anonymous, 1997).

PATHOGENESIS

DHF is defined by symptoms of DF accompanied by vascular leakage and evidence of capillary fragility and bleeding. Fluid extravasation secondary to vascular leak may become so severe as to result in hemodynamic compromise and shock (DSS). Plasma leakage into the serous spaces is evident in most cases of DHF. As described previously, the pleural spaces are those most commonly involved, but the pericardial and peritoneal effusions are not uncommon. In addition, serous membranes of involved spaces are notably edematous. Microscopic studies of autopsy specimens show pericapillary edema in soft tissues and swelling of capillary endothelial cells (EC). In general, the tissue damage observed is not very severe compared to the severity of illness (Bhamarapravati et al., 1967).

The immunopathologic mechanisms driving these clinical manifestations are complex and not entirely understood. Components of both the humoral and cellular immune systems play a role in precipitating events that result in severe disease (Green and Rothman, 2006). Antibody-dependent enhancement (ADE) and cross-reactive T cell responses are thought to be important immunologic mediators of DHF. Secondary DENV infection with a serotype different from that causing primary infection has been identified as a major epidemiologic risk factor for DHF (Sangkawibha et al., 1984; Burke et al., 1988; Halstead and Yamarat, 1965). ADE of infection is produced upon secondary DENV infection when heterologous antibody present in the host binds to the infecting DENV but is not able to neutralize the virus. These DENV–antibody complexes then attach to the Fcγ receptors on circulating monocytes aiding entry of the DENV into this target cell. Halstead demonstrated that peripheral blood leukocytes (PBL) from both nonimmune rhesus monkeys and humans were nonpermissive for DENV infection, in contrast to PBLs from immune rhesus monkeys and humans which supported the replication of DENV to high titer (Halstead et al., 1976; Marchette et al., 1976). He later demonstrated nonpermissive cultured PBLs could become permissive to DENV infection when nonneutralizing antibody was added to the culture medium (Halstead and O'Rourke, 1977a, 1977b). The ability of passively transferred DENV antibody to enhance DENV infection has been demonstrated in vivo in rhesus macaques, substantiating the theory of ADE. Titers of DENV were significantly higher in nonimmune rhesus monkeys given dengue-immune human cord blood serum than in those monkeys that received normal cord blood serum (Halstead, 1979). In addition, a role for ADE in the development of severe dengue disease in endemic areas is suggested by the timing of DHF in young infants 6–12 months of age when maternally derived DENV antibody titers decline below protective levels (Kliks et al., 1988; Pengsaa et al., 2006). It is during this critical time period that infants are at increased risk for severe disease following DENV infection despite the fact that they have never been previously infected with DENV and lack DENV-specific cellular immunity. Eventually with the complete degradation of maternal antibody, infants emerge from this period of enhanced susceptibility to DHF.

Investigators have found a correlation between the level of viremia and the severity of dengue disease, as higher levels of viremia were found in DHF/DSS patients than in those with DF (Libraty et al., 2002; Murgue et al., 2000; Vaughn et al., 2000). ADE may provide a mechanism for increased viral entry into monocytes leading to higher levels of viral replication in these patients. As discussed previously, during secondary DENV infection activated T cells produce IFN-γ. It has been reported that IFN-γ increases the number of Fcγ receptors on human monocytes (Perussia et al., 1983; Guyre et al., 1983). DENV infection of U937 cells, a human monocytic cell line, can be augmented by IFN-γ in the presence of anti-DENV antibody (Kontny et al., 1988). In addition, the percentage of DENV-infected cells appears to correlate with the number of Fcγ receptors on the U937 cells. Elevated levels of IFN-γ have been documented during the acute phase of DHF/DSS and in one study, peak IFN-γ levels occurred within 2 days of peak viremia (Nguyen et al., 2004; Libraty et al., 2002). Induction of Fcγ receptors on monocytes could potentially lead to increased viral entry and replication within monocytes, leading to higher levels of viremia and potentially, more severe disease.

Increased vascular permeability with resultant plasma leakage into the serous cavities is the clinical hallmark of DHF/DSS. The lack of structural damage to EC demonstrated in autopsy studies and the

short-lived nature of the vascular leak syndrome implicate serum inflammatory mediators as inducers of altered vascular permeability in serous tissues (Bhamarapravati, 1961; Bhamarapravati et al., 1967). A number of different cytokines as well as anaphylatoxins have been identified as putative effectors of the vascular leak syndrome. Complement activation has also been implicated in the pathogenesis of DHF/DSS (Russell et al., 1969; Churdboonchart et al., 1983; Suvatte et al., 1973). Depressed levels of complement; particularly C3, C4, and C5, have been documented in patients with DHF/DSS. The nadir of C3 and C4 coincided with, or occurred within 24h of, the onset of shock. The nonstructural protein NS1 has been identified as a possible precipitator of complement activation in patients with DHF (Avirutnan et al., 2006). The authors demonstrated that NS1 purified from DEN-infected cells activated complement and that significantly higher levels of NS1 were found in patients with DHF compared with DF. In addition, serum and pleural fluid levels of the terminal complement complex SC5b-9 were highly correlated with disease severity in this study. The role of complement activation in the vascular leak syndrome of dengue is further evidenced by the finding of elevated levels of C3a and C5a (anaphylatoxins) in DSS patients, which occurred at or around the time of defervescence (Bokisch et al., 1973; Malasit, 1987). Elevated plasma levels of C3a correlated with severity of disease in these patients. Both C3a and C5a cause the release of histamine, increase vascular permeability, and produce vasodilation providing a mechanism for the extravasation of plasma into the serous cavities.

It is becoming evident that an excessive cellular immune response to DENV infection, driven by activated, cross-reactive memory T lymphocytes, is critical to the immunopathology associated with DHF/DSS. Markers of T cell activation such as CD69, IFN-γ, interleukin-2 (IL-2), soluble interleukin -2 receptor (sIL-2R), soluble CD4 (sCD4), and soluble CD8 (sCD8) have been detected in the blood of patients with DHF/DSS (Kurane et al., 1991b; Green et al., 1999a), suggesting that such activation may play a role in the pathogenesis of severe dengue disease. In addition, elevated levels of tumor necrosis factor alpha (TNF-α), soluble TNF-α (sTNF-α), IL-2, interleukin 6 (IL-6), interleukin-8 (IL-8), and interleukin-10 (IL-10) measured in the blood of patients with DHF/DSS have correlated with severity of disease (Kurane and Ennis, 1994a; Hober et al., 1993, 1996; Bethell et al., 1998; Green et al., 1999b, 1999c; Raghupathy et al., 1998; Juffrie et al., 2000; Kuno and Bailey, 1994; Nguyen et al., 2004). Significantly elevated levels of TNF-α and/or sTNFR have been detected in the blood of patients DHF/DSS compared to both DF patients and normal controls (Hober et al., 1993, 1996, 1998; Gagnon et al., 2002; Nguyen et al., 2004; Iyngkaran et al., 1995). TNF-α is known to activate cultured EC and increase vascular permeability (Pober and Cotran, 1990). In in vitro studies, TNF-α has been demonstrated to increase the permeability of DENV-infected human EC, perhaps by inducing a morphological change in the cells (Dewi et al., 2004). Additionally, serum collected from four dengue patients during the acute phase of their illness induced the activation of human EC, with sera taken on the day of defervescence having the strongest activating effect (Cardier et al., 2005). TNF-α levels were markedly elevated in these samples and pretreatment of the dengue sera with anti-TNF-α antibody inhibited the EC activating effect, suggesting that TNF-α was critical for activation. Additionally, TNF-α may play a role in the hemostatic defects associated with DHF/DSS. Elevated TNF-α concentrations were significantly more common in the plasma of DF patients presenting with hemorrhagic manifestations than in those patients without hemorrhagic manifestations (Azeredo et al., 2001). Individuals with a TNF-α polymorphism that is associated with higher levels of TNF-α were 25 times more likely to develop DHF than those individuals without the polymorphism (Fernandez-Mestre et al., 2004).

IL-8 has also been implicated as a mediator of increased vascular permeability in DHF/DSS patients. It is secreted by a variety of cells including macrophages, monocytes, EC, and neutrophils. IL-8 is known to promote neutrophil adherence to vascular endothelium as well as to cause morphological changes to the EC that directly affects the permeability of the EC (Talavera et al., 2004). DENV infection of EC and monocytes in vitro induces the production of IL-8 and significantly higher levels of IL-8 have been found in DHF/DSS patients (Raghupathy et al., 1998; Juffrie et al., 2000; Bosch et al., 2002; Huang et al., 2000c). In addition, elevated levels of IL-8 and RANTES were detected in the pleural fluid of DHF/DSS patients (Avirutnan et al., 1998).

The underlying mechanisms responsible for the bleeding manifestations in DHF are not well understood. Postmortem studies of DHF/DSS cases have demonstrated the presence of hemorrhage and fibrin thrombi in the various tissues, suggesting the occurrence of DIC, at least in the most severe cases (Fresh et al., 1969; Srichaikul et al., 1975). Disturbances of coagulation and fibrinolysis have been demonstrated in all grades of DHF, with some correlation between the magnitude of derangement and the severity of disease (Srichaikul et al., 1977; Bhamarapravati, 1989; Isarangkura et al., 1987; Huang et al., 2001; Krishnamurti et al., 2001; Carlos et al., 2005). The

degree of DIC observed in most cases of DHF is not severe and is not thought to be the major cause of bleeding and shock in these patients (Srichaikul et al., 1977; Mitrakul et al., 1973). The most frequent laboratory findings of coagulopathy reported in DHF are markers of coagulation activation and include an elevated partial thromboplastin time (PTT), elevated thrombin time (TT), decreased fibrinogen level, and decreased platelet count. When compared to DIC induced by bacterial sepsis, fibrinogen is only moderately depleted and fibrin degradation products are not as elevated in DHF (Suvatte et al., 1973). Activation of the coagulation system occurs during the acute febrile phase of illness and is generally more pronounced than activation of the fibrinolytic system (Van Gorp et al., 2002; Srichaikul et al., 1977; Avila-Aguero et al., 2004). It is thought to occur primarily by the stimulation of the intrinsic pathway as the PTT is abnormal in nearly all cases of coagulopathy and the prothrombin time (PT) is often normal. Tissue factor, a critical procoagulant protein responsible for initiating the coagulation cascade, is synthesized predominantly by monocytes and EC. Levels of tissue factor and plasminogen activator inhibitor type 1 (PAI-1), a major inhibitor of fibrinolysis, were shown to be elevated in children admitted to hospital with DSS (Wills et al., 2002). Elevated levels of these procoagulant factors in the blood of DSS patients suggests that factors produced by activated monocytes, EC, or platelets may be responsible for initiation of the coagulation system. A variety of cytokines, including IL-6, have been described as activators of the coagulation system (van der Poll et al., 2001; Huang et al., 2003b) and may contribute to the coagulopathy observed in DHF. Elevated levels of IL-6 have been documented in the blood of patients with DHF/DSS (Kuno and Bailey, 1994; Nguyen et al., 2004; Juffrie et al., 2001; Avila-Aguero et al., 2004; Huang et al., 2000c, 2003b) and may be associated with the hemostatic defects observed in severe dengue. DENV-infected EC produce IL-6 and tPA, a mediator of fibrinolysis and increased levels of IL-6 were shown to correlate with elevated levels of tissue plasminogen activator (tPA) in the blood of DHF/DSS patients (Huang et al., 2003b). In addition, anti-IL-6-antibody inhibited the production of tPA by cultured EC suggesting that IL-6 can regulate DENV-induced tPA production by EC. TNF-α may indirectly influence coagulation activation by its effect on IL-6 and may play a direct role in fibrinolysis. Suharti et al. (2002) reported that TNF-α levels were significantly associated with d-dimer formation, an activation marker of fibrinolysis, in patients with DSS .

Thrombocytopenia is a hallmark of DHF and is present, to some degree, in all patients with DHF. The etiology of thrombocytopenia in dengue is twofold: increased destruction and decreased production of platelets. Platelet kinetic studies done in DHF patients have demonstrated hepatic sequestration and increased destruction of platelets, possible due to antigen–antibody immune complex formation on the platelet surface (Boonpucknavig et al., 1979; Mitrakul et al., 1977). Aspirates of bone marrow taken from DENV-infected patients early in infection documented a hypocellular marrow with reduced megakaryocytopoiesis (Nelson et al., 1964; Putintseva et al., 1986). Reduced granulocytopoiesis and erythrocytopoiesis in the bone marrow were also evident early in infection, indicating that the cause of the hypocellularity was at the level of a pluripotent hematopoietic stem cell or that DENV was infecting all cells lines. Studies using long-term marrow culture (LTMC) as a surrogate for bone marrow established that DENV-induced suppression of hematopoiesis occurred and was most consistent with altered cytokine production by stromal cells (La Russa and Innis, 1995; Murgue et al., 1997). Bone marrow stromal cells are very permissive for DENV infection and have been demonstrated to produce cytokines including IL-8, macrophage inflammatory protein-1α, and TNF-α, which can induce myelosuppression. Numerous studies have correlated elevated IL-10 levels with the severity of thrombocytopenia in DHF patients (Perez et al., 2004; Libraty et al., 2002; Azeredo et al., 2001). Although the role of IL-10 in causing thrombocytopenia in DHF is not yet known, IL-10 has been demonstrated to reduce the platelet count in normal healthy volunteers, primarily by reducing platelet production (Sosman et al., 2000). In DHF patients, IL-10 levels peaked at or near the time of defervescence and also correlated with the degree of plasma leakage. Because IL-10 is a known inhibitor of proinflammatory cytokines, it is thought that IL-10 may increase in response to elevated levels of INF-γ and TNF-α as a negative feedback mechanism (Green et al., 1999c).

Hepatic enlargement and elevation of liver transaminases are common clinical findings in children with DHF. Histopathological evaluation of liver biopsies has demonstrated a variety of abnormal findings including foci of midzonal hepatocellular necrosis, microvesicular steatosis, and the presence of Councilman bodies (Bhamarapravati et al., 1967; Huerre et al., 2001). Although the type of cell infected by DENV is controversial, DENV antigen has been found in the hepatocytes and Kupffer cells (Jessie et al., 2004; Huerre et al., 2001; Hall et al., 1991; Lucia and Kangwanpong, 1994). Despite the presence of antigen in hepatic cells, it remains unclear whether or not viral replication occurs in the liver and whether

or not DENV is directly hepatotoxic. Although DENV readily infects primary Kupffer cells in culture, viral replication was aborted and the infected Kupffer cells underwent rapid cell death by apoptosis (Marianneau et al., 1999). Libraty et al. (2002) reported that hepatic transaminase elevation was associated with sIL-2R, a marker of immune activation, and not with virus titer. Immune activation may be the primary mechanism of hepatocellular necrosis as $CD4^+$ T cell clones from a DENV-4-infected donor induced the lysis of cognate cells as well as bystander HepG2 cells (Gagnon et al., 1999). It is possible that hepatocyte damage is incurred when DENV-specific CTL are activated by DENV-infected Kupffer cells and then lyse hepatocytes via a bystander effect.

In summary, the immunopathological mechanisms by which DENV causes the clinical features of DHF are intricate and include aberrant humoral and cellular immune responses. Previous DENV infections may predispose to more severe disease by the induction of enhancing antibody and cross-reactive T cells. Upon secondary infection, DENV utilizes enhancing antibodies to gain entry to its primary target cell, the monocyte, leading to higher viral titers in the host. In addition, $CD4^+$ and $CD8^+$ T cells recognizing cross-reactive DENV epitopes become activated and induce the production of proinflammatory cytokines initiating the cytokine cascade. Dysregulation of these cytokines culminates in the clinical features of DHF/DSS; plasma leakage, hemoconcentration, and hemorrhagic manifestations.

VACCINES

History

Blanc and Caminopetros (1929) were the first to publish an approach to dengue vaccine development. They attempted to produce an attenuated living virus that would give rise to low-grade "symptomless" dengue with subsequent immunity. It was thought that DENV in blood could be attenuated by mixing it for 5 min with one-twentieth of its volume of ox bile, while the virus was killed by similar exposure to one-fifteenth of its volume of bile. Twenty-two persons were doubly inoculated, first with the 1:15 bile virus and later with the 1:20 bile virus; and when tested for immunity by challenge with wild-type virus 3 weeks later only two of the individuals developed dengue. It is not known which DENV serotype or serotypes were being used in this work.

Simmons et al. (1931) developed the US military's first dengue vaccine in 1929. These researchers conducted investigations in which 100% of 35 individuals experimentally infected with dengue were later found to be resistant to a second attack 400 days later. This suggested the possibility of durable immunity and a prophylactic vaccine. They benefited from the work of Siler et al. (1926) who confirmed that DENV was transmitted by *Aedes aegypti*, determined the period of infectivity of dengue patients, and determined the extrinsic incubation time for virus replication in *A. aegypti*. Simmons and colleagues prepared a "mosquito" vaccine by grinding 2010 DENV-infected *A. aegypti* mosquitoes in a sterile porcelain mortar with a salt solution and chemically pure phenol and formalin. After the suspension had stood for 48 h, it was transferred to a sterile bottle with the addition of 10 cc of sterile physiologic salt solution to further dilute the preservatives. It stood another 8 days to destroy bacteria and 20 cc of salt solution was added. This solution was slowly centrifuged to eliminate remaining insoluble matter. Before use, the vaccine was examined for bacteria (10 day aerobic and anaerobic cultures), bacterial toxins, and safety tested in rabbits, guinea pigs, and white mice, all of which remained normal. One milliliter doses were given to each of the three authors and then two volunteers. While these injections failed to prevent subsequent infection and disease, some of the volunteers developed only mild cases of dengue. In retrospect, the weakness of their approach was to give two doses of vaccine just 4 days apart and to challenge just 1 week after the second dose. Based on the work of Blanc and Caminopetros, the authors started to pursue a live attenuated vaccine derived by serial passage from mosquito to mosquito.

Both the Japanese and Americans made significant contributions to dengue vaccinology during WWII (Kimura and Hotta, 1944; Sabin, 1952). Sabin (1952) used a dermal neutralization test to show that there were two different DENV serotypes, the Hawaii and New Guinea strains B, C, and D later designated as DENV-1 and DENV-2 respectively. The test was performed by mixing and then incubating convalescent serum with acute serum containing known virus. The mixture was then injected intracutaneously into a human volunteer. The virus was considered neutralized if the subject did not develop local or systemic signs of infection. He confirmed that serotype-specific antibody was protective and observed that heterologous cross protection lasted for at least 2 months. He adapted the Hawaii strain virus by mouse brain passage for use as a vaccine in man. Tests conducted in human subjects showed that the virus became attenuated in humans after the 7th mouse brain passage (Sabin, 1952). Schlesinger et al. (1956) similarly adapted the New Guinea strain in mouse

brain and tested it as a monovalent vaccine or in combination with the attenuated Hawaiian strain and yellow fever 17D. The Sabin DENV-1 mouse brain adapted virus underwent a further seven passages in suckling mouse brain. Fourteen human subjects received this strain, designated MD-1, and were immunized without disease (Wisseman et al., 1963). In 1963 Wisseman and colleagues (Bellanti et al., 1966) conducted a field trial of a mouse brain adapted DENV-1 virus among 1113 adolescent males in Puerto Rico during a DENV-3 epidemic. Among the 561 vaccine recipients, the attack rate of DF was 39% of the rate observed for the placebo control group. Further work in mouse brain derived live virus vaccines were curtailed due to concerns with host cell contaminants and adventitious agents (Wisseman, 1966).

Animal Models

An immense hurdle to understanding the role of the immune system in the control of DENV infection, as well as its contribution to the immunopathology of DHF/DSS, is the lack of an animal model that reliably reproduces human disease. Dengue viruses have only three known natural hosts: humans, various nonhuman primates, and mosquitoes. In rural areas with a low prevalence of human DENV infection, sylvatic transmission of DENV has been documented (Rico-Hesse, 1990; de Silva et al., 1999; Fagbami et al., 1977; Wolfe et al., 2001) and nonhuman primates are thought to be the primary mammalian hosts (Rudnick, 1966). For these reasons, several species of nonhuman primates have been evaluated as animal models for both primary and secondary DENV infection (Halstead et al., 1973b, 1973c; Whitehead et al., 1970; Scherer et al., 1972, 1978; Schiavetta et al., 2003). Rhesus macaques have been the most extensively used nonhuman primate model for dengue. In studies done in the early 1970s, macaques were infected with each of the four DENV serotypes at doses ranging from as low as 8–50 pfu to as high as 50,000 pfu (Halstead et al., 1973b). As in human infection, monocytes were determined to be the cells in the peripheral blood of monkeys that were permissive for DENV infection (Halstead et al., 1977). These studies determined that the onset and duration of viremia in macaques after primary DENV infection was similar to that seen in humans, however peak virus titers were generally lower. In addition, the serological response of macaques was very similar to that described in humans. Despite the confirmation of viremia in the monkeys, they developed few clinical signs of dengue, even after secondary DENV infection. Modest axillary and inguinal lymphadenopathy was reported 4–10 days after infection and some animals developed leukopenia. In studies of heterologous DENV infection in more than 100 macaques, no animal developed a classic DHF/DSS syndrome (Halstead et al., 1973c). However, there was a significant increase in peak viremia titer in secondary DENV-2 infection compared to primary infection. One animal that received DENV-2 challenge 3 months after a primary DENV-4 infection developed some laboratory abnormalities associated with DHF including thrombocytopenia, elevated PT, decrease in complement level, and an early unsustained elevation in hematocrit. Additionally, the tissue distribution of DENV was studied after primary and heterologous secondary infection in these macaques (Marchette et al., 1973). Prior to the period of viremia, virus could be recovered only from the skin at the inoculation site and regional lymph nodes. During the period of viremia, virus was recovered primarily from the skin at the inoculation site and less frequently, from skin at remote sites and axillary and inguinal lymph nodes. Virus was only occasionally recovered from other sites such as the thymus, spleen, lung, and gastrointestinal tract. Interestingly, there was suggestive evidence of a greater amount and wider distribution of virus in the tissues after secondary infection.

Other nonhuman primates that have been demonstrated to support DENV infection include chimpanzees, gibbons, and owl monkeys. Chimpanzees experimentally inoculated with low-passaged clinical isolates of DENV strains 1–4 had the onset of viremia around day 2 postinfection and a duration ranging from 5 to 9 days (Scherer et al., 1978). The mean peak titers in the animals were lower than that generally seen in human infection and none of the animals developed clinical or laboratory evidence of dengue. Secondary challenge with a heterotypic virus was done in a subset of animals, none of which developed any clinical illness. Gibbons infected sequentially with heterologous DENV all became viremic after primary infection (Whitehead et al., 1970). Gibbons were challenged at 6 and 12 weeks after primary infection and low-level viremia was detected in some of the monkeys, primarily in those challenged at 12 weeks. No animal developed illness that was dengue-related after primary or secondary infection. Owl monkeys infected with 20,000 pfu of DENV became viremic but the susceptibility to the different DENV serotypes was inconsistent and the duration of viremia quite short (Schiavetta et al., 2003). Six of the 20 infected owl monkeys developed neutropenia. Overt illness, described as extreme lethargy and markedly decreased appetite, was reported in two of the infected owl monkeys, however one of these monkeys was never viremic.

The prohibitive cost and restricted availability of nonhuman primates has prompted investigators to evaluate other less expensive, more available species as potential animal models for dengue. A number of different inbred, gene knockout, and immunodeficient strains of mice have been used in the evaluation of potential dengue vaccines as well as to study the immune response to wild-type DENV infection. Suckling mice can be infected intracerebrally (i.c.) with nonadapted DENV and although the animals develop fatal neurological symptoms, they do not become viremic and do not develop clinical or laboratory evidence of DHF/DSS (Raut et al., 1996). Passaging of DENV in suckling mouse brain was an early method of developing candidate dengue vaccines, as some viruses would become attenuated with multiple passages (Schlesinger et al., 1956; Hotta, 1969; Sabin, 1952). In addition, the attenuation phenotype could be assessed in this model by the amount of neurological disease that developed after i.c. inoculation. Adult mice, in contrast, do not develop any symptoms of illness when infected peripherally with nonadapted DENV. To produce symptoms of encephalitis in adult mice requires challenge with highly mouse-adapted strains of DENV. DENV-2 antigen could be recovered from young adult mice inoculated intraperitoneally (i.p.) with a nonadapted DENV-2 virus, however no replicating virus was recovered from the sera or organs of infected animals and none of the animals became symptomatic (Boonpucknavig et al., 1981).

Because nonmouse adapted DENV do not replicate well, if at all, in older mice, more sophisticated mouse models have subsequently been developed. Numerous models utilizing severe combined immunodeficient (SCID) mice have been developed to improve DENV replication in the mouse. SCID mice reconstituted with human peripheral blood lymphocytes (PBL) were inoculated with DENV-1 to determine if these mice would support DENV replication (Wu et al., 1995). The infection rate of the hu-PBL-SCID mice was quite low, possibly due to a small number of human target cells in the reconstituted mice, and none of the mice produced antibody. In another experiment, investigators engrafted SCID mice with various hemopoietic cell lines to determine if mice could be infected peripherally with DENV (Lin et al., 1998). Only those SCID mice engrafted with K562 cells, an erythroleukemia cell line, were susceptible to DENV infection. Mice did not become infected with DENV unless the virus was injected directly into the K562 tumor mass. Infected mice exhibited limb weakness and paralysis and died approximately 4 weeks postinfection. High titers of virus were recovered from the brain and peripheral blood of infected mice and the titer of virus appeared to correlate with the extent of neurological symptoms. To improve the peripheral infectivity of DENV in a SCID mouse model, SCID mice were transplanted with a human hepatocarcinoma cell line, HepG2, which is known to support DENV replication (An et al., 1999). Although the HepG2 cells were injected into the spleen of the SCID mice, the majority of cells translocated to the liver soon after injection. At approximately 2 months after transplantation of the HepG2 cells, mice were infected i.p. with DENV-2. Approximately 80% of the infected mice became viremic by day 8 postinfection and developed titers ranging from 3.2 $\log_{10}$ to 6.8 $\log_{10}$ pfu/ml. Virus was detected in the livers of all infected animals with the HepG2 cells appearing to be the major target of infection, as the majority of these cells were destroyed during infection. The infected mice developed anorexia, weight loss, and eventually hindleg paralysis. Significant laboratory abnormalities that developed in infected mice included reduced platelet counts, elevated PTT, and an elevated serum TNF-α that developed with the onset of paralysis. Mice also developed an elevated HCT but this could be attributed to dehydration caused by the paralysis. The HepG2-engrafted SCID mouse model has been used to evaluate the role of DENV-specific $CD8^+$ cells in secondary DENV infection (An et al., 2004). The DENV-2 specific T cell clone 2D42 was isolated from infected BALB/c mice. 2D42 is a $CD8^+$ T cell clone that recognizes epitopes on the NS3 protein of DENV-2. Two days after HepG2-SCID mice were inoculated with 2D42 cells, they were infected with DENV-2 virus. The HepG2-SCID mice inoculated with 2D42 cells prior to infection developed dramatically lower platelet counts and died sooner than HepG2-SCID that did not receive the $CD8^+$ T cells. HepG2-SCID mice that received normal thymocytes prior to DENV-2 infection died earlier than did the mice that received the 2D42 cells indicating that DENV-specific $CD8^+$ may provide both a protective and pathogenic role in secondary DENV infection. Whether this model can be expanded to other DENV and other T cell clones has yet to be determined.

The nonobese diabetic (NOD)/SCID mouse has recently been described as a model for DF (Bente et al., 2005). Mice transplanted with human cord blood hematopoietic progenitor ($CD34^+$) cells developed a full range of dendritic cells, defined as $CD11^+$ or $CD123^+$ lineage negative, HLA-DR^+ cells. Eight or more weeks posttransplant the mice were infected subcutaneously with DENV-2 strain K0049, a strain selected for its ability to replicate well in human dendritic cells in vitro. The humanized NOD/SCID mice developed a significant decrease in platelets on

day 8 postinfection and a marked erythema of the skin in the majority of mice on days 2–4 postinfection that continued through day 14 in some mice. Viremia was detected by RT-PCR and peaked on day 2 and lasted until day 14 postinfection. Nonhumanized NOD/SCID control mice demonstrated lower viremias and did not develop erythema or decrease in platelet count. Virus could be detected in the spleen, liver, and skin of some of the hu-NOD/SCID mice but not in any of the control mice.

Because SCID mice do not have an intact immune system, other mouse models are being developed to help identify which components of the immune system are critical for the control of DENV infection, as well as those that may contribute to the immunopathology of DHF/DSS. Knockout mice deficient in both the IFN-α/β and IFN-γ receptor genes (AG129) were infected i.p. with both mouse-adapted and nonadapted strains of DENV-2 (Johnson and Roehrig, 1999). Only AG129 mice infected with the mouse-adapted strain became symptomatic indicating that both IFN-α/β and IFN-γ systems are important for the control of DENV. These mice developed neurological symptoms by day 7 that progressed to death by day 21 postinfection. Virus was recovered from the serum of AG129 mice, peaking at day 3 and persisting at low levels until day 9. Virus was also recovered from the spleens and brain tissue of the infected AG129 mice. In contrast, none of the wild-type 129 (WT129) mice developed any symptoms and no virus was recovered from tissues or serum. Additional studies with the IFN-α/β receptor deficient (A129), IFN-γ receptor deficient (G129) and AG129 mice determined that the activities of both IFN-α/β and IFN-γ are vital for protection against primary DENV infection (Shresta et al., 2004b). IFN-α/β may be important in the control of early DENV dissemination to CNS as well as other tissues. AG129 mice were more susceptible to both mouse-adapted DENV-1 and DENV-2 viruses, indicating that IFN-γ action may be more critical for protection against DENV than IFN-α/β. The DENV strain PL046 was further adapted to AG129 mice by alternating passages in AG129 mice and C6/36 cells (Shresta et al., 2006). Although the adapted virus, designated D2S10 did not cause significantly higher viremia titers in AG129 mice than did PL046, it was more virulent. Mice infected with D2S10 developed hunched posture, ruffled fur, and lethargy by day 3 or 4 postinfection. Interestingly, there was evidence of increased vascular permeability of the large and small intestine in these mice, although no evidence of increased vascular permeability of the pleural, pericardial, or peritoneal membranes was detected. TNF-α was implicated in these studies as a mediator of disease.

Unlike the IFN receptor knockout mice described above, the A/J mouse strain is an inbred immunocompetent strain that can be infected with high titers of a nonmouse adapted DENV-2 strain (Huang et al., 2000b). DENV-2 virus causes a nonfatal paraplegia in approximately 70% of infected A/J mice 2–3 weeks after infection. In addition, 10–14 days after infection, mice developed thrombocytopenia thought to be the result of anti-platelet antibody. Indeed, anti-platelet antibody was detected in the serum of infected A/J mice as early as 4 days postinfection and antibody levels were maintained for 2–3 weeks. Based on these results, other investigators have characterized the primary immune response to DENV-2 in this model (Shresta et al., 2004a). They confirmed that A/J mice can be infected peripherally with a nonmouse adapted strain of DENV-2 and that a proportion of mice develop paralysis. DENV-2 virus was recovered from CNS tissue of infected mice but not from the serum or any other organs. DENV-infected mice were found to have an increased number of NK cells expressing CD69, an early activation marker, at 3 days postinfection. In addition, there were a significant number of activated B cells detected in the spleens of DENV-infected mice compared with controls. Although an increase in activated T cells was also noted, it was not as significant. The only other DENV strain that was tested in this model was DENV-2 16881 and no mice developed paralysis after infection with the 16881 strain. This suggests this model may be restricted in its ability to evaluate other DENV.

As stated above, the time course of DENV replication and antibody response in nonhuman primates is comparable to what occurs in humans. For this reason, the attenuation phenotype and immunogenicity of experimental dengue vaccines can be evaluated in monkeys to identify the best candidate to be taken into human clinical trials. In addition, refinement of this model may prove useful for the study of the immunopathology of DHF/DSS. Mouse models have become helpful in dissecting out important components of the immune response to dengue and have provided some clues to which factors may be involved in DHF/DSS. In addition, mouse models that support virus replication of different nonmouse adapted DENV play an important role in the early evaluation of potential vaccine candidate viruses.

Vaccines in Development

While several candidate dengue vaccines have entered clinical trials in recent years, the development of safe and effective dengue vaccines faces many challenges. Dengue vaccine development proceeds

TABLE 19.2 A partial list of dengue vaccines under active development including the general approach, developers, number of dengue virus (DENV) genes in the vaccine for each serotype, and the clinical phase of development

Vaccine approach	Developer(s)	DENV genes	Status
Live-attenuated (traditional)	Sanofi-pasteur/Mahidol University	10	Tetravalent Phase 2
Live-attenuated (traditional)	GlaxoSmithKline Biologicals/Walter Reed Army Institute of Research (WRAIR)	10	Tetravalent Phase 2b
Molecularly attenuated	US National Institutes of Health	10	DENV-1 and 4 Phase 1
Molecularly attenuated	US Food and Drug Administration/WRAIR	10	Preclinical
Live chimeric (YFV)	Acambis/sanofi-pasteur	2	Tetravalent Phase 2
Live chimeric (DENV-4)	US National Institutes of Health	2 + 8	DENV-2 and 3 Phase 1
Live chimeric (DEN-2)	InViragen/CDC	2 + 8	Preclinical
DNA	Naval Medical Research Center/WRAIR	2	Preclinical
Purified inactivated virus	WRAIR	3	Preclinical
Recombinant subunit	Hawaii Biotech, Inc.	2	Preclinical

without the benefit of a full understanding of the pathogenesis of severe dengue disease or an adequate animal disease model. And unlike other multivalent vaccines where vaccines can be developed and fielded as they are developed, four dengue vaccines must be developed and combined as a single vaccine to avoid the theoretical risk of antibody-dependent immune enhancement of disease severity with subsequent natural exposure if a broadly protective immune response is not elicited with vaccination. Table 19.2 outlines nine leading approaches to vaccine development. The order of vaccine candidates reflects the bias that the presentation of more genes offers a greater opportunity for adequate immune responses across a genetically diverse human population and that live approaches are superior to inactive approaches.

Live Attenuated Virus Vaccines (Traditional Approach)

Most licensed human vaccines in the United States are empirically derived attenuated live viral vaccines [measles, mumps, rubella, adenovirus 4, adenovirus 7, varicella, rotavirus, smallpox, yellow fever, and influenza]. Note that one of these vaccines protects against another flavivirus (YFV) and that there is a live attenuated Japanese encephalitis vaccine available in China and elsewhere raising expectations for the development of a successful dengue vaccine. In 1971, a Dengue Task Force was formed by the Virus Commission, United States Armed Forces Epidemiology Board to foster cooperative efforts to develop dengue vaccines using traditional methods (Halstead, 1978). Subsequently, research teams from Mahidol University (Bangkok, Thailand) and the Walter Reed Army Institute of Research (WRAIR, Silver Spring, MD) independently developed monovalent, bivalent, trivalent, and tetravalent dengue vaccine candidates.

The Mahidol vaccine virus candidates, DENV-1 16007 PDK-13, DENV-2 16681 PDK-53, DENV-3 16562 PGMK 30/FRhL3, and DENV-4 1036 PDK-48, were clinical isolates grown in either primary dog kidney (PDK) cells (DENV-1, 2, and 4) or primary African green monkey kidney (PGMK) cells and then in fetal rhesus lung (FRhL) cells (DENV-3). Similarly the WRAIR candidates, DENV-1 45AZ5 PDK-27/FRhL3, DENV-2 16803 PDK-50/FRhL3, DENV-3 CH53489 PDK-20/FRhL3, DENV-4 341750 PDK-6/FRhL3 were all grown in PDK cells with terminal passages in FRhL cells (Bhamarapravati and Yoksan, 2000).

The Mahidol University monovalent vaccines were well-tolerated in adult flavivirus-naive volunteers in Thailand (Bhamarapravati et al., 1987; Bhamarapravati and Yoksan, 1997, 2000) and the United States (Vaughn et al., 1996; Kanesa-thasan et al., 2001b). Phase 1 clinical testing identified passage levels with minimal reactogenicity while inducing 100% seroconversion for all four monovalent components (some with a

booster dose) (Bhamarapravati and Yoksan, 1997). Bivalent and trivalent formulations using DENV-1, 2, and 4 vaccine candidates elicited uniform seroconversions in Thai subjects (Bhamarapravati and Yoksan, 1989). However, when all four serotypes were combined into a tetravalent vaccine and given in a single dose, only DENV-3 viremia and neutralizing antibody were elicited (Kanesa-thasan et al., 2001b). Studies evaluating formulations using lower doses of DENV-3 with one or two boosters were subsequently pursued to overcome this apparent viral interference phenomenon. New formulations were evaluated in adults (Sabchareon et al., 2002) and children (Sabchareon et al., 2004). While immunogenicity remained high following multiple dosing (up to 100% seroconversion following three doses of tetravalent vaccine over 12 months), moderate reactogenicity, which included one child who had a week long dengue-like illness and nearly universal systemic reactogenicity among Australian adult volunteers, prompted development of a replacement DENV-3 component (Kitchener et al., 2006). However, a new biologically cloned DENV-3 component was also highly reactogenic (Sanchez et al., 2006) and this vaccine development approach is not currently active.

While the WRAIR vaccine demonstrated protective efficacy as a tetravalent formulation in rhesus macaques (Sun et al., 2006), like the Mahidol vaccine, it has primarily been developed through a series of Phase 1 evaluations of monovalent and tetravalent vaccine candidates (Sun et al., 2003; Edelman et al., 2003; Kanesa-thasan et al., 2002). Among the initially selected passage levels, the seroconversion rates were 100, 92, 46, and 58% for single dose of DENV-1-4, respectively. The WRAIR DENV-2, 3, and 4 vaccine viruses were well-tolerated by volunteers. However, the DENV-1 PDK-20/FRhL3 monovalent candidate was associated with increased reactogenicity with 40% developing fever and generalized rash (Edelman et al., 1994; Mackowiak et al., 1994). In an effort to reduce reactogenicity, the DENV-1 component was replaced with a further passaged virus (PDK-27 rather than PDK-20) and to improve immunogenicity, the DENV-4 component was replaced with a lower passaged virus (PDK-6 rather than PDK-20). Current tetravalent formulations are in Phase 2 testing in North America and Asia.

There are important safety issues for live dengue vaccines. Foremost, is the theoretical risk of enhanced disease due to natural DENV exposure in endemic regions following DENV vaccination. Less than tetravalent dengue vaccines have not been fielded to date due to the generally accepted need for a vaccine to induce primary-type immune responses to all four DENV serotypes simultaneously. The simultaneous production of neutralizing antibodies to all four serotypes of DENV is predicted to minimize the risk of disease enhancement following natural infection. ADE appears to occur with neutralizing antibodies at subneutralizing concentrations, so a vaccine that induces protection for a period of time may later increase the risk for enhanced disease. This is particularly a concern for vaccines that induce low levels of neutralizing antibodies (Burton et al., 2000), but could be a problem for any vaccine given enough time. The lessons learned with inactivated respiratory syncyntial virus (RSV) and measles vaccines suggest that low-level neutralizing antibody responses, lack of induction of neutralizing antibody to important epitopes (e.g., G protein in RSV), high $CD4^+$ proliferation, and absent $CD8^+$ memory responses are associated with exaggerated disease with subsequent natural infection (Murphy et al., 1986). Skewing toward a Th-2 type response by vaccination may also play a role in disease enhancement (Griffin et al., 1994; Graham et al., 1993). It is anticipated that tetravalent seroconversion with adequate $CD8^+$ memory responses will preclude enhanced disease even many years following vaccination. Broad Th-1 responses seem most likely with live virus approaches to vaccine development.

A second concern is that enhanced vaccine reactogenicity is possible when a live tetravalent DENV vaccine is administered to persons with preexisting anti-flavivirus antibody. Specifically, preexisting monovalent anti-DENV antibody could neutralize one component of a live tetravalent vaccine and enhance the replication of heterologous viral components to cause DF or DHF. To date, enhanced disease has not been observed in yellow fever immune vaccine recipients (Bancroft et al., 1984), volunteers receiving closely spaced sequential DENV of different serotypes, or in volunteers screened for flavivirus antibody yet experiencing anamnestic antibody response patterns following vaccination (Kanesa-Thasan et al., 2003). In this last group, volunteers were screened using the plaque reduction neutralization assay for DENV. Preexisting flavivirus antibody was probably nondengue and perhaps represents a lesser risk. Empiric administration of tetravalent vaccines to volunteers with documented preexisting partial DENV immunity has yet to demonstrate an increased risk though the numbers of volunteers tested is small to date (Kanesa-thasan et al., 2002). There have been recent suggestions that wild-type DENV-4 and DENV-2 viruses may be naturally attenuated in many flavivirus-naive hosts (Vaughn, 2000). Safety data for DENV-4 and DENV-2 component vaccines administered to flavivirus-naive volunteers must be considered in this context. Given the observation that secondary DENV infections are

also largely subclinical (Burke et al., 1988; Endy et al., 2002), large numbers of partial dengue-immune volunteers will need to receive candidate vaccines before this risk can be adequately assessed. However, since live attenuated vaccine viruses replicate to very low levels in vaccinees, it is unlikely that ADE would be capable of increasing titers to levels associated with serious disease (Vaughn et al., 2000).

Other safety concerns with live attenuated vaccines include cell culture-derived adventitious agents, community spread of vaccine virus by local vector mosquitoes, vaccine virus neurovirulence, and the effects of vaccine administration to immunocompromised hosts.

Live Virus Vaccines Attenuated by Engineered Mutations

Identification of mutations capable of appropriately attenuating DENV for vaccine use has been a fundamental goal of dengue vaccine development. As described above, passage of DENV in PDK cells has lead to the accumulation of mutations associated with an attenuation phenotype, however, it was not until 2000 that specific mutations derived by this empirical approach were identified as contributing to the attenuation of the DENV-2 PDK-53 vaccine candidate (Butrapet et al., 2000). In a separate vaccine strategy developed at the Laboratory of Infectious Diseases (NIAID, NIH, Bethesda, MD), the DENV-4 full-length cDNA clone was used to engineer deletion mutations in the 5′ UTR for structure/function analysis of this region (Cahour et al., 1995). Although several mutant constructs yielded virus, the resulting viruses were not always genetically stable and were not further developed as vaccine candidates. However, deletion mutations introduced into the 3′ UTR of DENV-4 were more stable and conferred varying levels of attenuation in rhesus monkeys compared to the wild-type parent virus (Men et al., 1996). Among the deletions created, which ranged from 30 to 262 nucleotides, the 3′ 172-143 deletion mutation, later referred to as Δ30, showed a desirable balance between level of attenuation and immunogenicity in monkeys. The DENV-4 virus containing the Δ30 mutation was subsequently evaluated in adult human volunteers and was shown to be safe, asymptomatic, and immunogenic at all doses administered (10^1–10^5 pfu) (Durbin et al., 2001, 2005).

The favorable evaluation of the DEN4Δ30 vaccine in humans supported a unique strategy to create vaccine candidates for the other three DENV serotypes. Because the structure of the DENV 3′ UTR is well conserved among all four serotypes, it was reasoned that deletion of nucleotides analogous to the Δ30 mutation in each serotype would likely result in attenuation. Introduction of the Δ30 mutation into DENV-1 resulted in a vaccine candidate attenuated to levels similar to that observed in monkeys for DEN4Δ30 (Whitehead et al., 2003a) and well tolerated and immunogenic in humans (Durbin et al., 2006a). Although introduction of the Δ30 mutation into DENV-2 conferred only a modest level of attenuation (Blaney et al., 2004b), introduction of the Δ30 mutation into DENV-3 failed to attenuate the resulting virus (Blaney et al., 2004a). Nevertheless, the Δ30 mutation has been shown to contribute to the attenuation observed for chimeric viruses DEN2/4Δ30 and DEN3/4Δ30 (Blaney et al., 2004b; Whitehead et al., 2003b) and tetravalent formulations containing these viruses along with DEN1Δ30 and DEN4Δ30 have been tested in monkeys and shown to be attenuated and elicit balanced antibody responses (Blaney et al., 2005).

Other strategies to identify attenuating mutations for DENV have included the generation of point mutations throughout the virus genome. Chemical mutagenesis has been successfully used to identify point mutations exhibiting a range of useful phenotypes, including temperature sensitivity, small plaque size, enhanced replication in Vero cells, reduced replication in mouse brain, reduced replication in SCID mice transplanted with human liver cells, and reduced infectivity for mosquitoes (Blaney et al., 2002, 2003; Hanley et al., 2003). Paired charge-to-alanine mutagenesis of the DENV-4 NS5 coding region has yielded a menu of attenuating mutations (Hanley et al., 2002), and viruses bearing several of these mutations have been successfully tested in monkeys (Hanley et al., 2004) and are currently being evaluated in humans. Substitution or deletion of noncontiguous nucleotides in the 3′-terminal stem-loop structure of DENV genome has yielded viruses DEN2mutF, with reduced replication in tissue culture mosquito cells (Zeng et al., 1998), and DEN1mutF, with reduced replication in mosquito cells and attenuated replication in monkeys (Markoff et al., 2002). It is possible that the mutF set of mutations could be introduced into the remaining DENV serotypes to develop a tetravalent vaccine in a manner analogous to that proposed for the Δ30 mutation.

Live Attenuated Virus Chimeric Virus Vaccines

Recombinant DNA technology has made it possible to expedite the development of several unique attenuated DENV vaccine candidates. For more than a decade it has been possible to produce chimeric DENV in which the structural protein coding region of

a flavivirus is replaced by that from a specific DENV serotype. The generation of chimeric DENV was first reported by scientists at the NIH in 1991 (Bray and Lai, 1991) shortly after their recovery of DENV-4 from a full-length cDNA clone (Lai et al., 1991). Since that beginning, numerous chimeric viruses expressing DENV structural proteins have been created, as listed in Table 19.3. Intertypic DENV representing all four serotypes have been developed using various DENV-2 and DENV-4 viruses as the genetic background. In addition, interspecific chimeric DENV have been generated using flavivirus species such as YFV and JEV as the genetic background. Although the genetic materials for each chimeric virus approach have differed, the goal has remained the same: use chimerization to bring together the immunogenic structural genes of DENV and the attenuated NS genes of a related flavivirus to create safe vaccine candidates for each of the four DENV serotypes.

For the generation of chimeric viruses, it is generally accepted that the genetic backbone should be attenuated. However, experience has shown that chimerization itself can lead to attenuation. Intertypic chimeric viruses created with a wt DENV-4 background and wt DENV-2 structural genes were shown to be significantly attenuated compared to either wt parent virus in mice, mosquitoes, or rhesus monkeys (Whitehead et al., 2003b). Nevertheless, the use of an attenuated background further augmented the level of attenuation of the DENV-4/DENV-2 chimeric viruses (Whitehead et al., 2003b). Several attenuated vaccine viruses or vaccine candidate viruses have been used as the genetic background for creating chimeric dengue vaccine candidates. These include the use of YFV vaccine strain 17D (van Der Most et al., 2000; Guirakhoo et al., 2001; Caufour et al., 2001; Chambers et al., 2003), PDK passaged DENV-2 vaccine candidate PDK-53 (Huang et al., 2003a), and genetically modified vaccine candidate DEN4Δ30 (Whitehead et al., 2003b; Blaney et al., 2004b). For the most part, wild-type, unaltered dengue structural genes have been used with these attenuated backgrounds, which should ensure that infectivity and immunospecificity is preserved.

For chimeric viruses expressing DENV structural genes, it is clear that the level of attenuation observed for the background virus is maintained in the chimeric virus without the need for attenuating mutations in the structural genes. However, this has not been the case for certain other chimeric flaviviruses, such as chimeric YFV/JEV in which it was necessary to use

structural genes from an attenuated strain of JEV in order to create an attenuated chimeric virus, even though the genetic background was YF vaccine strain 17D (Chambers et al., 1999). It is unclear why chimerization itself leads to attenuation of the resulting virus. It is reasonable to assume that tropism, attachment, and infectivity of the dengue chimeric viruses is not altered compared to the parent virus from which the structural gene is derived since both viruses are coated on their surface with the same authentic E glycoprotein, an attractive feature of the chimeric virus vaccine approach. The basis of the observed attenuation is likely the result of decreased virus replication due to reductions in gene expression, genome replication, or packaging efficiency. The suggestion has been made that attenuation may reflect the relative incompatibility of the structural and NS proteins such as proteases (Bray and Lai, 1991). Chimeric DENV resulting from the substitution of the capsid C protein along with the prM and E proteins have been more attenuated than substitution of only the prM and E regions. In fact, substitution of the C, prM, and E region of DENV-2 into DEN4Δ30 resulted in a chimeric virus that replicated in tissue culture, yet demonstrated minimal replication in mice and undetectable replication in monkeys, possibly the result of an inefficient, host-mediated interaction between the DENV-2 C protein and the DEN4Δ30 genome during virus assembly (Whitehead et al., 2003b).

Several promising chimeric dengue vaccine candidates have been successfully evaluated in preclinical studies and in human studies. In general, the chimeric vaccine candidates that have been evaluated in nonhuman primates have demonstrated decreased levels of viremia and a reduced number of viremic days compared to parental viruses from which the structural genes were derived (Whitehead et al., 2003b; Bray et al., 1996; Guirakhoo et al., 2002, 2004; Blaney et al., 2004a). Based on the success of these nonhuman primate studies, selected vaccine candidates have been evaluated in human clinical trials. The ChimeriVax platform, developed by Acambis, Inc. (Cambridge, MA), is based on YFV 17D, and has been used to create chimeric vaccine candidates for each of the dengue serotypes. The monovalent ChimeriVax-DEN2 vaccine candidate was successfully evaluated in humans and shown to be safe and immunogenic (Guirakhoo et al., 2006). Early reports of the Phase 1 testing of the ChimeriVax tetravalent vaccine indicate that it is safe without any serious adverse side effects. Phase 1 testing of the NIH chimeric vaccine candidate DEN2/4Δ30 has shown it to be safe and immunogenic at a dose of 10^3 pfu (Durbin et al., 2006b), and clinical evaluation of DEN3/4Δ30 is currently underway.

Live Vectored Vaccines

Although numerous recombinant vector systems have been used to express DENV antigens, the resulting vaccine candidates have achieved very limited success. Early vaccine candidates including recombinant vaccinia viruses (VV) expressing C-prM-E-NS1-NS2A (Zhao et al., 1987), C-prM-E (Deubel et al., 1988), or E (Hahn et al., 1990) failed to induce significant DENV-specific antibodies in rodents or monkeys, although 3-week-old offspring born to immunized mice were resistant to dengue encephalitis following intracerebral challenge with wt DENV (Bray et al., 1989). Since mice were also protected against encephalitis following immunization with VV expressing nonstructural protein NS1 (Falgout et al., 1990), it would appear that cell-mediated immunity in the absence of a neutralizing antibody response to E protein plays a significant role in protection afforded by VV vectors. Recombinant VV vectors expressing full-length E protein have been shown to express only intracellular E protein, therefore, VV expressing C-terminal truncated E proteins lacking the hydrophobic membrane anchor region and subsequently secreted from the cell have been shown to be more immunogenic (Men et al., 1991). By analogy to other flavivirus expression systems, it has been suggested that expression of DENV prM and E leads to the formation of empty virus-like particles, and that co-expression of the C protein may destabilize or prevent secretion of these particles, thereby decreasing overall immunogenicity (Fonseca et al., 1994). In an updated approach, the replication-deficient modified vaccinia Ankara (MVA) was used as a vector to express the C-terminal truncated E protein of DENV-2 (Men et al., 2000). For studies in monkeys, two doses of this vector conferred relatively low levels of neutralizing antibody and only partial protection upon virus challenge, while three doses resulted in higher levels of neutralizing antibody and complete protection following challenge. Construction of MVA vectors expressing E protein of the other three dengue serotypes has not been reported.

Because of their safety and low pathogenicity in humans, replication-defective adenoviruses vectors have been used to express the E protein of DENV-2 (Jaiswal et al., 2003). Three doses of this vector were required to achieve a significant antibody response in mice. Because of the ability of the adenovirus genome to accommodate lengthy insertions, it is envisioned that a single recombinant adenovirus vector can be constructed to express the E proteins from all four dengue serotypes, and such work is reportedly underway (Jaiswal et al., 2003). Prime-boost strategies using adenovirus expressing domain III of the DENV-2

envelope protein or DNA vectors expressing the same domain have been shown to be immunogenic in mice (Khanam et al., 2006).

The rationale behind the live vectored vaccine approach is the proven safety of the vectors used to generate the various vaccine candidates. In addition, poxviruses and adenoviruses have been shown to be potent inducers of both humoral and cellular immunity. However, there is widespread immunity in the human population to both of these vectors. Recent evaluation in humans of a vaccinia-JEV vaccine candidate demonstrated that while vaccinia-naive volunteers mounted a neutralizing antibody response, vaccinia-immune volunteers failed to develop neutralizing antibodies (Kanesa-thasan et al., 2001a), indicating that preexisting antivector immunity may have rendered the recombinant vaccine ineffective. Nevertheless, several solutions have been proposed to overcome the observed immune inactivation. Priming with a DNA expression vector prior to boosting with the virus vector has been shown to circumvent antivector immunity (Yang et al., 2003). In addition, adenoviruses and poxviruses from other animal species have been suggested for use as vectors.

Nucleic Acid Vaccines

DNA vaccines consist of DNA constructs that are introduced into cells and subsequently translated into immunogenic proteins. The DNA construct is a plasmid that contains a eukaryotic promoter and termination sequences to drive transcription of DENV target genes in the vaccine recipient (Whalen, 1996). After the DNA vaccine enters cells, transcribed RNA is translated to produce proteins to be processed and presented to the immune system in the context of MHC molecules and generate humoral and cell-mediated immune responses. A variety of adjuvants have been studied in conjunction with the DNA vaccines to enhance immune responses. In addition, various routes of administration and methods of delivery have been investigated.

DNA vaccines afford advantages over conventional vaccines including ease of production, stability, and transport at room temperature, decreased likelihood of replication interference as can been seen with live attenuated approaches, and it is possible to vaccinate against multiple pathogens in a single vaccination (Gurunathan et al., 2000).

Preclinical evaluation of the first dengue DNA vaccine candidate expressing the PrM and E genes was published in 1997 (Kochel et al., 1997) following the early successes in animals with DNA vaccines targeting HIV (Wang et al., 1993), influenza (Ulmer et al., 1993), and malaria (Sedegah et al., 1994). Work by Kochel et al. at the Naval Medical Research Center (NMRC, Bethesda, MD) evaluated two eukaryotic plasmid expression vector systems expressing the PrM protein and 92% of the E protein for DENV-2 virus (New Guinea C strain). Both constructs induced neutralizing antibody in all mice (Kochel et al., 1997), with a subsequent improvement seen with the addition of immunostimulatory CpG motifs (Porter et al., 1998). In subsequent experiments using genes from the West Pacific 74 strain of DENV-1 virus and the pVR1012 plasmid, it was determined that the full-length E gene with PrM served as a better immunogen (Raviprakash et al., 2000) and was shown to reduced the frequency and duration of viremia in rhesus macaques following challenge with wild-type virus (Raviprakash et al., 2006). Konishi et al. (2000) successfully immunized mice with a similar DENV-2 vaccine construct using C-PrM-E genes, Purdy and Chang (2005) have expressed virus-like particles expressing PrM and E proteins in Chinese hamster ovary cell culture, and Costa et al. (2006) have shown protection in mice using a DENV-2 NS-1 construct. The NMRC has also pursued "DNA shuffling" and screening with some success in mice (Apt et al., 2006). At present, the DNA approach has produced modest neutralizing antibody levels in nonhuman primates with only a portion of animals fully protected from viremia (Putnak et al., 2003; Raviprakash et al., 2001, 2003). With the recognition that skin dendritic cells are high permissive for DENV replication (Wu et al., 2000), ongoing efforts are focused on vaccine delivery systems to target these cells.

DNA vaccines used in combination with other approaches, such as inactivated virus vaccines discussed below may increase the complexity and effectiveness of the immune response (Eo et al., 2001; Doolan and Hoffman, 2001; Tellier et al., 1998). Preliminary studies in mice and monkeys at the NMRC suggest that this approach may be effective for dengue (Simmons et al., 2001b, 2006). In the mice, DNA vaccination alone elicited primarily an IgG2a antibody response while the recombinant protein used elicited an exclusive IgG1 antibody response. Vaccination with different products in sequence or simultaneously elicited a more balanced distribution of both antibody subclasses. However, for a vaccine targeted for 1 billion children in the tropics, an 8-component vaccine will present obstacles of cost and complexity. The NMRC DNA vaccine is currently undergoing Phase 1 clinical testing to be followed by the assessment of prime-boost strategies.

The DNA approach also carries its own risks (Klinman et al., 1997). These include the theoretical risk of nucleic acid integration into the host's chromosomal

DNA to potentially inactivate tumor suppressor genes or activate oncogenes. This risk appears to be well below the spontaneous mutation frequency for mammalian cells (Nichols et al., 1995; Martin et al., 1999). However, if a mutation due to DNA integration is a part of a multiple hit phenomenon leading to carcinogenesis, it could take many years before this problem became evident. Another concern is that foreign DNA might induce anti-DNA antibodies leading to autoimmune diseases such as systemic lupus erythematosis. However, studies in lupus-prone mice, normal mice, rabbits, and people to date have not validated this concern (Parker et al., 1999; Mor et al., 1997) and, in fact, DNA vaccines are being proposed as an approach to the management of autoimmune diseases (Prud'homme et al., 2001; von Herrath and Whitton, 2000; Karin, 2000).

Infectious virus RNA derived directly from cDNA has been used to successfully immunize mice with nanogram amounts of tick-borne encephalitis virus (Mandl et al., 1998; Dubensky et al., 1998). This approach mimics natural infection with advantages of increased vaccine purity and stability over traditional cell culture-based approaches. It also eliminates the risk of DNA integration and anti-DNA autoimmune disease.

Whole Virus Inactivated Vaccines

Inactivated whole virus vaccines are the second most common type of licensed vaccine in the United States after live attenuated viral vaccines. Inactivated vaccines have at least two advantages over live attenuated vaccines; inactivated vaccines cannot revert to a more pathogenic phenotype and they are unlikely to interfere with each other in combination. Moreover, induction of cell-mediated and humoral immune responses has been demonstrated with inactivated flavivirus vaccines (Aihara et al., 2000). On the other hand, inactivated or killed vaccines express only the part of the viral genome that encodes structural proteins resulting in a less broad immune response. Other potential disadvantages of these vaccines are the difficulty in manufacturing preparations of sufficient titer, their increased cost per dose, and current requirements for multiple immunizations. Even so, two successful inactivated flavivirus vaccines are safe, effective, and licensed for use to prevent Japanese encephalitis (Hoke et al., 1988) and tick-borne encephalitis (Craig et al., 1999). Inactivated dengue vaccine may be useful as a traveler's vaccine or as a part of a prime-boost strategy with live or replicating vaccines.

A purified, inactivated DENV-2 vaccine compliant with good manufacturing practices has been manufactured by the Department of Biologics Research (WRAIR, Silver Spring, MD) and a DENV-1 equivalent will soon enter clinical trials (Putnak et al., 1996a, 1996b). For preparation of DENV-2-PIV, DENV-2 strain S16803, Vero cell passage three, was propagated in certified Vero cells. Virus from the culture supernatant fluid was concentrated by ultrafiltration and purified on sucrose gradients. The high-titer purified virus (approximately 9 $\log_{10}$pfu/ml) was inactivated with formalin at 22°C for 10 days. The DENV-2 vaccine with alum and other adjuvants induced high neutralizing antibody levels and protection against viremia in a primate model (Putnak et al., 1996a, 2005; Simmons et al., 2006).

Recombinant Subunit Vaccines

Dengue antigens, primarily prM and E proteins, can be expressed in bacteria, yeast, mosquito cells, or mammalian cells, and then purified to prepare nonreplicating, subunit vaccines. In general, a truncated E protein is expressed that lacks its carboxy-terminal hydrophobic membrane anchor region in an effort to maximize the secretion and solubility of the protein. These modified E proteins were shown in 1991 to be immunogenic and protective in mice following inoculation with recombinant vaccinia virus expressing the truncated E protein (Men et al., 1991) or with baculovirus-expressed truncated E protein (Putnak et al., 1991). Since that time, a number of expression systems have been used to generate E proteins: *E. coli* expressing domain III of the E protein of DENV-2 as a fusion protein with the maltose-binding protein (Simmons et al., 2001a), E-NS1 protein of DENV-2 as a fusion protein with staphylococcal protein A (Srivastava et al., 1995); *Pichia pastoris* expressing E protein of DENV-4 (Guzman et al., 2004), DENV-2/hepatitis B surface antigen hybrid (Bisht et al., 2002), or subviral particles of DENV-1 (Sugrue et al., 1997); baculovirus expression in *Spodoptera frugiperda* cells of full-length E protein aggregates of DENV-2 (Kelly et al., 2000), His-tagged E protein of DENV-2 (Staropoli et al., 1997), hybrid E protein of DENV-2/DENV-3 (Bielefeldt-Ohmann et al., 1997), or E proteins of DENV-2 and DENV-3 (Delenda et al., 1994); *Drosophila melanogaster* cells (Schneider-2) stably expressing E protein of DENV-2 (Putnak et al., 2005); and CHO-K1 cells stably expressing subviral particles of DENV-2 (Konishi and Fujii, 2002). Not surprisingly, all the subunit preparations listed above elicited moderate to high levels of antibody following immunization of mice. Although such vaccines are anticipated to achieve a high level of safety, it is generally accepted that multiple doses

will be required and that adjuvants will be needed to increase immunogenicity.

To date, a DENV subunit vaccine has not been tested in humans. However, two studies in macaques have recently been completed using monovalent DENV-2 or DENV-4 truncated E proteins. Guzman et al. (2003) immunized macaques with four doses of 100μg of E protein (DENV-4), using alum as an adjuvant. DENV antibody titers were barely detectable by ELISA and hemagglutination-inhibition following all four doses and at the time of virus challenge, neutralizing antibody titers were only 1:30. Although partial protection against wt DENV-2 challenge viremia was demonstrated, the researchers considered the results insufficient to recommend the subunit preparation as a vaccine candidate and suggested that factors including conformational differences between recombinant and native E protein, antigen presentation, and immunization schedule could have influenced the lack of full protection.

In collaboration with Hawaii Biotech, Inc. (Alea, Hawaii), Putnak et al. (2005) immunized macaques with two doses of DENV-2 truncated E protein produced in drosophila cells and formulated with each of five different adjuvants containing alum salts with or without the addition of 3D-MPL (Corixa, Inc.) or QS-21 (Antigenics, Inc.) adjuvants. Additional macaques were immunized with experimental preparations of live attenuated vaccine virus or formalin inactivated vaccine virus. DENV neutralizing antibody titers prior to challenge varied widely (1:60–1:5300) among the subunit vaccinated monkeys and several exhibited significant challenge virus replication even in the presence of relatively high levels of virus neutralizing antibody. Nevertheless, one group of monkeys receiving the highest dose of antigen along with both 3D-MPL and QS-21 were completely protected, an improvement over previous results with baculovirus-expressed structural proteins of DENV-4 (Eckels et al., 1994). In all of the reported macaque studies, there was no evidence of enhanced challenge virus replication, even in the presence of minimally protective antibody levels. It is likely that additional vaccination regimens including higher antigen doses or more frequent boosting will be required to maintain antibody titers at protective levels.

PROSPECTS FOR THE FUTURE

In recent years there has been heightened awareness of the global morbidity and mortality related to dengue. As a result, there has been a resurgence in dengue research, particularly in the area of vaccine development. Vaccination is thought to have the greatest potential to reduce the incidence of dengue in endemic areas. As discussed in previous sections, the prospect of an effective vaccine for the prevention of dengue is closer to becoming a reality. The number of candidate dengue vaccines has expanded to include live attenuated dengue vaccines, both recombinant and biologically derived; subunit protein vaccines; DNA vaccines; vectored vaccines; and whole virus inactivated vaccines. The pace of vaccine development has increased but the challenges to the implementation of a successful dengue vaccine program are still significant. Prior to the initiation of large-scale vaccine trials in endemic regions, the infrastructure must be in place to determine not only the efficacy of the vaccine but to also evaluate the impact of vaccination on disease severity in dengue-exposed as well as dengue-naive individuals. It will be essential that accurate case definitions for DF/DHF/DSS be consistently applied during these trials. The WHO classification system of dengue disease, although useful for decades, may need to be refined to more effectively identify and triage which dengue patients will go on to develop severe disease (Deen et al., 2006). Efforts to this end are ongoing and it is expected that the WHO will provide guidelines for the design and conduct of dengue vaccine trials in endemic areas.

An expanding area of dengue research is that of therapeutics. As discussed above, the treatment for dengue is limited to supportive measures only. Currently there are no licensed antiviral or other therapeutic agents available for the treatment acute dengue illness. Several possible targets for antiviral therapy have been identified including viral attachment, the viral polymerase, and other components of viral replication (Takhampunya et al., 2006; Vasudevan et al., 2001; Altmeyer, 2004). In addition, further understanding of the aberrant immune response may provide opportunities for the use of immune modulating drugs to prevent or treat disease progression in dengue.

A third area of intensive research in dengue is the development of an animal model that reproducibly mimics the clinical picture seen in humans. Such a model would be extremely useful in determining the components of the immune response that contribute to the hemorrhagic and vascular leak syndromes so characteristic of severe dengue. Novel diagnostic and therapeutic agents could then be evaluated and optimized in preclinical testing, improving the ability to identify the most useful agents for clinical practice. Vaccine development would also benefit from an animal model which reproducibly mimics human

disease; to not only identify attenuation characteristics, but to also assess the risk of DHF/DSS conferred by vaccination to populations of dengue-endemic regions. Progress continues to be made toward the development of a useful animal model and, with the ability to genetically manipulate specific components of the immune response in mice expanding, such a prospect may not be far off.

KEY ISSUES

- DENV is the most important mosquito-borne viral pathogen infecting more than 100 million persons annually.
- There are four serotypes of DENV, each capable of causing the full spectrum of clinical disease.
- Epidemiological studies have demonstrated the greatest risk factor for severe dengue disease is secondary infection with a DENV serotype different from that which caused primary infection.
- The immunopathologic mechanisms of severe or enhanced dengue are complex and involve elements of both the humoral immune system, via ADE, and the cellular immune system.
- Neutralizing antibody directed against the structural protein E is thought to be the most important mediator of protection from DENV.
- Long-lasting, perhaps lifelong, homotypic immunity is generated after primary DENV infection.
- Only short-term heterotypic immunity is generated after primary infection.
- There are currently no antiviral treatments for DENV; treatment is supportive only.
- There are currently no licensed vaccines for the prevention of dengue disease, however numerous candidate vaccines are in development.
- A viable vaccine for the prevention of dengue will have to protect against all four serotypes of DENV.
- Future areas of DENV research include continued vaccine development and implementation, development of novel diagnostic and therapeutic agents, and further characterization of aberrant immune response seen in severe dengue.

ACKNOWLEDGMENT

The authors wish to thank John Bisbing for his management of the reference database used in the writing of this chapter.

OUTLINE

ABSTRACT

Marburg virus (MARV) and Ebola virus (EBOV), family Filoviridae, were discovered in 1967 and 1976, respectively, but remained largely unknown until 1995 when EBOV reemerged in Kikwit, Democratic Republic of the Congo (DRC). Since then Angola, DRC, Gabon, Republic of Congo, Sudan, and Uganda have experienced outbreaks of EBOV and MARV hemorrhagic fever, which varied from a few cases to several hundreds with case fatality rates ranging from 50–90%. In addition, EBOV has emerged as a devastating pathogen for the great apes in some of these countries leading to a dramatic reduction of these endangered species. More recently, different fruit and insectivore bats have been implicated as potential reservoirs for MARV and EBOV. Being highly pathogenic for human and nonhuman primates, and the subject of former weapon programs, makes filoviruses one of the most feared pathogens worldwide today. The lack of pre- and post-exposure intervention makes the development of

rapid diagnostics, new antivirals, and protective vaccines a priority for the preparedness of many nations. Further insight into the immunology and pathogenesis of filoviruses will help to establish the urgently needed immune protective markers to evaluate experimental vaccine candidates. This chapter reviews and evaluates the current status of filovirus vaccine research, a field that has made tremendous progress in the past decade leading to several promising vaccine platforms of which one is currently in phase I clinical trials. All these platforms show excellent pre-exposure protective efficacies in macaques, the gold standard animal model, but in particular one candidate vaccine has proven promising in post-exposure treatment. It is expected that within the next decade a vaccine for MARV and EBOV will be available.

INTRODUCTION

Marburg virus (MARV) was identified as the causative agent of several human cases of hemorrhagic fever that occurred in Marburg, Germany, in 1967 (Siegert et al., 1967). The first recorded emergence of Ebola virus (EBOV) was in Central Africa, in southern Sudan and northern Zaire, now the Democratic Republic of the Congo, in the summer of 1976. Both viruses were classified in the order of Mononegavirales, as they are using a non-segmented, negative-strand RNA genome as a genetic template for replication. The family of Filoviridae was proposed in 1982 to segregate EBOV and MARV on the basis of newly characterized morphological, physiochemical, and biological features (Feldmann et al., 2003; Kiley et al., 1982). The family of Filoviridae is divided into the Marburgvirus and Ebolavirus genera which are further subdivided into distinct species such as *Lake Victoria marburgvirus* (LVMARV) and *Zaire*, *Reston*, *Sudan* or *Cote d'Ivoire ebolaviruses* (ZEBOV, REBOV, SUBOV, or CIEBOV, respectively) (Feldmann et al., 2004).

ANTIGENS ENCODED BY AGENT

Filoviruses are long, cylindrical, filamentous, enveloped particles that can be straight, curved, or coiled and of variable lengths although with a consistent diameter of approximately 80 nm (Fig. 20.1). Their negative-strand RNA genome is non-segmented and measures approximately 19 kb in length (Feldmann et al., 2003; Sanchez et al., 2007). The genomes of filoviruses encode for seven genes, although EBOV has the distinctive feature of expressing an additional protein through RNA editing (Sanchez et al., 1996; Volchkov et al., 1995). MARV and EBOV express a nucleoprotein (NP), a transmembrane glycoprotein (GP), an RNA-dependent RNA polymerase (L), and four additional virion structural proteins: VP24, VP30, VP35, and VP40 (Feldmann and Kiley, 1999; Sanchez et al., 2007) (Fig. 20.1). For EBOV, RNA editing occurs in the GP gene and results in expression of a truncated version of the glycoprotein, designated soluble glycoprotein (sGP), which is secreted into the extracellular environment of infected cells. NP, VP30, VP35, and the L protein are associated with the virus genomic RNA to form the ribonucleoprotein complex (RNP). NP, VP35, and L are essential and sufficient for the transcription and replication of MARV, whereas EBOV also require the presence of VP30. The inside of the viral membrane is coated with the matrix protein VP40 and a second membrane-associated protein VP24. The external surface of the virus membrane is spiked with homotrimers of $GP_{1,2}$ which are processed through the endosomal pathway including folding, disulfide bridge formation, glycozylation, and cleavage of the precursor GP into GP_1 and GP_2 by furin or a furin-like endoprotease. Trimers of $GP_{1,2}$ spikes mediate receptor binding and fusion and are thus the major target for neutralizing host immune responses (Feldmann et al., 2001).

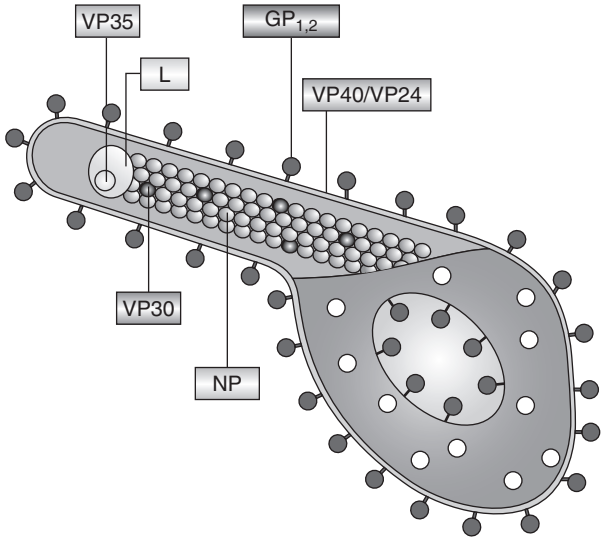

FIGURE 20.1 Schematic illustration of a filovirus particle. Four proteins form the RNP: polymerase or large (L) protein, NP, virion structural protein 30 (VP30), and virion structural protein 35 (VP35). The glycoprotein (GP) is anchored with the carboxy-terminal part in the virion membrane. Homotrimers of GP form the spikes on the surface of the virion. VP40 is the matrix protein and VP24 another membrane-associated protein. Adapted from Feldmann et al. (2003) (see color plate section).

EPIDEMIOLOGY

Outbreaks of filovirus infections have primarily been localized to Central Africa (Fig. 20.2) and despite their dramatic consequences on affected communities they are of relatively low impact on global human health (Sanchez et al., 1995). However, filovirus infections are feared worldwide as imported cases or the result of an intentional release (Borio et al., 2002). With mortality rates ranging from 23–90% and documented human-to-human transmission, the introduction or intentional release of adequately formulated filoviruses in a densely populated area, such as a major city, could be devastating. No clinical modalities are currently available to the general public. However, several strategies, including vaccines and antiviral drugs, are being evaluated and a few promising candidates have successfully passed advanced preclinical testing.

CLINICAL DISEASE, PATHOGENESIS, AND TREATMENT

Filoviruses cause hemorrhagic fever with a survival rate that can be as low as 10% among infected individuals, listing them among the most lethal viruses known to man (Wilson et al., 2001a, 2001b). The mode of primary transmission to humans remains evasive. Fruit bats are suspected to be a natural reservoir of EBOV and MARV, and could also act as a primary source of infection to the great apes, which in turn have transmitted infections to humans in the past (Leroy et al., 2005; Towner et al., 2007). Filoviruses are extremely infectious in experimental animal models, although natural spread among apes and humans is less efficient and normally requires direct contact. However, there is experimental and epidemiologic evidence indicating that filoviruses can also be transmitted through mucosal exposure (Jaax et al., 1996; Johnson et al., 1995). The disease course of a filovirus infection in human or nonhuman primates is dramatic, leading to a fulminant syndrome characterized by systemic inflammation, multi-organ failure, and coagulopathy with hemorrhages (Borio et al., 2002; Feldmann et al., 2003; Sanchez et al., 2007). The incubation period may vary from 6 to 21 days. Initial symptoms are nonspecific, such as fever, headache, nausea, diarrhea, and abdominal pain. Severe clinical cases rapidly progress over a 7–14-day period to the fully blown hemorrhagic fever syndrome and death (Baskerville et al., 1978; Bowen et al., 1978; Fisher-Hoch, 1983; Sanchez et al., 2007). The virus appears to initially infect monocytes, macrophages, and dendritic cells leading to dysregulation of the innate immunity and a systemic inflammatory response syndrome. The end result is massive destruction of critical organs (e.g., liver), vascular damage, and hemorrhages (Feldmann et al., 2003). While its clinical course is well described, the specific mechanisms underlying the pathogenicity of filovirus infections have not been defined due to difficulties in obtaining clinical specimens, studying the disease in remote areas where outbreaks occur, and the level of

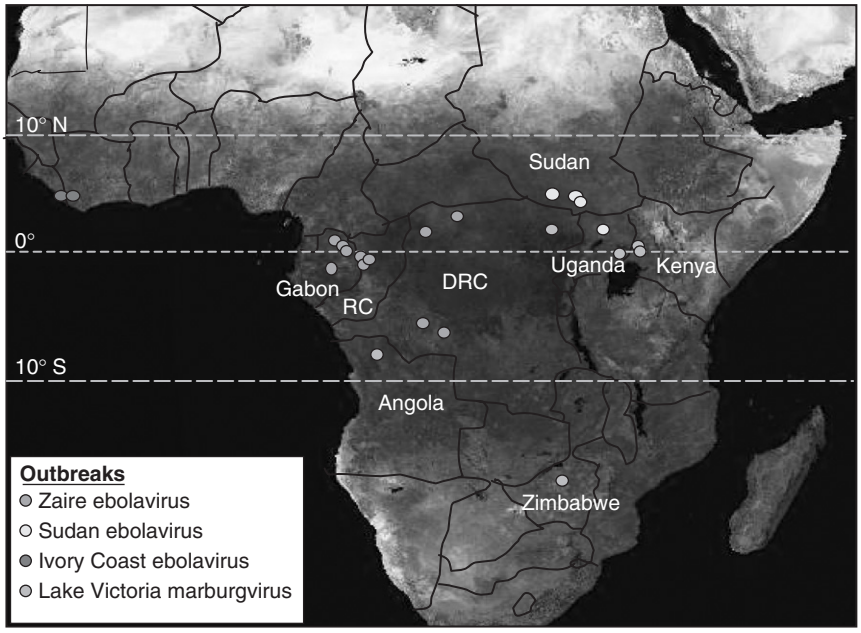

FIGURE 20.2 Summary of location, timeline, and types of filovirus outbreaks in Africa. RC, Republic of Congo; DRC, Democratic Republic of Congo. Adapted from Groseth et al. (2007).

biohazard containment required for clinical analysis. In addition, the rapid progression of the disease has afforded little opportunity to develop acquired immunity and has hindered identification of the components of the immune system that may protect against filovirus infections.

VACCINES

Attempts to develop vaccines for filoviruses began shortly after MARV and EBOV were discovered. Immunization regimens of formalin-fixed or heat-inactivated virion preparations were first evaluated in guinea pigs and nonhuman primates. Unfortunately, the level of protection achieved was inconsistent among different studies. However, all studies demonstrated partial protection of vaccinated guinea pigs or nonhuman primates suggesting that complete protection could be generated with a more efficient immunization strategy (Bausch and Geisbert, 2007; Chupurnov et al., 1995; Geisbert et al., 2002, 2003; Ignatyev et al., 1994, 1996; Lupton et al., 1980; Mikhailov et al., 1994).

More recently, the focus of filovirus vaccine development has been more on EBOV (Table 20.1). Protocols have mainly concentrated on the use of subunit vaccines based on a single or a combination of viral structural proteins to induce protective immunity against EBOV. The GP, NP, and the viral structural proteins VP24, VP30, VP35, and VP40 were evaluated as potential antigenic determinants of protective immune responses in different immunization strategies (Table 20.1). Initially, vaccine carriers of viral antigens included naked DNA, liposomes, vaccinia, alphavirus replicons, and virus-like particles (VLPs) (Geisbert et al., 2002; Pushko et al., 2000, 2001; Vanderzanden et al., 1998; Warfield et al., 2003; Wilson et al., 2001a; Xu et al., 1998). DNA immunization of mice with both EBOV GP and NP constructs stimulated detectable cytotoxic T cell responses to both antigens and some degree of protection (Vanderzanden et al., 1998; Xu et al., 1998). However, the optimal protocol of DNA-based vaccine with GP and NP in guinea pigs resulted only in partial protection against EBOV (Chupurnov et al., 1995; Vanderzanden et al., 1998; Xu et al., 1998). Immune sera from vaccinated guinea pigs did not inhibit EBOV replication in vitro and passive transfer in naïve animals failed to protect them against EBOV. Recombinant vaccinia viruses expressing EBOV NP, VP35, VP40, or VP24 failed to protect guinea pigs from a lethal challenge with EBOV. Vaccinia-encoding GP was the only construct capable of inducing some levels of protection in guinea pigs but failed to protect *Cynomolgus macaques* (Geisbert et al., 2002). Serum antibody titers by ELISA and endpoint titers in the 80% plaque reduction neutralization test ($PRNT_{80}$), which detect neutralizing antibody (NAB) remained low following immunization with vaccinia expressing EBOV GP. Immunization with VEEV replicons expressing GP resulted in low but detectable endpoint titers of NAB in $PRNT_{80}$. Specific, non-neutralizing antibodies were also detected by ELISA in response to immunization with EBOV VP24, VP30, VP35, VP40, and NP but it is not clear what role these antibodies may play in protection against the lethal challenge. The best immunization strategy with VEEV-based vaccine resulted in mixed protection in mice and guinea pigs and failed to protect nonhuman primates (Pushko et al., 2000).

Complete protection of nonhuman primates against EBOV was first reported in 2000 with the use of naked DNA in combination with replication incompetent adenoviruses (Ads) based on serotype 5 (Adhu5) administered in a prime-boost regimen (Sullivan et al., 2000) (Table 20.1). This approach was later improved by a single immunization with recombinant Adhu5 expressing GP and NP (Sullivan et al., 2003). A vaccine based on vesicular stomatitis virus (VSV) was also shown to protect nonhuman primates against a lethal challenge with EBOV (Jones et al., 2005). Recently, a recombinant human parainfluenza virus type 3 (HPIV3) vector expressing ZEBOV GP also showed full protection of guinea pigs and nonhuman primates against a homologous ZEBOV challenge (Bukreyev et al., 2006, 2007) (Table 20.1).

However, the first success in fully protecting nonhuman primates against a lethal challenge of filovirus was demonstrated against MARV following immunization with a VEEV-based vaccine expressing GP and NP (Hevey et al., 1998). Several immunization strategies were also evaluated in parallel against MARV including DNA, Adhu5, alphavirus replicons, VSV, VLPs, vaccinia, and bacculovirus vaccine platforms (Table 20.2) (Becker et al., 1996; Daddario-DiCaprio et al., 2006a; Hevey et al., 1997, 1998, 2001; Jones et al., 2005; Riemenschneider et al., 2003; Swenson et al., 2005; Warfield et al., 2004). Similarly to EBOV vaccinated animals, MARV infection resulted in variable protection of immunized animals depending on the vaccine strategy and animal model selected. Remarkably, the first demonstration of post-exposure filovirus vaccine efficacy in nonhuman primates was demonstrated against MARV with 100% survival of VSV-MARV vaccinated animals (Daddario-DiCaprio et al., 2006b). This was also done more recently for EBOV with 50% survival among VSV-EBOV vaccinated animals (Feldmann et al., 2007).

VACCINES IN DEVELOPMENT

Adenovirus as Vaccine Vectors

Vectors based on recombinant adenoviruses (Ads) were initially mostly considered in the setting of gene therapy. A number of different serotypes of Ads have been isolated from humans causing a spectrum of illnesses ranging from upper respiratory tract infection to diarrheal diseases (Horwitz, 2001). These viruses are non-enveloped with linear double-stranded genomes of approximately 36 kb in length (Shenk and Williams, 1984).

The initial applications of Ads as vectors for gene therapy were based on recombinants in which the immediate early gene E1 is deleted (Rosenfeld et al., 1991; Stratford-Perricaudet et al., 1990). This substantially attenuated the virus, diminishing its toxicity and allowing for expression of heterologous genes. Virtually all experiments performed to date with adenoviral vectors utilized a construct based on Adhu5 for adenovirus serotype 5 (Adhu5). Ad vectors were shown to elicit vibrant B and T cell responses to both the Ad capsid proteins as well as the transgene products (Yang et al., 1994a, 1994b). Consequently, re-administration of the vector is ineffective because of neutralizing antibodies fiber capsid protein. In addition, target cells expressing the transgene product are quickly eliminated as a result of rapid re-activation of cytotoxic T lymphocytes (CTL) to both the transgene product as well as residually expressed viral genes. The intensity of the immune response is promoted mainly through the transduction of antigen-presenting cells in vivo (Jooss et al., 1998).

The strength and amplitude of the immune response following in vivo administration of Ads compelled several scientists to consider them as vaccine

carriers. In recent years adenoviral vectors have been shown to elicit important immune responses to various antigens including bacterial, viral, and even self-antigens in the context of cancer vaccines. Antigens derived from pathogens such as anthrax, plague, hepatitis C, rabies, and SARS were successful at stimulating strong immune responses often correlating with protection of susceptible animals against challenge with the infectious agent (Gao et al., 2003; Makimura et al., 1996; Tan et al., 2003; Vos et al., 2001).

In conjunction with naked DNA, Ad vector was the first vaccine capable of protecting nonhuman primates against ZEBOV challenge (Sullivan et al., 2000). In that study, cynomologus monkeys were immunized three times with a mixture of plasmid DNAs encoding the NP of ZEBOV and GPs of different EBOVs (ZEBOV, SEBOV, CIEBOV) followed by a booster of Ad expressing ZEBOV GP five months after priming with DNA. The monkeys were challenged with a low dose of ZEBOV (6 plaque-forming units (pfu) per animal) and only vaccinated animals survived the challenge. Antibody responses, T-cell proliferation, and CTL responses indicated that antibody and T-helper CD4+ cells were important for protection and that cell-mediated immunity although possibly important might not have been an absolute requirement. This would be in agreement with observations that passive transfer of EBOV immune serum can be protective in different animal models normally susceptible to infection. This approach was further improved to obtain complete protection of cynomolgus macaques to ZEBOV only 28 days post-vaccination with a single dose of Adhu5 expressing GP mixed with Ad expressing NP (Sullivan et al., 2003). This work led to a Phase I clinical trial by the U.S. National Institutes of Health (NIH) with early results demonstrating that the DNA component is well tolerated and capable of eliciting an immune response against EBOV GP in normal adults (Martin et al., 2006). More recently, the NIH initiated another Phase I clinical trial in normal adults immunized with the first-generation Adhu5 expressing the EBOV GP with the objective of evaluating safety and immune responses to the vaccine (http://clinicaltrials.gov/show/NCT00374309).

An important problem in the use of currently available adenoviral vector for human vaccines is natural pre-exposure to the virus, which leads to a long-lasting immunity capable of compromising vaccine efficacy. Infection with natural Ads is frequent during the first quarter of life resulting in high levels of serum NAB to Ad serotype. Approximately 30–50% of the human population in North America and over

90% in developing countries has levels of NAB capable of compromising Ad vaccine efficacy against EBOV in different animal models (Kobinger et al., 2006). Several studies have shown that these levels of NABs can also neutralize relatively high doses of different vaccine vectors based on Adhu5 (Chirmule et al., 1999; Fitzgerald et al., 2003; Xiang et al., 2002). Experimental studies demonstrated that several animal models including mice, guinea pigs, and nonhuman primates could no longer generate a protective immune response in the presence of circulating NAB against the Ad particles (Kobinger et al., 2006; Nanda et al., 2005). Results from the STEP HIV clinical trial reported an increased number of HIV seroconversionin Ad-vaccinated individuals with prior immunity to adenovirus (Moorel et al., 2008). Consequently, alternate strategies such as the evaluation of different vaccine vectors based on distinct serotypes of human or simian Ads that are not commonly circulating in the human population as well as different routes of immunization are currently being investigated (Jones et al., 2007; Kobinger et al., 2006; Nanda et al., 2005; Patel et al., 2007; Roy et al., 2004). Human Ad serotype 6, against which the prevalence of NAB in humans is less than 5%, has shown comparable immunogenicity to Adhu5 in nonhuman primates (Capone et al., 2006). A vaccine regimen based on chimpanzee Ads were also shown to be protective against ZEBOV and SARS viruses in different animal models pretreated with human NABs capable of inhibiting the efficacy of Ad serotype 5-based vaccine (Kobinger et al., 2006).

Vesicular Stomatitis Virus as Vaccine Vectors

VSV is a non-segmented negative-stranded RNA virus and belongs to the family Rhabdoviridae, genus *Vesiculovirus* (Lyles and Rupprecht, 2007). Its simple structure and rapid high-titered growth in mammalian and many other cell types have made it a preferential tool for molecular and cell biologists in the past 30 years (Lyles and Rupprecht, 2007). Naturally occurring human infections with VSV are rare. However, several cases of VSV infection have been reported in individuals directly exposed to infected livestock and researchers directly exposed within laboratory environments (Lyles and Rupprecht, 2007). Most VSV infections are thought to be asymptomatic in humans; however, febrile illness, including chills, myalgia, and nausea, has been reported in infected individuals (Roberts et al., 1999).

The VSV genome is simple and well characterized at the molecular level, which makes the manipulation and production of VSV vaccine vector relatively easy. Replication of the virus occurs within the cytoplasm of infected cells and is not known to undergo genetic recombination or integration into the cellular genome. Similar to Ad-based vector, recombinant VSV is able to accommodate relatively large inserts and multiple genes in its genome. This ability to incorporate multiple inserts of significant sizes also offers advantages over other RNA virus vectors, such as those based on alphaviruses and poliovirus (Davis et al., 1996; Liljestrom and Garoff, 1991; Morrow and Rixon, 1994; Xiong et al., 1989).

VSV can stimulate robust immune responses against self as well as foreign viral antigens making this virus a potent vaccine carrier. Several candidate vaccines based on VSV were shown to elicit immune protection correlating with strong humoral and cellular immune responses in different animal models (Dietzchold and Rupprecht, 1996; Zinkernagel et al., 1978). The VSV vaccine platform was the first to prevent AIDS in nonhuman primates infected with SHIV, a hybrid human and simian immunodeficiency virus that is lethal to macaques (Li et al., 1992). VSV-based vaccine has since then demonstrated efficacy against a number of pathogens, such as herpes simplex 2, tuberculosis, *Listeria monocytogenes*, SARS, Lassa virus, EBOV, and MARV viruses, in different animal models including mouse, guinea pigs, and nonhuman primates (Geisbert et al., 2005; Jones et al., 2005; Kapadia et al., 2005; Klas et al., 2006; Natuk et al., 2006; Xing and Lichty, 2006). Neutralization of VSV-based vaccines is unlikely to be problematic in humans since there is a low rate of preexisting immunity to VSV as demonstrated by the low seroprevalence of VSV antibodies in the general population (Roberts et al., 1999). Several of these VSV vaccine vectors remain replication-competent, which probably explains, at least in part, the substantial immunogenicity inherent to this vaccine carrier. A unique and remarkable ability of VSV-based vaccine is the rapidity by which immunization induces protection. Nonhuman primates can survive a lethal challenge when vaccinated 30 minutes after exposure to EBOV (Feldmann et al., 2007) and MARV (Daddario-DiCaprio et al., 2006a, 2006b). Cross-protection was also demonstrated with the VSV-MARV vaccine in nonhuman primates against a closely related strain of MARV. However, cross-protection against EBOV was not achieved following immunization with the VSV-MARV vaccine (Daddario-DiCaprio et al., 2006a).

Routes for Vaccine Delivery

The route of vaccine administration can have a significant effect on the strength of the immune response against a given pathogen. In general, parenterally administered vaccines largely stimulate systemic responses, whereas vaccines administered by a mucosal route may lead to efficient mucosal and

systemic responses through different mechanisms (Lajeunesse et al., 2004; Boyaka et al., 2003). Mucosal vaccination can also overcome barriers of parenteral immunization caused by preexisting systemic immunity to the vaccine carrier from previous exposure (e.g., natural infection, vaccination) (Basset et al., 2003; Zhou and Ertl, 2006). Rapid progression of filovirus infections and the level of biohazard containment required for analysis of clinical samples have significantly hindered identification of the components of the immune system necessary for effective protection against infection. A prominent feature of fatal EBOV infection is the relative lack of a virus-specific immune response (Baize et al., 1999, 2002; Heffernan et al., 2005). In contrast, survivors have exhibited strong IgM antibody responses, clearance of viral antigen, and sustained T cell responses (Ksiazek et al., 1999; Leroy et al., 2001; Sanchez et al., 2004). This strongly suggests that both cellular and humoral immune responses are necessary for protection against EBOV infection. Administration of filovirus vaccines currently in development by various routes may provide some insight to the types of immune responses necessary for protection against infection.

To date, the primary method of administration of filovirus vaccine candidates is by intramuscular injection (Bramwell et al., 2005; Jones et al., 2005; Sullivan et al., 2000), the same route by which many newly approved vaccines are being administered (Arvin and Greenberg, 2006). Although this route of delivery ensures that the entire vaccinating dose and formulation enters the body intact, it poses significant safety risks for healthcare providers, patients, and the community. This is especially important in developing countries where not only is the demand for these vaccines high, but also the rate of occupational needle-stick injuries (Pruss-Ustun et al., 2005). As a result, significant training programs must be in place prior to mass vaccination campaigns, which may be necessary in the event of a sudden outbreak of infection. In addition, actions necessary to prevent disease transmission significantly reduce the number of people that can be vaccinated in a reasonable amount of time, and limit the utility of this delivery method when national vaccination campaigns are required.

Needle-free vaccine delivery is an attractive vaccination strategy for many reasons. Vaccines administered in this manner will offer improved safety with respect to disease transmission and reduce the pain associated with vaccination. In many cases, self-vaccination may be possible. This approach also increases the potential for the vaccine to be formulated and produced in a manner that may reduce or abolish the necessity for maintaining the "cold chain" required for proper storage of vaccines to remote areas, which has been estimated to burden worldwide programs (Das, 2004). For these reasons, this method of delivery is supported by many public health organizations, including the World Health Organization, the Global Alliance for Vaccines and Immunization and the Centers for Disease Control and Prevention (Giudice and Campbell, 2006). Currently, needle-free vaccine delivery approaches focus on administration under the skin (the subcutaneous route), the external surface of the skin (the transdermal route) and mucosal surfaces, specifically oral and nasal immunization. To date, mucosal immunization is the only method of needle-free vaccine delivery that has been commonly and successfully used in vaccination programs and which may be useful in the design of vaccination strategies against filoviruses (Bramwell et al., 2005; Levine and Sztein, 2004; Neutra and Kozlowski, 2006).

Several Ad or VSV-based vaccine candidates designed to afford protection against infection with *Mycobacterium tuberculosis,* influenza, papilloma virus, rabies, measles, respiratory syncytial virus, and HIV have also been administered by the intranasal route (Jiang et al., 2006; Kahn et al., 2001; Publicover et al., 2005; Reuter et al., 2002; Roberts et al., 1998; Schlereth et al., 2003; Xing and Lichty, 2006; Zhou et al., 2006). A recombinant HPIV3 vector expressing the EBOV GP could fully protect guinea pigs following intranasal vaccination (Bukreyev et al., 2006). Two doses of this vector with granulocyte-macrophage colony-stimulating factor could also afford complete protection to nonhuman primates vaccinated through the respiratory route (Bukreyev et al., 2007). Results from many studies strongly suggest that both Ad and VSV vectors are capable of crossing the respiratory tract and inducing strong cellular and humoral immune responses after a single immunization. Recently, reports indicated that nasal administration of Ad or VSV-based Ebola vaccine induces full protection of mice against a lethal challenge with ZEBOV (Jones et al., 2007; Patel et al., 2007). In the future, intranasal vaccination strategies against filovirus infection may prove a useful alternative to intramuscular immunization. This may become extremely relevant in the context of sudden outbreaks and malicious intentional release.

PROSPECTS: PHARMACOLOGY AND TOXICOLOGY OF VACCINES AND VACCINE VECTORS

In general, the primary component of a vaccine is either the pathogen of interest in an inactivated or

an attenuated form, a purified protein subunit of the pathogen, or a plasmid or other vector (virus or bacterial) capable of eliciting endogenous production of antigenic components of the target pathogen (Barouch, 2006; Clark and Cassidy-Hanley, 2005; Dudek and Knipe, 2006; Mayr et al., 2005). Other components of vaccine products, which cannot be discounted during preclinical development, are adjuvants to promote and strengthen the immune response, excipients for stabilization of antigens and vectors, and the delivery device/container closure system. The pharmacology and toxicology of filovirus vaccines is not well studied and relevant studies are currently in progress.

PROSPECTS FOR THE FUTURE

Despite several promising results, vaccine development is still in the experimental stages. The process of moving an experimental vaccine candidate into clinical trials is a time-consuming and expensive process. It has become clear that the rodent models (mouse and guinea pig), although important for the development of antivirals, therapeutics, and vaccines, are not necessarily predictive for the efficacy of the same drugs in nonhuman primates, which are the gold standard for predicting efficacy in humans. A lack in proper biocontainment, in particular animal space, has been a major drawback in the process of vaccine development against filoviruses and related high-containment pathogens. This lack will most likely be properly addressed in the future with the current construction of several facilities in the United States and worldwide. Vaccine development also needs industrial partners, which are largely missing today. Programs need to be established that will make it interesting for companies to contribute to the development of approved vaccines for human use. Nevertheless, it is expected that a first-generation MARV and EBOV vaccine will be available over the next decade at least for medical, personal, first responder, and other high-risk professional groups.

KEY ISSUES

- Ebola and Marburg hemorrhagic fevers are considered highly communicable diseases.
- Bats might serve as reservoirs for EBOV and MARV.
- Currently there is no licensed treatment for or vaccine against EBOV and MARV.
- Progress has been made to understand the pathogenesis of EBOV and MARV in experimentally infected animals, and massive virus replication, immune suppression, vascular leakage, and organ destruction have been identified as key determinants.
- Several vaccine candidates have shown promising results in the protection against EBOV and MARV challenges in different animal models. The most promising candidates are based on replication-deficient Ad vectors, replication-competent vesicular stomatitis and HPIV3 vectors, and VLP preparations.
- There is little understanding about protective parameters in the host and correlates of protective immunity have not been well defined.
- To have utility in outbreak and biodefense settings as well as for laboratory exposures, the ideal preventive vaccines against EBOV and MARV need to confer protection in a single-dose regime and/or work in post-exposure prophylaxis.
- It is expected that first-generation vaccines will be available against EBOV and MARV over the next decade at least for high-risk exposure groups and post-exposure treatment.

Alphaviral Encephalitides

Scott C. Weaver and Slobodan Paessler
Department of Pathology, Centers for Tropical Diseases, and Biodefense and Emerging Infectious Diseases, and Sealy Center for Vaccine Development, University of Texas Medical Branch, Galveston, TX, USA

OUTLINE

ABSTRACT

Alphaviruses that typically cause encephalitis include eastern (EEEV), Venezuelan (VEEV), and western equine encephalitis viruses (WEEV). All are important emerging viral pathogens of humans, equids, and other domesticated animals. Although these viruses do not exhibit the high human fatality rates characteristic of some more virulent biothreat viruses, all are highly infectious via the aerosol route and highly incapacitating,

making them biothreat agents. Despite vaccine development efforts dating back many decades, licensed human vaccines are not available. Investigational new drug vaccines against VEEV and EEEV are offered to at-risk laboratory workers through the U.S. Army Special Immunizations program. However, these vaccines suffer from reactogenicity and poor rates of seroconversion (VEEV) and poor immunogenicity requiring multiple doses and frequent boosters (EEEV). Veterinary vaccines are widely available in America but most suffer from poor and short-lived immunogenicity, and the risk of residual, virulent virus in inactivated preparations. Recent advances in understanding of molecular aspects of alphavirus pathogenesis and genetics promise improvements in live-attenuated vaccines against all three encephalitis alphaviruses, as well as safer virus strains for inactivated vaccine preparations. Virus-like particles that express either alphavirus or other antigens, based on alphavirus replicon genomes, are also being widely developed as vaccine platforms.

INTRODUCTION

Alphaviral encephalitides comprise three groups of viruses in the family *Togaviridae*, genus *Alphavirus*: the eastern (EEEV), western (WEEV), and Venezuelan equine encephalitis viruses (VEEV) (Weaver et al., 2005). Like most alphaviruses, they are all mosquito-borne, relying on biological (requiring replication in the mosquito vector), and horizontal transmission in nature (Griffin, 2007). All are also zoonotic viruses that rely on birds or small mammals as reservoir hosts within enzootic foci of transmission. These viruses regularly cause encephalitis in humans and equids in many regions of the tropical, subtropical, and temperate Americas (Tsai et al., 2002). Although other alphaviruses, including Sindbis and Semliki Forest viruses, cause encephalitis in laboratory mice, and have been used as models of human encephalitis, only EEEV, VEEV, and WEEV cause encephalitis during natural transmission. All three were isolated during the early part of the 20th century and are relatively well understood from an epidemiologic and ecologic standpoint. However, little progress has been made in preventing or controlling human disease. Effective veterinary vaccines have contributed to reducing disease in equids and other domestic animals, but no licensed human vaccines have been produced. Furthermore, no effective antivirals have been identified and protection of the human population remains focused on vector control and limiting exposure to mosquito bites (Tsai et al., 2002).

SHORT HISTORY OF THE DISEASES

Alphaviral encephalitides were first recognized in the 19th century in the northeastern United States, where outbreaks of equine encephalitis consistent with EEE were noted (Hanson, 1957). Equine outbreaks consistent with VEE were first recognized in northern South America during the 1920s (Walton and Grayson, 1988), and WEE outbreaks were first recognized in California in 1930 (Reisen and Monath, 1988). Virus isolations were made shortly after the recognition of a likely viral etiology for these epizootics; EEEV was first isolated from horses in Argentina in 1930 (not identified until later) and in the eastern United States in 1933 (Ten Broeck and Merrill, 1933); VEEV was first isolated from a horse in Venezuela in 1938 (Kubes and Rios, 1939; Beck and Wyckoff, 1938), and WEEV was isolated from a horse in California in 1930 (Meyer et al., 1931). Human isolates of all three viruses followed soon thereafter, although VEEV was not recognized as an important human pathogen until the 1960s (Weaver et al., 2004). These three different alphaviruses were quickly recognized as distinct using in vivo neutralization tests, and later characterized in greater detail using complement fixation, hemagglutination inhibition, plaque reduction neutralization, and other serological tests.

ETIOLOGIC AGENTS

Classification

The alphaviruses were initially categorized as group A arboviruses based on antigenic relationships and virion morphology (Calisher et al., 1980). Although originally grouped with the flaviviruses as members of the family *Togaviridae*, genetic studies later revealed fundamental differences in genome organization, and other genetic and replication characteristics. Eventually, the alphaviruses became one of two genera in the family *Togaviridae*, the other being Rubella virus, the sole member of the genus *Rubivirus* (Weaver et al., 2005). Currently, the genus *Alphavirus* includes 29 species; several include antigenically or genetically based subtypes, which can have fundamental differences in epidemiological and virulence properties. All alphaviruses are arthropod vector borne except for

Salmon pancreatic disease and Southern elephant seal viruses, which have not been demonstrated to have vectors.

Antigens Encoded by Agent

The alphavirus genome encodes seven major proteins; four of these are called nonstructural because they are not incorporated into virus particles (Fig. 21.1). The nonstructural proteins are translated from genomic, positive strand RNA in the cytoplasm and participate in various ways in genome replication and modifications, and in their own nonstructural polyprotein processing. Differential temporal cleavage patterns of the nonstructural polyprotein regulate the synthesis of plus and minus strand RNA during replication. The structural proteins are encoded by a separate open reading frame that is transcribed as a subgenomic message and synthesized in excess of the genomic RNA. The structural polyprotein is translated in the cytoplasm in the following order; the capsid, followed by the E2 and E1 envelope glycoprotein. The capsid possesses a serine protease activity, cleaves itself from the nascent polyprotein, and remains in the cytoplasm. The remainder is processed through the secretory apparatus with cellular proteases responsible for further cleavages. Both E2 and E1 are glycosylated, and become embedded into the plasma membrane as heterodimers. Virions mature when 240 copies of the capsid protein combine in the cytoplasm with 1 molecule of genomic RNA to form a nucleocapsid; the nucleocapsid then recognizes the cytoplasmic tail of the E2 protein to initiate budding, which results in envelopment of the virion by the plasma membrane and 240 copies of the embedded E2/E1 dimer. The final arrangement includes 80 trimers of the E2/E1 dimers, which form spikes on the virion surface (Fig. 21.1). The E2 proteins protrude to form the outer part of these spikes, while the E1 protein lies primarily underneath, parallel with the envelope (Pletnev et al., 2001). Of the structural proteins, only the E1 structure has been solved to atomic resolution, and is homologous to the flavivirus E protein (Lescar et al., 2001).

Preparation of alphavirus antigens for serological tests can rely on cell cultures or animal tissues (Beaty et al., 1989). In either case, antigens extracted are composed primarily of the structural proteins, which are produced in much greater quantities than the nonstructural proteins in infected cells. Antigens produced from purified virus include only the structural proteins. Hemagglutination relies primarily on the E1 protein, which contains a highly conserved fusion motif thought to mediate endosome membrane fusion at low pH for entry into the cytoplasm following receptor-mediated endocytosis. However, E2 also has some involvement. This E1 fusion motif is exposed upon a reduction to acidic pH (Gibbons et al., 2004). Most neutralization epitopes, determined by the binding sites of monoclonal antibodies that neutralize infectivity, are found on the E2 protein, with a few mapped to E1. The E2 protein is also thought to be the most important for interactions with cellular receptors, which are poorly understood for alphaviruses. The E1 protein contains more epitopes conserved among alphaviruses than E2, and this probably explains the greater cross-reactivity seen among alphaviruses in E1-dependent hemagglutination inhibition tests than in neutralization. Specific E2 and/or E1 epitopes have been mapped and characterized in some detail for VEEV, WEEV, and EEEV (Roehrig and Bolin, 1997; Roehrig, 1993; Pereboev et al., 1996; Roehrig et al., 1990).

PROTECTIVE IMMUNE RESPONSE

Antibody

Alphavirus infection induces a typical humoral immune response, with IgM appearing within one

week of infection and persisting for a few months. The IgG response usually appears after 1–2 weeks and persists for years. A variety of evidence indicates that titers of serum-neutralizing antibodies are strongly predictive of protection against alphaviral disease (Griffin, 2007; Tsai et al., 2002). The end of viremia often coincides with the first appearance of IgM, and passive transfer studies have demonstrated that antibodies can protect against VEE and WEE, including both neutralizing and non-neutralizing, and those directed against E2 and E1 (Hunt and Roehrig, 1985; Roehrig, 1993). Protection from VEEV infection is apparently mediated primarily by antibody. However, the correlation between protection and neutralizing serum antibody titers is inconsistent when infection is aerosol-mediated (Elvin et al., 2002); induction of local respiratory tract immunity, including specific IgG and IgA, potentially correlates with protection against aerosol exposure.

Cell-Mediated Immunity

Alphaviruses induce cell-mediated immunity including CD4 and CD8 T lymphocytes, and macrophages. The role of cell-mediated immunity in recovery and protection from disease is not well established (Griffin, 2007). In fact, some studies have failed to identify any cell-mediated immunity after VEEV (Jones et al., 2003) and Sindbis infection of mice (Rowell and Griffin, 2002). However, cell-mediated immunity in combination with innate and humoral immunity may be required to prevent the development of encephalitis and/or for clearance from the brain. Mice with selective immune deficiencies can be protected by vaccination against VEEV, with the α/β T cell subset playing a more important role than γ/δ T cells (Paessler et al., 2007). Sindbis virus RNA has been shown to persist in the brains of infected mice, and can be cleared noncytolytically by a combination of antibodies directed at the E2 protein and interferon gamma (Griffin et al., 1997; Binder and Griffin, 2001). Attenuated variants of VEEV replicate persistently in the brains of some immunodeficient animals after challenge with wild-type virus (Paessler et al., 2007).

EPIDEMIOLOGY

All three alphaviral encephalitides are zoonotic, mosquito-borne viruses that are maintained in enzootic cycles by small mammalian or avian reservoir hosts. VEEV occurs in forest or swamp habitats ranging from North to South America (Fig. 21.2). VEEV emerges to cause equine epizootics and epidemics when enzootic variants, generally in subtype ID that occur in northern South America, mutate to become equine virulent and viremia competent (Weaver et al., 2004; Greene et al., 2005b; Anishchenko et al., 2006). Equine amplification in agricultural settings results in widespread spillover to humans who reside near horses, donkeys, and mules. In contrast, EEEV and WEEV do not rely on amplification in secondary hosts, but spill over directly from enzootic, avian cycles into humans and domestic animals that reside near these habitats. In the case of EEEV, enzootic circulation in North America occurs in hardwood swamp habitats inhabited by the enzootic vector, *Culiseta melanura*, and possibly other *Culex* spp. vectors (Cupp et al., 2004; Weaver, 2001). In Central and South America, forest habitats are the sites of enzootic foci and *Culex* (*Melanoconion*) spp. are the most common vectors. In Latin America, EEEV is associated with little human disease, probably due to inherently reduced virulence compared to North American strains (Aguilar et al., 2005, 2007a). WEEV occurs in avian cycles associated with agroecosystems in western North America, South America, and probably Central America. In North America, *Cx. tarsalis* is the principal vector, while other mosquitoes probably transmit in Latin America (Reisen, 2001; Reisen and Monath, 1988).

Significance as Public Health Problem

Of the three alphaviral encephalitides, VEEV is by far the most important pathogen both from a human and equine standpoint. Epidemics and equine epizootics have typically involved up to hundreds of thousands of cases in both hosts, with high mortality rates in equids and high morbidity in humans. Attack rates in both hosts often exceed 50% in affected areas, and most human infections are apparent (Bowen and Calisher, 1976). Mortality in horses, usually due to overt encephalitis, is typically 30–80%. Humans usually develop a severe, highly debilitating febrile illness, and some patients, especially children, develop neurological disease with convulsions, disorientation, and drowsiness, occasionally culminating in coma and death. Although overall mortality rarely exceeds 1% in humans, rates of neurological disease and permanent sequelae are usually 5–15%. Epidemiologic studies have also identified teratogenic effects of human VEEV infection with many premature abortions and stillborn births during outbreaks (Rivas et al., 1997; Briceno Rossi, 1967), and nonhuman primate studies have confirmed these findings (London et al., 1977).

Historically, EEEV and WEEV have caused massive equine epizootics involving thousands to tens of thousands of cases in North and South America.

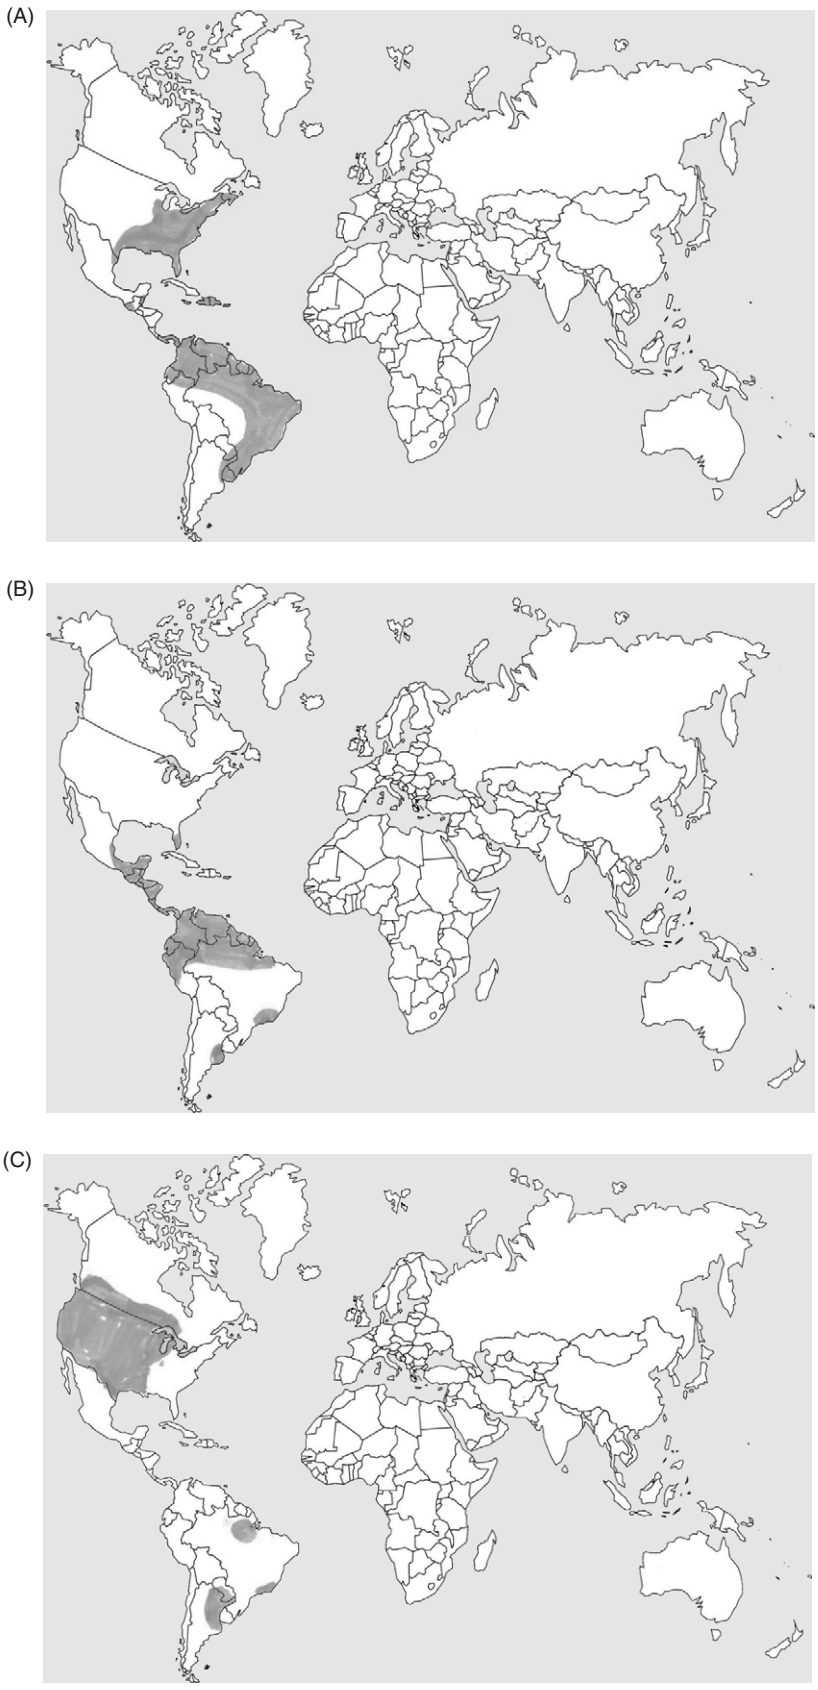

FIGURE 21.2 Map showing the distribution of the encephalitic alphaviruses: (a) VEEV, (b) EEEV, and (c) WEEV.

In North America, EEEV is also an important pathogen of emus, pheasants, turkeys, pigs, sheep, deer, and a variety of bird species (Beckwith et al., 2002; Gottdenker et al., 2003; Tate et al., 2005; Weaver, 2001; Bauer et al., 2005; Day and Stark, 1996). In recent decades, WEE epizootics have declined dramatically for unknown reasons (Reisen, 2001; Reisen and Monath, 1988), while EEEV has continued to cause sporadic epizootics involving hundreds of horses, primarily in states along the Atlantic and Gulf coasts (Weaver, 2001; Morris, 1988). However, human cases with both EEEV and WEEV have averaged only about 5 and 15 annually, respectively, since 1964.

In summary, EEEV and WEEV generate only small numbers of human cases and there is probably no potential for a commercial human vaccine market for these biothreats. VEEV causes considerable endemic and epidemic disease, but principally in developing countries of Latin America, so a commercially viable vaccine would need to be inexpensive.

Potential as Biothreat Agents

All three alphavirus encephalitides are considered potential biothreat agents (Sidwell and Smee, 2003). All can cause severe human disease, culminating in fatal encephalitis. However, rates of attack and apparent infection vary widely. VEEV causes high attack rates and high rates of apparent infection, but human cases are rarely fatal. The nonspecific febrile disease that precedes encephalitis is, however, highly debilitating as well as immunosuppressive. These characteristics of typical human VEE suggest that VEEV would be highly effective at immobilizing armed forces. Although mortality rates are low, the combination of extremely efficient aerosol infectivity and moderate (5–15%) rates of neurological disease in children also suggests that VEEV might be used for terrorism. In contrast to VEEV, EEEV causes high rates of inapparent human infections during natural epidemics; during a 1959 epidemic in New Jersey, the apparent: ratio was estimated at 1:23 (Goldfield et al., 1968). However, also in contrast to VEEV, apparent EEE cases usually lead to neurological disease that is often fatal. Survivors of EEEV infection often suffer permanent neurological sequelae, making it a feared virus in endemic locations. Although laboratory infections probably attributable to aerosol exposure have been reported, these cases are far fewer in number than for VEEV despite the fact that EEEV is isolated regularly in many state health laboratories in North America. This history, along with higher aerosol EEEV doses required to initiate primate disease (Reed et al., 2007) compared to VEEV (Reed et al., 2004, 2005b), suggests that EEEV is less infectious via the aerosol route.

The long history of laboratory infections suggests that VEEV is more infectious for humans than EEEV or WEEV (SALS, 1980; U.S. Department of Health and Human Services, 1999). Experimental aerosol infections of cynomolgous macaques corroborate these data; the VEEV ID_{50} is 7×10^4 PFU (Reed et al., 2004), while EEEV is more than 10 times higher (10^6 PFU) (Reed et al., 2007), as is WEEV (2×10^6 PFU, LD is >7.3 $\log_{10}$ PFU) (Reed et al., 2005a).

CLINICAL DISEASE

EEEV

According to the U.S. Centers for Disease Control and Prevention, 220 confirmed cases of EEE occurred in the U.S. from 1964 to 2004. EEEV is the most virulent of the encephalitic alphaviruses, with a case-fatality rate estimated at >33%. After a very short (4–10 days) incubation period symptoms begin with sudden onset of fever, headache, and general muscle pains of increasing severity. In human cases of encephalitis, fever, headache, vomiting, respiratory symptoms, leucocytosis, hematuria, seizures, and coma may occur. Surviving children generally suffer more severe sequelae. Death due to encephalitis usually occurs 2–10 days after the onset of signs and symptoms, and survivors generally suffer progressive, disabling mental and physical sequelae. These survivors usually live a normal life span, but without gainful employment, and a patient with sequelae costs an average of US$3 million in treatment expenses (Villari et al., 1995).

In Latin America, equine EEE outbreaks are common in some regions but there is little evidence of human disease (Weaver, 2001). EEEV-specific human antibodies have been reported in many regions of Latin America. However, no evidence of human disease has been found in Argentina despite intensive epidemiological studies following extensive equine epizootics, or in an enzootic focus near Iquitos, Peru where people are undoubtedly exposed to the virus (Aguilar et al., 2007a). It is likely that the South American variety of EEEV is less infectious and/or less virulent for humans than is the North American variety (Weaver, 2001).

VEEV

In equines and humans, VEEV causes a spectrum of disease ranging from unapparent to acute encephalitis

in all age groups, with no sex bias observed. However, children are more likely to develop fatal encephalitis and suffer permanent neurological sequelae than adults. VEEV also infects the fetus in pregnant women and causes birth defects as well as spontaneous abortions and stillborn births. In humans, the incubation period is usually 2–5 days (Johnson and Martin, 1974). Most infections are apparent with high attack rates during epidemics. Symptoms appear abruptly, including malaise, fever, chills, and severe retroorbital or occipital headache. Myalgia typically centers in the thighs and lumbar region of the back. Signs usually include leukopenia, tachycardia, and fever, frequently accompanied by nausea, vomiting, and diarrhea. Signs and symptoms of central nervous system (CNS) disorders occur less frequently and typically include convulsions, somnolence, confusion, and photophobia. Acute disease usually subsides 4–6 days after onset, followed by asthenia that can last for several weeks. The illness is sometimes biphasic with recurrence 4–8 days after onset. A small proportion of human cases proceed to stupor and coma, sometimes followed by death (generally less than 1% of cases).

WEEV

Following an incubation period of about 2–10 days, WEEV causes a broad spectrum of human disease ranging from unapparent to fatal encephalitis. Illness typically begins with the sudden onset of headache, followed by dizziness, chills, fever, myalgias, and malaise (Tsai et al., 2002). Prodromal symptoms intensify over several days, often with an acute exacerbation of dizziness and vomiting, increasing somnolence or confusion. Neck stiffness is present in about 50% of cases, and neurologic signs usually include weakness and generalized tremulousness, especially of the hands, lips, and tongue. Stupor or coma develop in $<$10% of cases. General improvement begins several days after the defervescence of fever, typically within a week to 10 days after the onset. In infants, the initial presentation and clinical progression is more rapid, evolving from a nonspecific illness of fever, irritability, and diarrhea to convulsions and coma. Overall, mortality is 4% and is highest among the elderly, although serious sequelae are more common in recovered infants and children, including extensive brain damage resulting in mental retardation, developmental delays, convulsions, spasticity, and extrapyramidal movement disorders. Perinatal illness following late trimester or postpartum maternal infection have also been reported.

TREATMENT

Treatment of VEE, EEE, and WEE is limited to supportive therapies to maintain fluid balance and prevent intracranial pressure. Little can be done to prevent neurological disease and death in infected patients (Tsai et al., 2002; Weaver, 2001). Intracranial pressure, which contributes to morbidity and mortality, can be treated, as well as convulsions. Airway protection is needed in patients with loss of consciousness, along with hyperventilation accompanied by anesthesia and sedation. Cerebral blood flow can be maintained via $PaCO_2$ regulation. Brain swelling can be minimized by regulating serum sodium and osmolarity.

Because EEEV, VEEV, and WEEV are maintained in zoonotic mosquito-borne transmission cycles often found in swamps and forests, little can be done in an ecologically acceptable manner to control virus circulation (Weaver, 2001). Control usually relies on early detection of enzootic amplification in birds or rodents, followed by mosquito control to reduce vector populations. Sentinel birds used for detection of seroconversion, as well as adult female mosquito collections for virus isolation, can detect high levels of EEEV and WEEV circulation. Equine disease usually precedes human VEE disease. Personal protection against mosquito bites is usually the most effective means of VEE, EEE, and WEE prevention, especially for individuals who reside, work, or recreate near equids (VEE) and enzootic habitats (EEE, WEE). Equine vaccination is effective in preventing VEE epizootics and epidemics, but must be maintained continuously, especially in northern South America where the progenitors of major outbreaks occur (Weaver et al., 2004).

Although Ribavirin has been shown to have some inhibitory effect on alphaviruses in vitro, no human trials have been described. Because neurological disease follows a prodromal illness for at least several days to about a week, human cases are often diagnosed when acquired immunity is already detected and virus is cleared from the periphery. At this time, it is unlikely that antiviral treatment alone can control CNS disease. Stimulators of innate immunity, such as poly-IC, or interferons administered directly are known to prevent alphaviral disease in animals when administered before or soon after infection (Worthington et al., 1973; Worthington and Baron, 1971; Finter, 1966; Bradish and Titmuss, 1981; Aguilar et al., 2005). However, early treatment is generally impossible because the alphavirus incubation period is usually 24h or longer. Based on previous studies

(Coppenhaver et al., 1995), combination treatments of poly-IC and alphavirus antibodies (Phillpotts et al., 2002) may protect against disease even if administered after invasion of the CNS, and should be explored further.

PATHOGENESIS

Description of the Disease Processes

EEEV

Pathogenesis of EEEV infections leading to invasion of the human CNS is poorly understood. Clinical studies using magnetic resonance imaging and computed tomography show changes in the basal ganglia and thalami suggesting brain edema, ischemia, and hypoperfusion in the early stage of disease (Deresiewicz et al., 1997). Gross pathological investigations of fatal human cases report brain edema with necrosis, facial or generalized edema, vascular congestion and hemorrhage in the brain and visceral organs (Farber et al., 1940; Femster, 1938, 1957; Getting, 1941; Azimi and Grossman, 1997; Jordan et al., 1965; Bastian et al., 1975). Loss of neurons, perivascular cuffing, microglial proliferation, vasculitis, and focal inflammatory infiltration are the most typical findings of human encephalitis. Vascular lesions are also common with thrombi and extravasation of red cells, and necrosis and demyelinization also occur (Rozdilsky et al., 1968). In the brain, antigen is localized to the perikaryon and neuronal dendrites, with little detected in glial cells (Garen et al., 1999). Cell death by apoptosis is conspicuous, primarily in glial and inflammatory cells. Neuronal death is associated with cytoplasmic swelling or eosinophilia and nuclear pyknosis. The degree of inflammation is not correlated with the presence of antigen, especially in cerebral cortex and spinal cord, where infected cells already have presumably been cleared before death of the patient. EEEV infection is also accompanied by visceral and pulmonary congestion. Apoptosis occurs in glial and inflammatory cells, but is less commonly associated with neuronal cell death (Garen et al., 1999). Similar lesions occur in primates after intracerebral inoculation (Nathanson et al., 1969).

Mice (Liu et al., 1970), hamsters (Paessler et al., 2004), guinea pigs (Walder et al., 1980), and rhesus (Nathanson et al., 1969) and Cynomolgus macaques (Reed et al., 2007) have been used for experimental EEE pathogenesis studies. Murine models for EEEV (Liu et al., 1970) reproduce the lymphoid involvement and cerebral pathology. Most strains of EEEV produce high rates of fatal encephalitis in peripherally infected mice (Schoepp et al., 2002; Liu et al., 1970); hamsters more faithfully reproduce the vasculitis associated with microhemorrhages in the brain that dominates the pathological picture in fatal human EEE (Paessler et al., 2004). In mice, initial replication is detected in fibroblasts, osteoblasts, and skeletal muscle myocytes near the site of subcutaneous infection (Vogel et al., 2005). Virus is first detected in the brain one day after infection, with rapid interneuronal spread leading to direct neuronal death by day 4. Invasion of the CNS by EEEV probably occurs by a vascular route, rather than via peripheral nerves or the olfactory bulb like VEEV. In hamsters, neuronal cell death is detectable only in late stages of disease after EEEV replicates in a variety of visceral organs, produces viremia, and penetrates the brain (Paessler et al., 2004). In general, the virus is capable of establishing productive infection in all parts of the mouse or hamster brain. Experimental studies have suggested early infection of periventricular and perivascular neuronal cells in the basal ganglia and hippocampus (Paessler et al., 2004). In contrast to VEEV, EEEV appears to rapidly infect the brain of animals via the blood, and the first antigen-positive neuronal cells are located in the basal ganglia and brain stem in the hamster model (Paessler et al., 2004). Certain findings in animal models, such as the hamster, are similar to early clinical manifestations of EEEV infections in humans. The inflammatory response can be very prominent in the brain if animals survive at least five days and is usually produced by macrophages, lymphocytes, and neutrophils. Some of the animal models also display the peripheral pathological changes described in fatal human EEE cases, including congestion and numerous microhemorrhages in the liver, spleen, and lung (Fig. 21.3).

VEEV

The infection of humans mostly produces a "flu-like" disease, and neurological disease (VEE) may be characterized by disorientation, ataxia, mental depression, and convulsions, which can be detected in up to 14% of infected individuals, especially children (Johnson and Martin, 1974). Overall mortality rates during epidemics rarely exceed 1%. Sequelae following VEE-related neurological disease in humans and rats is common and described elsewhere (Leon, 1975; Garcia-Tamayo et al., 1979). The typical complication of VEEV infections that is reported is a long-term immunosuppression in patients upon clinical recovery. The predominant pathological findings in fatal human VEE cases reveal: (a) in the CNS: edema, congestion,

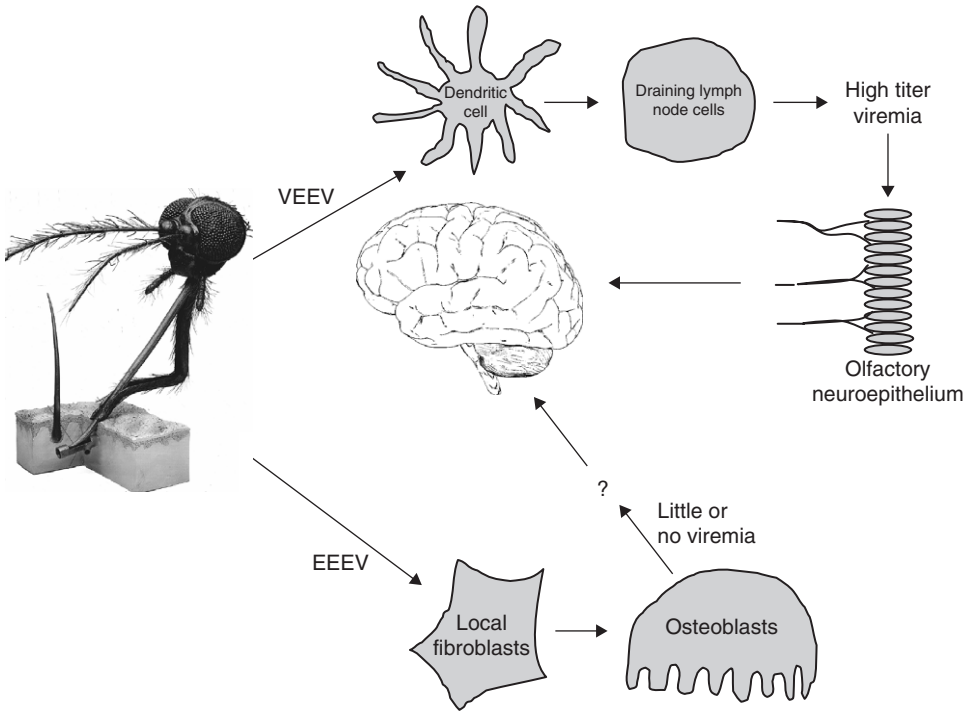

FIGURE 21.3 Illustration of VEEV and EEEV pathogenesis based on findings in the mouse models. WEEV pathogenesis is less well understood, but probably more closely resembles that of EEEV because there is little evidence of extensive lymphoid involvement. Most studies of peripheral infection have used needle inoculation of animals, but mosquitoes deposit alphavirus-infectious saliva both intra- and extravascularly in the dermis (Smith et al., 2006; Turell and Spielman, 1992), so natural, mosquito-borne pathogenesis could differ.

hemorrhages, vasculitis, meningitis, and encephalitis; (b) in the lungs: interstitial pneumonia, alveolar hemorrhage, congestion, and edema; (c) in lymphoid tissue: follicular necrosis and lymphocyte depletion; and (d) in the liver: diffuse hepatocellular degeneration (de la Monte et al., 1985; Ehrenkranz and Ventura, 1974; Johnson et al., 1968). Laboratory mice, hamsters, and guinea pigs are well developed as animal models for VEE, with a murine model for VEEV-induced encephalitis and lymphotropism being established (Davis et al., 1994, 1995; Kundin, 1966; Jackson et al., 1991). Previous studies have demonstrated that the murine model is characterized by biphasic disease, which starts with the productive infection of lymphoid tissue and ends in the destruction of the CNS by viral replication and a "toxic" neuroinflammatory response, which is uniformly lethal (Gorelkin, 1973; Grieder et al., 1995, 1997; Schoneboom et al., 1999, 2000; Garcia-Tamayo et al., 1979; Ryzhikov et al., 1991, 1995). By the time encephalitis has developed in an infected mouse, the infectious virus is usually absent from the peripheral organs and blood. However, virus replicates to high titers in the brain and mice die 5–7 days after infection due to fatal encephalitis (Anishchenko et al., 2004; Paessler et al., 2003). The route of VEEV invasion of the CNS has been studied extensively, and appears to rely on entry into the brain via the olfactory nerve and possibly the dental nerves (Ryzhikov et al., 1995; Charles et al., 1995; MacDonald and Johnston, 2000; Aronson et al., 2000). All VEEV strains including enzootic and epizootic produce similar disease in a variety of mouse strains, both inbred and outbred (Wang et al., 1999).

WEEV

Like the other human alphaviral encephalitides, WEE pathogenesis is poorly understood. In postmortem examinations the brain appears normal or exhibits a moderate degree of vascular congestion (Tsai et al., 2002). Perivascular infiltrates of lymphocytes, plasma cells, and neutrophils are characteristic, along with vascular necrosis in some cases. Lesions are distributed mainly in the subcortical white matter, the internal capsule, thalami, basal ganglia, substantia nigra, dentate nucleus, and molecular layer of the cerebellum and gray matter of the brainstem and spinal cord. Neurons are found in various stages of degeneration. Widely scattered focal areas of demyelination are seen.

Although pathogenesis studies of WEEV in small animal models are quite limited, the mouse has

received most of the focus. With many WEEV strains, only partial mortality occurs following peripheral infection; higher levels of mortality accompany intracranial and intranasal infection (Liu et al., 1970; Julander et al., 2007). Bianchi et al. (1993) studied three epizootic (associated with equine epizootics) WEEV strains (McMillan, CBA87, and CBACIV 180) and an enzootic strain (AG80-646). Neurovirulence and neuroinvasiveness for adult mice correlated with viremia and virus replication in the brain. Epizootic viruses were neurovirulent and neuroinvasive, whereas the enzootic strain was attenuated. Intranasal infectivity of eight WEEV strains revealed that all were 100% lethal for adult BALB/c mice, with some variation in the time to death (Nagata et al., 2006). Based on the time of death the high-virulence phenotype (rapid death) included strains California, Fleming, and McMillan, and the low-virulence group included CBA87, Mn548, B11, Mn520, and 71V-1658.

Histopathological findings of WEEV infection in baby mice include lesions in muscle, cartilage, and bone marrow (acute necrotizing degeneration), while infection in three-week-old mice causes diffuse meningoencephalitis and lesions in the heart, lungs, kidney, liver, and brown fat (Aguilar, 1970; Monath et al., 1978). In addition to mice, guinea pigs, rabbits, and newborn chickens have also been evaluated as models for WEE along with hamsters. Guinea pigs suffer fatal disease from epizootic strains but survive enzootic AG80-646 strain infection. However, rabbits showed the inverse pattern of disease, with the enzootic strain lethal (Bianchi et al., 1997). Viremia level correlated with the virulence in all of these models. In hamsters, (Julander et al., 2007) infected intraperitoneally, disease progression is rapid, with viremia and virus replication in the brain, liver, and kidney 2–4 days after inoculation. Foci of virus replication occur in neurons of the cerebral cortex and midbrain. In cynomolgous macaques, WEEV produces partial fatality when administered in high doses via the aerosol route (Reed et al., 2005a). Three to four days of fever occur four to six days after infection. Clinical signs of encephalitis begin coincident with fever onset, and progress rapidly, accompanied by elevated white cell counts (predominantly neutrophils and monocytes). Immunohistochemical evidence of WEEV antigen is found in the brain and CNS, along with a marked lymphocytic infiltrate (Reed et al., 2005a).

Immune Response to Infection

IFN-α and -β are important in protecting against alphaviral disease (Grieder and Vogel, 1999; Spotts et al., 1998). Previous studies showed a correlation between alphavirus virulence and resistance to IFN-α and -β. Some studies with VEEV suggested that the IFN-α and -β resistance or sensitivity phenotype correlated with epizootic potential and equine virulence (Spotts et al., 1998; Jahrling et al., 1976), although others observed little or no difference (Anishchenko, 2004). In contrast, IFN-γ is believed to have a lesser role in protecting against alphavirus infection.

The appearance of neutralizing IgM usually coincides with the clearance of peripheral infection, but replication in the CNS continues. Noncytolytic clearance of SINV from the murine CNS involves immune-mediated, noncytolytic clearance from neurons, an activity that requires both CD4+ and CD8+ T cells, and that T cells mainly require IFN-γ for clearing virus from certain neuron populations (Binder and Griffin, 2001). However, RNA can persist after infectious virus is no longer detected. The early lymphoid phase of VEEV infection ends with the appearance of IgM about 3–4 days postinfection, and the CNS pathology in a VEEV-infected mouse has a significant immunologic component in addition to direct killing of neurons via apoptosis (Charles et al., 2001). Although neutralizing antibodies are believed to be the principal determinants of immune protection, recent studies of vaccinated mice with immune deficiencies indicate that antibodies are not absolutely required for protection, and that α/β T cells can also protect against fatal disease (Paessler et al., 2006, 2007). IFN-γ receptor KO mice did not show any major difference in viremia or mortality compared to wild-types, supporting the conclusions of previous studies that showed no difference in disease outcome in IFN-γ-receptor deficient mice infected with SFV (Muller et al., 1994).

Detailed studies of the immune response to VEEV strain TC-83 demonstrate immune responses in draining lymph nodes 24 h following murine vaccination, with increased levels of activated B cells and both CD4(+) and CD8(+) T cells (Bennett et al., 2000). Activated monocyte/macrophages and natural killer cells are also seen between 6 h and 7 days postvaccination. VEEV-specific IgG appears in the serum on day 5 postvaccination, with titers rising on days 7, 14, and 21. Isotypes of IgG measured on days 7 and 21 are predominantly of the IgG2a subclass, indicating a Th1-mediated response. Cytokine mRNAs detected in the serum include the Th1 cytokine IFN-γ and the inflammatory cytokine TNF-α, whereas the Th2 cytokine IL4 is not detected (Bennett et al., 2000).

In studies with Sindbis virus as a model of alphaviral encephalitis, cellular genes such as *bax*, *bak*, and *bcl-2*, which regulate the apoptotic pathway, can modulate the outcome of infection (Jan et al., 2000). During Semliki Forest virus–induced murine encephalitis,

infiltrating leukocytes and neural precursor cells undergo apoptosis, while productively infected neurons undergo necrosis (Sammin et al., 1999). Immature mouse neurons infected with Sindbis or Semliki Forest viruses die of caspase-dependent apoptosis, while mature neurons survive by producing factors inhibiting viral-induced apoptosis. Apoptosis is induced at the time of alphavirus fusion with the cell membrane, and virus replication is not required (Jan and Griffin, 1999). Virus fusion apparently initiates the apoptotic cascade by inducing sphingomyelin degradation and ceramide release. In mature mice, antibody clears virus from the infected cells, however, viral RNA persists in infected neurons. The interruption of continued antibody production leads to viral reactivation. In contrast, T cells are not protective, although CD8(+) cells may act indirectly, possibly via cytokines, to assist in the clearance of viral RNA from neurons.

VACCINES

History

VEEV Vaccines

Vaccines to protect equines and humans against VEEV were first produced soon after the virus was isolated in 1938 (Beck and Wyckoff, 1938; Kubes and Rios, 1939). These formalin-inactivated preparations were initially made from mouse brain and other animal tissues following infection with virulent, unmodified subtype IAB strains (Randall et al., 1949). Genetic studies showing an extremely high degree of sequence conservation among IAB strains isolated from 1938 to 1973 (Kinney et al., 1992; Weaver et al., 1999), as well as the isolation of live virus from at least one human vaccine preparation (Sutton and Brooke, 1954). The lack of IAB outbreaks since 1973, coincident with the replacement of inactivated VEEV vaccines by the live-attenuated TC-83 strain, supports the vaccine origin hypothesis for all IAB outbreaks during the 1960s and 1970s.

The TC-83 attenuated VEEV vaccine strain was produced in 1961 by 83 serial passages of the subtype IAB stain Trinidad donkey in guinea pig heart cells (Berge et al., 1961), and soon thereafter was administered to humans at risk for laboratory infection (McKinney et al., 1963). Reverse genetic studies indicate that two mutations are the principal determinants of attenuation: genome nucleotide position 3 in the 5′ untranslated region, and amino acid position 12 in the E2 envelope glycoprotein (Kinney et al., 1993). TC-83 is generally administered in live form prepared from chicken embryo cells (Cole et al., 1976) as U.S. Food and Drug Administration (FDA) Investigational New Drug No. 142 (Pittman et al., 1996). A formalin-inactivated version called C84 has also been used in humans since the 1970s as FDA IND No. 914 (Pittman et al., 1996; Edelman et al., 1979). Evaluation of 821 vaccinated laboratory workers, including some boosted with C-84, showed 82% seroconversion (80% plaque reduction neutralization titers ≥1:20). Side effects occurred in 23% of vaccinees but no long-term sequelae were noted (Pittman et al., 1996).

In the case of contraindications or lack of seroconversion to TC-83, a formalin-inactivated version, C-84 is used (Cole et al., 1974). Unlike TC-83, this vaccine produces only occasional, mild, local, and systemic reactions; it augments preexisting VEEV antibody titers in seropositive recipients of TC-83, and induces high titers of cross-reactive antibodies in nonimmune subjects after one primary and two booster vaccinations, with circulating antibody persisting for at least 14 months (Edelman et al., 1979). However, some rodent studies indicate that TC-83 protects mice better against aerosol challenge (Jahrling and Stephenson, 1984). Other studies using cynomolgous macaques indicate that TC-83 (single dose) and C-84 (3 doses) elicit similar neutralizing antibody responses and protect against peripheral infection, but neither protects all animals against aerosol exposure (Pratt et al., 1998). Neither pre-challenge antibody titers nor lymphoproliferative responses predicted well the outcome of challenge. Microspheres composed of poly (DL-lactide-co-glycolide) augmenting IgG antibody levels and neutralization titers to the C84 inactivated VEEV vaccine and afford enhanced protection against VEEV challenge (Greenway et al., 1995).

The TC-83 vaccine induces VEEV-specific IgM and IgG in the respiratory tracts of immunized mice, and passive intranasal immunization with IgG protects against aerosol challenge (Phillpotts, 1999). The mucosal lymphotropism of attenuated VEEV strains probably explains their efficacy against aerosol challenge of mice (Charles et al., 1997), although a role for cell-mediated immunity in protection has also been suggested (Elvin et al., 2002). Some studies have shown that TC-83 induces limited cross-immunity against heterologous VEEV subtypes (Fillis and Calisher, 1979); others showed breakthrough infections and disease only after aerosol challenge. The risk of breakthroughs appears to increase with time after vaccination, and is more likely with epizootic, homologous serogroup IA/B viruses than with enzootic, heterologous strains (Phillpotts and Wright, 1999).

Another issue with live alphavirus vaccines is immunologic interference with a second vaccination.

Persons previously vaccinated with VEEV strain TC-83 exhibit poor neutralizing antibody responses to a live-attenuated chikungunya virus (CHIKV) vaccine, and vice versa. ELISA antibody responses demonstrate cross-reactive IgG to VEEV after primary CHIKV immunization, followed by an anamnestic response upon subsequent VEEV vaccination (McClain et al., 1998).

EEEV and WEEV Vaccines

Although live-attenuated WEEV (Hughes and Johnson, 1967; Binn et al., 1966) and EEEV (Brown and Officer, 1975; Brown et al., 1975) vaccine strains were tested in the 1970s, only multivalent, formalin-inactivated vaccines against VEEV, EEEV, and WEEV are currently administered to horses. In equids, these vaccines protect against challenge after two initial doses (Barber et al., 1978) but require frequent, lifelong boosters (Waldridge et al., 2003). The EEEV vaccine is also immunogenic and efficacious in some but not all avian species (Tengelsen et al., 2001; Snoeyenbos et al., 1978; Olsen et al., 1997; Clark et al., 1987). Both immunologic cross-reactivity among alphaviruses and extensive strain variation are potential issues with alphavirus vaccines. For example, the presence of preexisting EEEV or WEEV antibodies appears to interfere with TC-83 immunogenicity in horses (Vanderwagen et al., 1975; Ferguson et al., 1978). Due to antigenic differences among EEEV strains, the inactivated vaccine prepared from a North American strain elicits high-neutralizing titers against most or all North American isolates, but not against South American strains (Strizki and Repik, 1995). These data suggest that the current equine vaccines produced in the U.S. may not be efficacious in Latin America. The risks of using wild-type, virulent alphavirus strains in inactivated vaccine preparations continue despite indications that this virus was responsible for initiation of VEE epizootics from the 1940s to 1970s (Weaver et al., 1999). The occurrence of EEE in a California horse shortly after vaccination, also suggesting residual live virus, also underscores the risks associated with these vaccines (Franklin et al., 2002).

Veterinary Vaccines

The TC-83 vaccine strain was initially used in live form during the 1969–1971 epizootic that swept through much of Central America, Mexico, and into Texas. Extensive field testing in horses showed live TC-83 vaccine to be safe and efficacious (Walton et al., 1972) with long-lasting immunity (Walton and Johnson, 1972). Viremia titers were generally below the predicted infection threshold of epizootic vectors (Baker et al., 1978), vaccine virus was isolated from mosquitoes in Louisiana (Pedersen et al., 1972), raising environmental concerns. In Texas, TC-83 proved minimally reactive with no documented abortions or deaths attributable to vaccination, and most antibody titers were maintained for at least 11 months. Vaccine virus was isolated 1–14 days after vaccination and antibody appeared about a week after vaccination. The lack of VEEV isolations from horses with antibodies against EEEV and WEEV suggested some degree of cross-protection (Calisher and Maness, 1975), as did some serologic (Ferguson et al., 1977) and animal model studies (Cole and McKinney, 1971).

Duration of Immunity

Human and murine immunity generated by TC-83 against homologous subtype IAB strains lasts at least 7–9 years, while cross-reactive immunity against other subtypes is not as long lived (Burke et al., 1977; Fillis and Calisher, 1979). Most human TC-83 vaccinees retained neutralization titers for at least 6 years, and many TC-83 responders who were also boosted with C-84 remained seropositive for over 10 years. However, many TC-83 nonresponders who were boosted with C-84 failed to retain titers ≥1:20 for more than 1–2 years (Pittman et al., 1996).

Contraindications of Vaccination, Including Special Risk Groups

Pregnant women, persons infected with human immunodeficiency virus (HIV), or persons in any way immunosuppressed or immunocompromised are excluded from vaccination under the U.S. Army's Special Immunization Program. A known allergy to egg products also grounds for exclusion. Pancreatic involvement in hamster infections with VEEV (Gorelkin and Jahrling, 1974) is the rationale for exclusion of diabetic persons from vaccination with strain TC-83.

Adverse Events

Adverse reactions to the TC-83 live VEEV vaccine strain have included a mild, febrile illness often including malaise, headache, fever, chills, myalgia, sore throat, and occasionally, nausea, arthralgia, anorexia, vomiting, diarrhea, erythema, and rash. Adverse events to the inactivated VEEV and EEEV vaccines include typical local and systemic allergic

TABLE 21.1 New alphavirus vaccines under development

Agent	Vaccine type	Attenuation or immunogenicity strategy	References	Stage of development
VEEV	Live virus	Ablation of E3-E2 cleavage site, compensatory mutation in E1 protein gene	Davis et al. (1995), Pratt et al. (2003), Reed et al. (2005b)	Phase I human studies completed

reactions. Long-term sequelae following alphavirus vaccination have not been reported. A case of hydrops fetalis and fetal demise resulting from TC-83 vaccination of a pregnant woman indicated that this vaccine should not be used during pregnancy (Casamassima et al., 1987).

Current Licensed Vaccines

Although EEEV, VEEV, and WEEV vaccines have been administered to persons at risk by the U.S. Army under IND protocols since the 1960s, there are no alphavirus vaccines licensed for human use. Human vaccines against alphaviruses have never been licensed.

VACCINES IN DEVELOPMENT

Past alphavirus vaccine development has focused on the use of live, attenuated viruses or inactivated, whole virus. Although some recent development strategies have utilized DNA that encodes alphavirus structural proteins (Riemenschneider et al., 2003) most recent efforts have focused on improved strategies for alphavirus attenuation and the use of replicon particles.

Need for Improved Alphavirus Vaccines

As with other live RNA virus vaccines including polio where attenuation was derived via cell culture adaptation, resulting in a small number of attenuating point mutations, the TC-83 VEEV strain is probably unstably attenuated due to selection in humans or domestic animals for reversions. This inherent problem, probably reflected in the high rates of reactogenicity among human vaccinees (Pittman et al., 1996), was the impetus for the development of new live vaccine strains using genetic engineering strategies for improved stability of attenuation. Currently, two basic attenuation strategies are under development, along with the use of replicon particles that are limited to a single cycle of replication in vaccinees (Table 21.1).

Discovery/Basic Science

Antigen Discovery

Little effort has been reported on attempts to discover and exploit new alphavirus antigens for vaccines.

Preclinical Development

Adjuvant Development

The IND alphavirus vaccines described above are generally used with only Alum adjuvant. However, microspheres composed of poly (DL-lactide-co-glycolide) enhance IgG and neutralizing antibody responses as well as mucosal immunity to the VEEV C-84 vaccine (Greenway et al., 1995, 1998) and thus show promise for further development. Recent studies indicate that the alphavirus replicon particles have intrinsic systemic and mucosal adjuvant activity due to their RNA replication activity (Thompson et al., 2006).

Delivery Technology

Delivery of alphavirus structural proteins as DNA vaccines has shown promise in mice (Riemenschneider et al., 2003), but results with primates or large animals have not been reported.

Development of Animal Models

As described above, mice, hamsters, and guinea pigs have been used most commonly as animal models for human and equine EEE, VEE, and WEE. Recently, Reed and colleagues have conducted detailed pathogenesis studies using cynomolgous macaques exposed to alphavirus aerosols. These primates develop fever 4–6 days after WEEV exposure, with a duration of 3–4 days (Reed et al., 2005a). Clinical signs of encephalitis begin after the cessation of fever, with elevated white blood cell counts dominated by neutrophils and monocytes. In animals that die, immunohistochemical evidence of viral antigen is found in the brain and CNS with marked lymphocytic infiltrates. Experimental aerosol infections of cynomolgous macaques with VEEV subtypes IE or VEE complex subtype IIIA Mucambo virus develop fever, viremia, and lymphopenia in a dose-dependent manner (Reed et al., 2004). Most develop clinical signs of encephalitis, including loss of balance and hypothermia. Following aerosol exposure to EEEV, cynomolgus macaques develop encephalitis that corresponds with the onset of fever and tachycardia (Reed et al., 2007). Viremia is transient or undetectable and the onset of illness was dose dependent. A prominent leukocytosis occurs, with neutrophils predominating.

New Alphavirus Vaccine Platforms

Although a bacterially expressed E1 envelope glycoprotein from WEEV was shown to be immunogenic in mice, it exhibited poor protection (Das et al., 2004). The entire structural protein region (C-E3-E2-6K-E1), or the complete glycoprotein region (E3-E2-6K-E1) of VEEV expressed by baculoviruses are highly immunogenic in mice and protected these animals against challenge, while individual glycoprotein regions (E3-E2 and 6K-E1) are incompletely processed but nevertheless provide complete protection (Hodgson et al., 1999). Vaccinia-based VEEV vaccines have also been produced and shown to be immunogenic and protective in the mouse model (Kinney et al., 1988a, 1988b; Bennett et al., 1998). Various vaccinia constructs including all or only some of the structural proteins protect mice well against peripheral challenge but provide only partial protection against aerosol exposure (Phillpotts et al., 2000). The inability of these vaccines to elicit a sufficient IgA response may be responsible for the lack of efficacy against airborne challenge.

Recombinant, defective type 5 adenoviruses expressing the E3-E2-6K structural genes of VEEV protect against homologous challenge virus but less so against enzootic VEE complex strains (Phillpotts et al., 2005). A DNA vaccine against VEEV has also been shown to be efficacious in mice (Riemenschneider et al., 2003).

Purified envelope glycoproteins extracted from VEEV, EEEV, and WEEV are also immunogenic and protective (Pedersen, 1976). Novel gene-shuffling techniques are also under development to produce multivalent alphavirus vaccines (Locher et al., 2005). DNA vaccines against WEEV has shown partial efficacy in mice (Nagata et al., 2005).

New Alphavirus Vaccine Concept Development

Two main discoveries that led to the novel alphavirus attenuation strategies are outlined in Table 21.1. First, the discovery that WEEV is the descendent of a recombinant alphavirus (Hahn et al., 1988; Weaver et al., 1997) led to the interest in generating by recombinant DNA technology artificial recombinants to study interactions among alphavirus genes (Kuhn et al., 1996). These studies determined that chimeric alphaviruses involving two different species are highly attenuated, although the mechanism of attenuation is not known. The lack of attenuation in chimeras derived from different strains of the same alphavirus, for example, different subtypes of VEEV (Greene et al., 2005a; Powers et al., 2000), suggests that incompatibilities between more distantly related sequences or proteins results in suboptimal interactions and replication efficiency, although this is manifested more in vivo than in vitro. This attenuation has been exploited to develop several chimeric vaccine candidates against VEEV and EEEV (Table 21.1). The second basic discovery that led to a new alphavirus attenuation strategy was the identification of VEEV mutants that result in a lack of cleavage between the E3 and E2 proteins during secretory processing of the PE2 polyprotein (Davis et al., 1995). RNA transcripts derived from cDNA clones containing deletions in this cleavage site are nonviable but give rise to a small proportion of viable revertants with second-site suppressor mutations and incorporate unprocessed PE2 into virions. The combination of the lethal PE2 cleavage mutation and a suppressor mutation at E1 position 253 is highly attenuated and immunogenic (Pratt et al., 2003; Reed et al., 2005b; Hart et al., 2000).

Another basic alphavirology development that has translated into new vaccine strategies is the replicon particle. Because only the nonstructural proteins and cis-acting RNA sequences are required for alphavirus genome replication, the structural protein genes can be replaced by foreign antigens that are expressed at high levels in infected cells (Frolov et al., 1997; Liljestrom and Garoff, 1991). However, for these

replicon genomes to enter the cytoplasm for replication, they must be either introduced by chemical or electromagnetic transfection methods, or packaged into virus-like particles by capsid and envelope proteins provided in trans from a second genetic construct. Often, two separate, transcribed "helper" plasmids encode the structural packaging proteins to avoid the generation of complete viral genomes via recombination (Pushko et al., 1997). Another approach is to develop packaging cell lines that constitutively express the structural proteins (Polo et al., 1999). Because the replicon genomes are defective and cannot produce structural proteins, they express the foreign genes during only one round of replication and cannot spread to other cells, an important safety consideration. The alphavirus replicon systems have been used primarily to express immunogens from other viruses or proteins (Zhou et al., 1994; Davis et al., 2002), but can also be used to immunize against homologous or heterologous alphaviruses without the safety concerns of a live replicating virus.

Another recent discovery that will probably lead to new, live alphavirus vaccine development approaches is the molecular basis of the shutoff of vertebrate host cell gene expression that occurs during alphavirus infections which undoubtedly contributes to virulence. Unlike the Old World Sindbis and Semliki Forest viruses that regulate this shutoff via their nsP2 (Frolova et al., 2002; Garmashova et al., 2006), EEEV (Aguilar et al., 2007b), and VEEV (Garmashova et al., 2007) use the capsid protein for this purpose. The mechanism of WEEV host cell gene expression shutoff is unknown, but the derivation of its capsid gene from an EEEV ancestor suggests it also uses the capsid protein. Inactivation of this capsid function could therefore be exploited for alphavirus attenuation.

Attenuated VEEV Strain V3526

Because of the human reactogenicity of the TC-83 vaccine and other concerns from animal studies such as glucose intolerance and reduced insulin release after vaccination (Rayfield et al., 1976), next generation, live-attenuated VEEV vaccine strains have been developed using infectious cDNA clones derived from the Trinidad donkey strain. Attenuation was achieved by inserting either attenuating mutations or a PE2 cleavage-signal mutation combined with an E1 gene resuscitating mutation. The latter strain, called V3526, is immunogenic for mice and nonhuman primates (Pratt et al., 2003). V3526 induces systemic and mucosal protection in mice more efficiently than TC-83 (Hart et al., 2000) and is stably attenuated after cell culture and mouse passages, remaining less neurovirulent in mice than TC-83 (Ludwig et al., 2001). V3526 also appears to have a lower risk for environmental transmission and distribution (Turell et al., 1999; Rao et al., 2004). Although this vaccine strain elicits neutralizing antibodies in macaques only against homologous subtype IAB VEEV strains, it protects against both IAB and IE strains in aerosol challenges (Reed et al., 2005b).

Chimeric alphaviruses have recently been developed as vaccine candidates. A chimera derived from a cDNA clone including the 5′ 2/3 of the WEEV genome, encoding the nonstructural proteins, and the 3′ 1/3 of the EEEV genome, encoding structural proteins, is highly attenuated in mice (Schoepp et al., 2002). This chimera protects against EEEV but not WEEV challenge. A chimeric clone encoding the nonstructural proteins of Sindbis virus and the structural proteins of the VEEV TC-83 strain is also highly attenuated and protects against wild-type VEEV challenge (Paessler et al., 2003).

Clinical Trials

Phase I

Clinical Phase I trials of the VEEV TC-83 and C-84 vaccines are described above (Pittman et al., 1996). Results of Phase I trials of the U.S. Army's inactivated EEEV and WEEV vaccines have not been published. A Phase I trial of the V3526 attenuated VEEV vaccine was completed in 2006, but the results have not yet been reported. No Phase II or III studies have been undertaken for any alphavirus vaccines.

POSTEXPOSURE IMMUNOPROPHYLAXIS

No studies of alphavirus immunoprophylaxis have been reported.

PROSPECTS FOR THE FUTURE

Several new strategies for generating robustly and stably attenuated alphaviruses have been described recently, and offer promise for the generation of improved, live virus vaccines. However, the stability of the attenuation phenotypes will require close scrutiny due to the potentially fatal consequences of reversion to wild-type virulence. Additional studies of the determinants of attenuation will be required to predict phenotype stability, as well as experiments to test stability

empirically. These new attenuation strategies should also lead to improvements in the efficiency and safety of inactivated vaccine production for both human and veterinary use, which currently rely on the propagation of wild-type, virulent, select agent strains in some cases. Replicon particles, which combine most of the safety of inactivated vaccines with improved immunogenicity, also offer promise not only for alphaviral disease, but for other antigenic targets using alphavirus vectors. Further effort is needed to better define the critical determinants of both humoral and cellular immunity, so that other new strategies such as virus-like particles or DNA-based immunization can be exploited for alphaviruses.

KEY ISSUES

- No human alphavirus vaccine suitable for licensure is currently in clinical development.
- An ideal alphavirus vaccine for biodefense purposes would require only one dose, generate long-lasting immunity, be relatively inexpensive to produce, and be stable for long-term storage.
- An ideal human vaccine for protection against endemic and epidemic VEE in Latin America would have the same properties, but cost would be an overriding issue.
- Because EEEV and WEEV typically cause only small numbers of human cases in the U.S., there is probably not a sufficient market for commercial vaccine development.
- A safe and effective equine vaccine is critical for preventing epidemics of VEE, which rely on equine amplification for transmission to large numbers of people.
- The current equine vaccine against VEEV relies on only two point attenuating mutations, suggesting the possibility that reversion could generate a VEE epidemic involving large numbers of human cases.
- Further identification and characterization of critical alphavirus antigens is needed to exploit newer vaccine platform technologies for biodefense.

OUTLINE

ABSTRACT

Foot-and-mouth disease (FMD) is a devastating disease of livestock that has had a significant impact on world economies and public health. Its importance to mankind is confirmed by the fact that FMD virus (FMDV) was the first animal virus discovered, and that FMD was among the first animal diseases for which vaccines were developed.

Due to its rapid spread and the high cost of eradication campaigns, countries that are free of the disease are susceptible to huge economic losses if the disease were to be introduced either accidentally or deliberately in an act of agroterrorism. Vaccines developed in the 1950s and 1960s have helped to control this scourge in many nations, and these products have been further developed and refined over the last 30 years. Although these vaccines are very useful as part of eradication campaigns in countries where FMDV is enzootic, it is not feasible to use these products in prophylactic vaccination of entire regions. In addition, these vaccines are not ideally suited to control outbreaks in disease-free countries. Thus, for the portions of the world that are currently FMD free, there is a need for new vaccines that can be applied in the areas surrounding an outbreak to rapidly dampen the spread of infection. Although the market for this type of vaccine is small, there are several groups trying to satisfy this important need. This chapter will detail the history of FMD vaccine development emphasizing recent advances and prospects for future development.

INTRODUCTION

The first reports of foot-and-mouth disease (FMD) date from 1514, when a livestock disease compatible with the signs of FMD was described. These signs include the formation of fluid-filled vesicles on the mouth, feet, nares, and teats of the affected animals, producing severe discomfort but rarely death. Although this gruesome disease is limited to cloven-hoofed animals, it has severely affected mankind through its impact on animal agriculture. In areas of the world where food and draft animals are essential for subsistence agriculture, FMD can affect nutrition. In countries that have highly developed animal industry and free trade, outbreaks cause economic devastation. This latter aspect of the disease has raised concern that the etiologic agent of the disease, FMD virus (FMDV), could be used as a bioterrorist weapon.

Due to its economic importance, high virulence, and utility as a model for studying virus evolution and speciation, FMD has been extensively examined and is the subject of many reviews (Brown, 2003; Doel, 2003; Domingo et al., 2003; Grubman and Baxt, 2004; Jackson et al., 2003; Knowles and Samuel, 2003; Mason et al., 2003; Sutmoller et al., 2003; Thomson et al., 2003). The purpose of this chapter is to briefly recount the development of vaccines that can be used to effectively reduce the impact of FMD in enzootic countries and to describe the development of second-generation vaccines with enhanced safety and/or efficacy that may be particularly well suited to use in the face of an outbreak as "emergency vaccines."

Brief History of FMD

FMDV was responsible for thousands of outbreaks of the disease in Europe at the end of the 1800s, prompting the German government to provide funding to Frederick Loeffler to identify the etiologic agent of the disease and develop methods to control it. Loeffler applied state-of-the-art ceramic filter technology that had been used to separate disease-causing bacteria from their toxins to demonstrate that the infectious agent or "instigator" in the lymph from FMD vesicles was smaller than the smallest known bacteria. Since he reasoned that the disease-causing agent could have been a toxin, he undertook serial animal-to-animal passages with diluted filtered preparations to demonstrate that the "instigator" was infectious. The results of these studies, which were published in 1898 (Loeffler, 1898; Loeffler and Frosch, 1898), heralded the start of animal virology. A summary of Loeffler's achievements with FMD was published several years later (Loeffler, 1909). This document recounted his studies demonstrating that FMD induces a protective immunity to reinfection, and that convalescent serum could be used as a "highly beneficial prophylactic." In the same work, Loeffler reported how convalescent serum could be successfully administered in the field and indicated that administration of serum followed by the "instigator" present in the lymph of diseased animals could induce active immunity to FMD. In this report, Loeffler emphasized the value of developing both serum and active immunity to control FMD; however, his death a few years later prevented his pursuit of more effective products to control FMD.

During the first few decades of the 1900s, studies on FMD helped to further characterize the nature of the agent and the immune response it elicited, demonstrating among other things that there were multiple serotypes of the virus, providing a preview for one of the largest obstacles to controlling the disease, namely, the need for multivalent vaccines.

In the first third of the 20th century, the United States experienced multiple outbreaks of FMD. Most of these outbreaks appeared to result from direct importation of virus-contaminated products. In the case of the 1908 outbreak, retrospective analyses ascribed the mode of introduction as an FMDV-contaminated seed stock of vaccinia virus that was imported from Japan for production of the human smallpox vaccine (Mohler and Rosenau, 1909). The outbreak in 1914, the most severely experienced in U.S. history, affected 22 states and the District of Columbia. Control of this outbreak,

which lasted for 20 months, included the destruction of over 170,000 animals (Mohler, 1924). The last outbreak in the United States, which occurred in 1929, was ascribed to importation of infected garbage offloaded from ships and fed to pigs, in clear violation of the U.S. Department of Agriculture (USDA) regulations (Mohler, 1929). Ironically, this mechanism of transmission is still repeating itself 75 years later, as evidenced by a similar episode that introduced the Pan-Asian strain of FMDV into the port of Durban, South Africa, in 2000.

The United States has remained FMD free since 1929. This situation can be attributed to a number of factors, including the extensive efforts by the United States, from 1946 to 1954, in assisting Mexico to eliminate FMD by a combination of slaughter and ring vaccination and the absence of land routes connecting the United States to FMD-affected areas (the United States helps to maintain an FMD vaccination-free "sentinel" zone along the northern border of Colombia, permitting rapid detection of FMD that could threaten disease-free Central America). The USDA also maintains strict import restrictions on biological products (including foods, medicines, and animal-derived research products) and live animals, thus helping to reduce the likelihood of accidental introduction of FMD. Recently, the Department of Homeland Security has initiated programs to help prevent deliberate introduction of FMD into the United States.

Economic Impact and International Agencies that Control FMD

In the early 20th century, the devastating nature of outbreaks of animal diseases imported into Europe resulted in the formation of an international agency, the Office International des Épizooties (OIE). Although founded originally to control rinderpest, which had been introduced into Europe by trade with Africa, FMD soon became one of the most important diseases that the OIE tracked and controlled. Today, the OIE receives voluntary reports of the activity of FMD and several other animal diseases and has the ability to declare countries "free" of FMD, following a rigorous investigation of a country's surveillance data and infrastructure. The FMD "disease-free" status, which is used by trading partners to control importation of live animals, can add considerable value to a country's animal products. As a result, countries that cannot prove they are free of FMD have a severe economic disadvantage, and when outbreaks occur in countries that wish to quickly regain their disease-free status, national agricultural authorities may implement draconian slaughter policies to eliminate the disease. In this context, the fact that FMD vaccination can actually mask the circulation of live FMDV can provide an economic disincentive for vaccination (see below). Figure 22.1, which shows the

FIGURE 22.1 Countries that reported FMD between January 2003 and August 2007 (courtesy of Nick J. Knowles, World Reference Laboratory for Foot-and-Mouth Disease).

current distribution of FMD in the world, demonstrates the presence of the disease in many developing countries and absence from large industrial countries that pay the highest prices for animal products.

Due to these economic factors, as well as its potential to directly affect animal productivity (and hence human nutrition), the Food and Agriculture Organization (FAO) of the United Nations (UN), the World Health Organization (WHO), and the Pan American Health Organization (PAHO) all maintain programs for tracking and controlling FMD.

DESCRIPTION OF THE DISEASE

Disease Presentation and Pathogenesis

The signs of FMD are variable, depending on both host and virus strains. Susceptible hosts include essentially all cloven-hoofed animals, but the majority of research efforts have been focused on economically important livestock species: cattle, pigs, and sheep. Among these three species, disease signs may vary substantially, and altered pathogenic properties have been associated with individual isolates. In susceptible hosts infected with virulent isolates, FMD is characterized by fever, vesicular lesions, and erosions of epithelium of the mouth, tongue, nares, muzzle, feet, and teats of affected animals (Grubman and Baxt, 2004). Signs of disease can appear within 24 h of contact with the agent, but the time of onset of the disease and the severity of infection depend on the infectious dose, the individual isolate, the host species, and the individual animal's age and health status. Recovery of large amounts of virus from vesicular lesions indicates that FMDV replicates to high titers in oral and pedal epithelial tissues, but recovery of the virus from the blood and exhaled breath indicates replication in other sites contribute to pathogenesis and spread.

FMDV can spread by many different methods; direct inoculation by multiple routes can reproduce the disease, and contact transmission among animals occurs quite readily. The virus can also persist on surfaces in animal containment facilities and can be transferred by workers or equipment. These methods of spread are of major importance in outbreak propagation, but airborne spread is perhaps the most dreaded mechanism since it is the least likely to be controlled by sanitary measures, even those that involve destruction of affected herds. Once FMDV enters a susceptible animal, it rapidly reproduces, permitting shedding to surrounding animals by highly efficient contact transmission. Early studies on the development of FMD lesions in a guinea pig model for FMD demonstrated that following establishment of foci of infected cells in the *stratum spinosum* layer of the epithelium, lesions progressed, filling with vesicular fluid and ballooning cells that are a hallmark of the infection (Galloway and Nicolau, 1928). Twenty years later, an "explant" tissue culture system was used to demonstrate a similar progression of infection in fragments of bovine lingual epithelium (Frenkel, 1949).

Carrier State

Almost a century ago, Loeffler predicted that animals that had recovered from FMD could become chronic carriers of the agent of the disease, and that the existence of such carriers could explain some outbreaks of FMD (Loeffler, 1909). However, it was not until the late 1950s that a chronic infection defined as the "carrier state" was definitively demonstrated (van Bekkum et al., 1959). In this work, van Bekkum and coworkers demonstrated that infectious FMDV could be recovered from the oral/pharyngeal tract of convalescent animals, using an apparatus (a cup probang) designed for the recovery of tuberculosis bacilli. Subsequent studies on the carrier state demonstrated that up to 50% of convalescent bovines become carriers (as defined by recovery of live virus 28 days or later postinfection), and that these animals can carry the virus for many years. It has also been demonstrated that vaccinated animals exposed to live virus can become carriers (Sutmoller et al., 2003). In addition, Cape buffalo (an important wildlife reservoir of FMDV in sub-Saharan Africa) appear to become carriers for life, and sheep but not pigs also become carriers (Sutmoller et al., 2003).

To date, there has been no documented experimental transmission of FMDV from carrier cattle to naive livestock animals in the laboratory; however, laboratory transmission has been observed from Cape buffalo to domestic cattle (Thomson et al., 2003). Further, molecular epidemiological analyses of an outbreak in northern Zimbabwe in 1991 strongly suggest a role for carrier buffalo in disease transmission to livestock (Thomson et al., 2003). Despite the paucity of data on a role for carriers in sustaining or generating outbreaks, the fact that carriers can be readily generated among apparently healthy animals that have been vaccinated and then deliberately infected (Sutmoller et al., 2003) has led to important rules for certification of "FMD disease-free status" by the OIE. Specifically, the possibility that vaccinated animals could become subclinically infected and subsequently become carriers has contributed to the development of OIE guidelines that permit a country to be declared free of FMD only after a year without evidence of infection if animals vaccinated to control the outbreak

are not destroyed. On the other hand, OIE guidelines for disease-free status require only 3 months without evidence of infection if vaccination is *not* employed. These guidelines were responsible, in part, for the fact that all vaccinated animals were destroyed in the aftermath of the 2001 outbreaks in the Netherlands (Bouma et al., 2003). After the 2001 FMD outbreak in Europe, the 1-year period required in countries that have vaccinated was reduced to 6 months to help reduce pressure on countries to implement widespread slaughter of apparently healthy vaccinated animals.

MOLECULAR BIOLOGY OF FMDV

Genome Structure and Polyprotein Synthesis

FMDV is the type member of the genus *Aphthovirus* of the family Picornaviridae and is an antigenically variable virus consisting of seven serotypes: A, O, C, South African Territories (SATs) 1–3, and Asia-1. Although the FMDV genome shares many features with other picornavirus genomes, it contains several features that are either unique to FMDV, its genus, or in other cases only present in a subset of picornavirus genomes. Like all picornaviruses, FMDV has a positive-sense RNA genome that is covalently linked via a 5′-terminal uridine to a small protein, 3B (also known as VPg). The genome encodes a single long polyprotein that is co- and posttranslationally processed into a large number of mature products by viral-encoded proteinases. Figure 22.2 shows a schematic diagram of the genome with the "mature" protein products identified; however, it is likely that several partially cleaved precursor products serve essential functions in viral replication (Mason et al., 2003).

The FMDV genome begins with a long 5′-untranslated region (5′UTR) that has a highly conserved secondary structure containing several sub-features. At the 5′-end of the genomic RNA is a 370-base domain originally identified by enzymatic digestion with nucleases that cleaved this short portion of the genome from the downstream poly(C) tract (Mason et al., 2003; Fig. 22.2). This highly structured RNA, known as the S-fragment, can be folded into a long stem-loop structure (Fig. 22.2). The poly(C) tract is followed by a series of pseudoknots of unknown function. Naturally occurring strains can have three or four pseudoknots, but viruses with as few as two pseudoknots have also been identified (Mason et al., 2003). The pseudoknots are followed by a short stem loop, the *cre* (*cis*-acting replicative element), that is an essential RNA replication element (Mason et al., 2003). The *cre* is followed by a complex RNA structure that was defined almost two

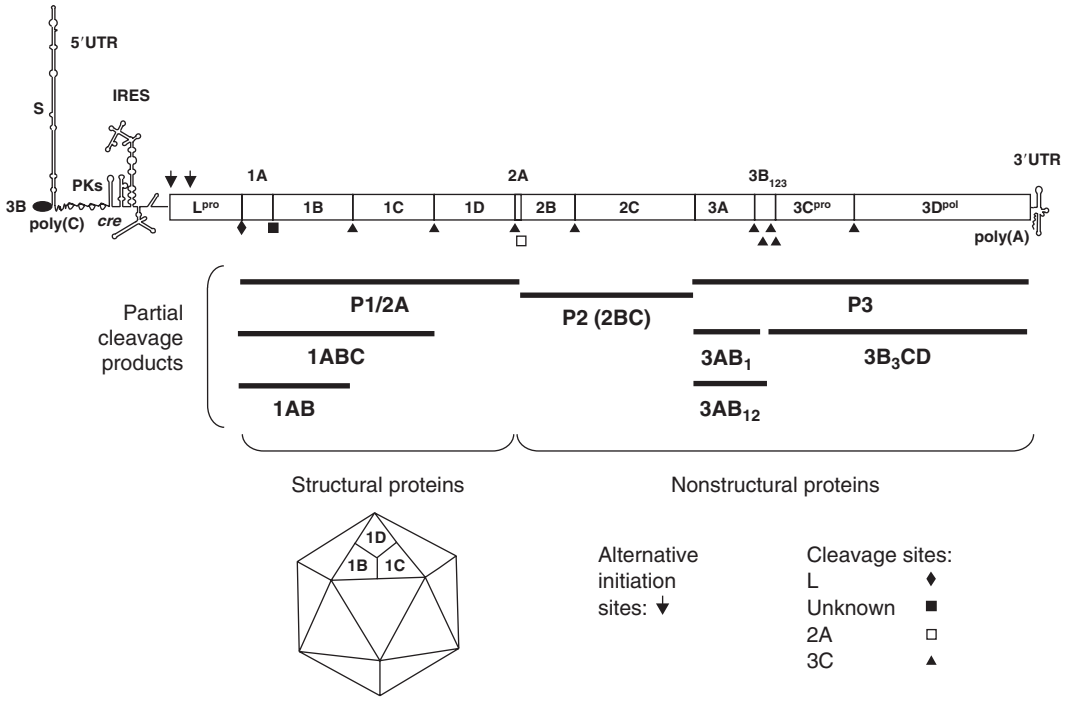

FIGURE 22.2 Schematic diagram of the FMDV genome showing the position of the genetic elements. Open boxes indicate protein-encoding regions; lines indicate RNA structures; UTR = untranslated region; S-fragment = short fragment of the genome; poly(C) = poly cytosine tract; PK = pseudoknot; *cre* = *cis*-acting replicative element; IRES = internal ribosome entry site. Reprinted with permission from Mason et al. (2003).

decades ago as the internal ribosome entry site (IRES) (Mason et al., 2003). The IRES directs host cell ribosomes to the initiation codons at the start of the viral polyprotein-coding region, which in the case of FMDV are found over 1200 bases from the 5′-end of the viral genome. Translation initiation from an IRES, differs from translation initiation of the majority of cellular mRNAs, which initiate protein synthesis following ribosome binding to the 7-methyl-guanosine (MeG) cap found at the 5′-end of the mRNAs. IRES function is critical to the pathobiology of FMDV and other picornaviruses since the utilization of an alternative translation initiation system permits the virus to shut off translation of critical host cell factors, allowing the virus to outrun its host (Mason et al., 2003).

Unlike most picornaviruses, the aphthovirus polyprotein does not initiate with its structural proteins; rather, it initiates with the leader proteinase (L^{pro}). L^{pro} cleaves the polyprotein between its C-terminus and the N-terminus of the capsid precursor protein P1-2A. This cleavage releases the growing polypeptide chain with a free N-terminal glycine on protein 1A, which is subsequently myristylated by cellular enzymes. In addition to its role in maturation of viral proteins, L^{pro} cleaves cellular proteins—including eIF-4G, an essential protein in recruitment of RNAs to the ribosome—and has been identified as an important virulence factor (Mason et al., 2003).

The P1-2A capsid precursor is cleaved at its C-terminus by 2A, a short peptide that autocatalytically removes itself from the P2 polyprotein and remains associated with P1 until subsequent processing (Mason et al., 2003). The P2 and P3 precursor polypeptides code for a number of viral nonstructural (NS) proteins, including the 3C proteinase, $3C^{pro}$, and the RNA-dependent RNA polymerase, $3D^{pol}$. $3C^{pro}$ is responsible for most of the cleavages of the viral polyprotein, including the processing of P1-2A into the capsid proteins 1AB, 1C, and 1D (Mason et al., 2003). The processing of capsid protein 1AB occurs by an unknown mechanism, is autocatalytic, and is required for generation of infectious virus (Mason et al., 2003).

Virion Structure

The FMDV virion is composed of 60 copies of each of four different proteins encapsidating the 3B-linked genome. Of these four proteins, three—1B, 1C, and 1D—are externally exposed while the fourth, 1A, is entirely interior in the virion. X-ray crystallographic analyses have revealed that like other picornaviruses, the FMDV surface proteins have a conserved eight-stranded β-barrel structure (Acharya et al., 1989). Further, two of these proteins, 1C and 1D, contain internal N-terminal extensions that appear to be missing on 1B. However, protein 1A appears to serve as the N-terminal extension of 1B during folding, consistent with the fact that 1AB is present at the early stages of virion morphogenesis (Jackson et al., 2003). Although much of the impetus for determining the structure of the FMDV capsid came from the pursuit of better vaccines, the first crystallography studies on a type O virus (Acharya et al., 1989) failed to reveal an ordered structure for the loop between the G and H β-barrels of protein 1D, which had been shown by a variety of methods to contain strongly neutralizing epitopes (Brown, 1992). Interestingly, this loop is also disordered in the structures for type C (Lea et al., 1994) and type A (Fry et al., 2005) viruses but was present on forms of a type O virus crystallized under reducing conditions (Logan et al., 1993). These data are consistent with a large number of epidemiology-, peptide-, and epitope-mapping studies indicating that this portion of the capsid has genetic and structural flexibility that appears to contribute to the ability of the virus to rapidly undergo antigenic variation (Domingo et al., 2003), complicating vaccine-based control of FMD (see Antigenic Variation).

Antigenic Variation

Early work on FMDV discovered the existence of multiple serotypes by demonstration that convalescent animals could not be reinfected by the same isolate but were susceptible to diseases caused by isolates from a different location (Vallée and Carré, 1922). These studies were repeated in a second laboratory (Waldmann and Trautwein, 1926) that used similar techniques to show that there were three different serotypes of virus circulating in Europe in the early 1900s (originally designated A, B, and C, but later renamed A, O, and C to be consistent with the A and O strains identified by Vallée and Carré). The ramifications of these finding are very significant. Despite the ability of animals to be resistant to reinfection with the same serotype, they can be infected with a different serotype, so naive animals can suffer multiple episodes of FMD. Thus, countries with multiple serotypes of FMDV need multivalent vaccines, and countries that want vaccines to protect their animals from all strains of FMDV need to vaccinate with a heptavalent vaccine.

An additional problem with vaccination coverage is that FMDV can evolve rapidly in the field, and as a result, vaccines for individual serotypes, particularly type A, can rapidly become out-of-date, as field strains evolve (Doel, 2003). A portion of the reason

for this rapid evolution appears to be the flexibility of the G–H loop of the capsid structure (see Virion Structure), which has also appeared to limit the utility of peptide-based vaccines (see Protein and Synthetic Peptide Vaccines) targeted to this region of the virion surface (Domingo et al., 2003).

The ability of FMDV to undergo extensive genetic variation in cell culture as well as in the field has made it a model for the study of viral quasispecies and evolution (Domingo et al., 2003). In addition, this flexibility, most easily recognized by sequencing the 1D portion of the genome, has revolutionized the study of FMD outbreaks, allowing readily comparable sequence data generated from multiple laboratories to be utilized in place of serology to identify serotypes and subtypes, and even track viral changes during individual outbreaks (Knowles and Samuel, 2003).

DEVELOPMENT OF TRADITIONAL VACCINES FOR FMD

Animal-Derived Vaccines

In the 1930s, as technology progressed in the development of vaccines for both animal and human diseases, the methods utilized to formalin-inactivate toxins were applied to material derived from FMDV-infected animals. This procedure involved the growth of FMDV in the tongues of live animals, followed by slaughter 2 days later, and the collection of the diseased epithelium. The epithelial material containing large quantities of viral antigen was then inactivated with formaldehyde-containing solutions and then formulated into a vaccine using an aluminum hydroxide adjuvant. Using this method, only 200 doses of vaccine could be made from each animal (Sutmoller et al., 2003), thus requiring a large number of animals for commercial vaccine production. To obtain this large number of animals, these vaccines were produced in animals housed near slaughterhouses, and for economic reasons, the meat from the infected animals was then sold in the market. Given our knowledge of how easily FMD outbreaks can be propagated, these combination vaccine plant and slaughterhouse facilities were likely to have generated their own vaccine business since they could have been a source for outbreaks in the surrounding community. Despite the somewhat barbaric process of intentionally causing disease in food animals, the vaccines were efficacious. Nevertheless, the need to infect live animals, the large volume of material needed, and the presence of a significant amount of bovine antigens in the preparation left considerable room for further development.

Cell Culture-Derived Inactivated Vaccines

The development of Frenkel's tongue epithelium method to cultivate FMDV produced a method of vaccine generation that was safer and more economically effective than vaccines derived from infected live animals. The basis of the vaccine was an "organ culture" produced by sterile removal of the epithelium of the tongue from freshly slaughtered cows, followed by mincing and suspension in a nutrient broth in large fermenters (Frenkel, 1951). Virus harvests from these fermenters were formaldehyde-inactivated using methods similar to those applied to the homogenates of diseased epithelium prepared directly from infected cattle (see Animal-Derived Vaccines). These vaccines were among the first to be used extensively in Europe, and their application in the Netherlands coincided with a dramatic drop in the number of FMD outbreaks (Brown, 1992).

The next generation of vaccines for FMDV followed the rapid acceleration of eukaryotic cell cultivation technology developed for basic research and human vaccine production in the 1950s and early 1960s. Work at the USDA's Plum Island laboratory demonstrated that primary cultures of embryonic bovine kidney cells were an effective substrate for virus growth and vaccine preparation (Bachrach et al., 1955). Later work with the baby hamster kidney (BHK) cell line demonstrated that this cell line could be used to grow virus (Mowat and Chapman, 1962), and BHK cells have become the "workhorse" for FMDV antigen production system being used at large manufacturing plants throughout the world to produce essentially all of the antigens now used to prepare FMD vaccines. In some cases, vaccines are prepared using suspended cultures of BHK cells, but there is clear evidence that growth of cells in suspension can result in selection of viruses with altered antigenic properties (Bolwell et al., 1989). More recent studies indicate that tissue culture propagation can select viruses with altered receptor utilization, antigenic structure, and virulence (Sa-Carvalho et al., 1997), probably because selection of viruses in cell culture to permit utilization of different receptors can result in changes in the virion structure that affect both tropism in vivo and antigenic structure. Antigenic variants selected in vitro can be as important to FMD control as the evolution of variants in the field since efforts to produce vaccine strains with improved growth properties in cell culture can select variants with altered cell-binding properties and antigenic structures yielding vaccine antigens with inferior immunogenicity.

A major advance in the production of safe and effective FMD vaccines came from the realization that formaldehyde-inactivated virus harvests could contain residual infectivity, and thus FMD vaccines could,

in some cases, produce outbreaks. Fears that FMD vaccines themselves could cause outbreaks have contributed to the "curious" resistance to FMD vaccination that is perceived by many practitioners of human health as an inability of the animal health community to understand basic vaccination strategies.

The problem with formaldehyde inactivation is not limited to FMD vaccines. In the case of poliovirus, formalin inactivation was essential to the production of the first inactivated polio vaccine (IPV). However, soon after IPV went into widespread use, the investigations of the "Cutter incident" demonstrated that certain lots of formaldehyde-inactivated IPV made by Cutter Laboratories were linked to cases of poliomyelitis, and that live virus could be recovered from these lots of IPV (Nathanson and Langmuir, 1963). These findings attributed the infection of vaccinees to the inability of formaldehyde to penetrate aggregates of poliovirus in the viral harvests used as the source of antigen for IPV. This problem in vaccine manufacture was eventually remedied by introduction of a filtration step, whereas in the case of FMD vaccines, an alternative inactivant replaced formaldehyde (see below). In the case of polio, the relatively low infectivity of the virus (less than 1% of those infected were expected to develop symptoms of the disease) made the incidence of disease due to "incomplete" inactivation rare. In the case of FMDV, which is much more virulent, the incompletely inactivated virus in vaccine preparations is much more likely to produce disease (and outbreaks). However, during early stages of FMD vaccination campaigns, when outbreaks caused by "naturally" circulating strains were quite high, the relatively small numbers of outbreaks that could have been caused by incompletely inactivated vaccines would have been difficult to detect. However, the application of molecular epidemiology to outbreaks in the late stages of the FMD eradication campaign in Europe revealed that many outbreaks could be linked to formaldehyde-inactivated vaccines prepared from subtypes of FMDV that were not currently circulating (Beck and Strohmaier, 1987). This seminal work helped to prompt the switch to a different class of chemical inactivants, the imines. Imines were introduced as inactivants in the late 1950s in experimental products (Brown and Crick, 1959), and unlike aldehyde-based inactivants, imines display linear inactivation kinetics, allowing for greater certainty in obtaining a completely inactivated product (Bahnemann, 1990). Today, all FMD vaccines produced in European and South American manufacturing facilities utilize imine inactivation and, in most cases, employ partial purification of the viral antigen to remove BHK cell antigens. The resulting viral antigens are then formulated into vaccines by the addition of aluminum hydroxide/saponin or a mineral oil emulsion (Doel, 2003).

Live-Attenuated Vaccines (LAVs)

Following adaptation of FMD to grow in suckling mice (Skinner, 1951), it was soon appreciated that mouse-passaged viruses were attenuated in some animal species. This prompted efforts to develop these adapted viruses as more reliable (and potentially less expensive) vaccines to replace the animal-tissue-derived inactivated products available at the time (see Cell Culture-Derived Inactivated Vaccines). Thus, live-attenuated products were developed in the United Kingdom, but large-scale testing in South Africa revealed their incomplete attenuation, resulting in disease in the vaccinated population, and only provided protection for about 70% of the vaccinated animals (Martin and Edwards, 1965). At the same time, mouse adaptation was pursued in the Soviet Union as a method to produce LAVs for FMD, and the technology was transferred to the People's Republic of China, which utilized mouse-adapted viruses that were amplified in rabbits (to produce larger volumes of inocula) until quite recently (J. Callis and Q. Zhao, personal communication). Simultaneously with these animal-based attenuation and propagation methods, researchers in South America pursued adaptation of FMDV to chicken embryos to attenuate the virus. These vaccines also suffered from incomplete attenuation, and as vaccine plants in the Europe and South America developed better methods to grow a viral antigen for inactivated vaccines (notably the adoption of the BHK cell culture system) and reliably inactivated it, live-attenuated products were largely dropped.

Emergency Vaccines

Although FMD outbreaks in disease-free nations are devastating, continuous vaccination with the existing products is not cost effective. This is due to multiple factors, including the high cost of vaccination for a rapidly turned over livestock population, and the need to vaccinate against all circulating strains of virus. Furthermore, if the intent is to protect against deliberate introduction of FMD, the breadth of vaccine coverage would need to be extended to historical strains that are currently not in circulation. There is also a concern that vaccination might facilitate undetected spread of infection since animals vaccinated with existing vaccines can become infected (Orsel et al., 2007). These and other factors, many of which are based on economic concerns that vaccination confounds ready detection of a disease, preventing rapid return of countries suffering outbreaks to trade in animal products, have led many countries, including the United Kingdom, to never implement vaccination

in response to an outbreak. In the case of the United States, the last FMD outbreak occurred before the availability of useful vaccines, so the precise criteria that will be applied in the face of an outbreak remains unclear. Nevertheless, North America, Europe, and Japan maintain vaccine banks that could be utilized to slow outbreaks. Due to the above-mentioned concerns that vaccines might produce a population of animals that could become asymptomatic carriers or shedders, the major utility of these banked vaccines might be to slow spread of the infection, and all vaccinated animals might be destroyed as part of outbreak control. This strategy was utilized in the Netherlands in 2001, where the "vaccinate and destroy" policy was implemented, in part, to allow for more orderly destruction of all animals in the zones surrounding the confirmed outbreaks. Interestingly, there were infections detected on some farms shortly after vaccines were applied, suggesting that vaccines that induced immunity more quickly could have utility in outbreak situations.

These latter findings reinforce the need for "outbreak" vaccines that provide a rapid immunity, a criterion that is less important in a countrywide eradication campaign or prophylactic vaccination of a border region with a country that has enzootic FMD. Nevertheless, the horrific outbreak in the United Kingdom in 2001 has caused several researchers to focus on the rapid acquisition of immunity for a small, but potentially profitable, vaccine bank market where high-priced vaccines might be justified to protect critical genetic stock or rapidly induce immunity in the ring around an outbreak. Studies to explore the ability of traditional vaccines to provide the short-term immunity needed for ring vaccination have noted that swine (which are potent excreters of virus in outbreaks) cannot mount a protective immune response within the first week of vaccination (Doel et al., 1994). However, more recent studies, prompted by the catastrophic depopulation of animals in the United Kingdom in 2001, have demonstrated in cattle that vaccination can reduce shedding and disease within 4 days of administration (Cox et al., 2005; Golde et al., 2005).

SECOND-GENERATION VACCINES FOR FMD

Although the traditional cell culture-derived inactivated vaccine is effective, there are a number of concerns with its use, particularly during outbreaks in disease-free countries. These include difficulty in differentiating vaccinated animals from the infected ones, the need to induce rapid protection in the event of an outbreak in a disease-free country, the inability of inoculation with this vaccine to block the development of the carrier state, the need for expensive high-containment facilities for vaccine production, and so forth. Despite the excellent safety record of these high-containment facilities, there was an outbreak of FMD in the United Kingdom in August 2007 on farms near the Pirbright high-containment laboratory caused by a strain of virus present in both an FMD vaccine-manufacturing facility and the Institute of Animal Health located at this site. This occurrence may necessitate further scrutiny of a manufacturing process that requires the growth of thousands of liters of infectious FMDV that contains millions of cattle-infectious units per milliliter (Doel, 2003). Moreover, in terms of manufacture of FMD vaccines in the United States, federal law only allows work with infectious FMDV at the Plum Island laboratory. Therefore, the United States is completely dependent on foreign manufacturers for vaccines, a situation that has received additional attention following the September 11 terrorist attacks. Over the past 25–30 years, investigators have attempted to address these concerns by using new technologies to develop alternative vaccines.

Genetically Engineered Live-Attenuated or Inactivated Vaccines

As described above, in the 1950s and the 1960s, attempts were made to develop live-attenuated FMD vaccines by classical procedures. Although this approach was successfully used by Sabin to develop an oral poliovirus vaccine, it was not successful for FMDV (see Live-Attenuated Vaccines). With the advent of recombinant DNA techniques and the construction of full-length infectious FMDV cDNA clones (Rieder et al., 1993; Zibert et al., 1990), efforts were made to design genetically engineered infectious clones that either had specific mutations in selected regions of the genome (McKenna et al., 1995) or deletion of an entire protein-coding region (Piccone et al., 1995).

Mason and coworkers engineered an infectious clone in which a portion of the G–H loop of 1D required for virus binding to susceptible cells was deleted and virus particles were produced that were unable to bind to cells (McKenna et al., 1995). This virus did not cause disease in either suckling mice or swine and cattle inoculated with deleted virus in an oil emulsion developed an FMDV-specific neutralizing antibody response and were protected from clinical disease when challenged with virulent homologous virus (McKenna et al., 1995). These workers also engineered an infectious clone that contained a serotype

A virus in which the G–H loop of 1D was substituted with the homologous region from serotype O or C (Rieder et al., 1994). Chemically inactivated vaccines prepared from the chimeric viruses induced antibodies in guinea pigs that neutralized both type A and either type O or type C viruses. Swine inoculated with the inactivated A/C chimera were protected from challenge with type A virus and partially protected against challenge with type C.

In an alternative approach, Piccone et al. (1995) constructed a full-length clone from a laboratory strain of type A12 virus that lacked the complete coding region of an NS protein, L^{pro}. The advantage of this approach as compared to the classical method of attenuation is that the risk of reversion to virulence is significantly reduced. Virus derived from this clone, leaderless virus, was infectious in BHK-21 cells demonstrating that L^{pro} was not essential for virus growth in this cell culture system. Subsequent studies demonstrated that leaderless virus was attenuated in both swine and cattle (Chinsangaram et al., 1998b; Mason et al., 1997). Based on the above observations, leaderless virus was examined as an LAV candidate (Chinsangaram et al., 1998b; Mason et al., 1997). Both swine and cattle inoculated with this virus developed a significant neutralizing antibody response but did not develop clinical disease. Challenge of vaccinated cattle, by both direct inoculation in the tongue and by contact with a naive infected animal in the same room, and challenge of vaccinated swine, by exposure to an infected animal in the same room, resulted in less severe and delayed clinical disease as compared to naive animals, but the vaccinated animals were not completely protected. These results indicate the potential for the rational design of LAVs by deleting a particular coding region but demonstrate the difficulty in designing these viruses, so that they do not cause clinical disease and yet can replicate sufficiently to induce a protective immune response.

Subsequently, a leaderless virus was constructed with a capsid-coding region from a field strain of serotype O in the genetic background of strain A12 (Almeida et al., 1998). This virus was avirulent in cattle but caused a mild disease in swine and was transmitted to a naive animal in the same room. Thus, although L^{pro} is a major virulence factor, it is clear that there are multiple regions of the FMDV genome involved in pathogenesis, and a more complete understanding of these factors is necessary in order to develop a useful LAV.

Nevertheless, attenuated FMDVs including leaderless virus and genetically engineered viruses lacking or with altered cell-binding sites could be used as a source of antigen for traditional inactivated vaccines (Chinsangaram et al., 1998b; McKenna et al., 1995). The use of these attenuated strains of viruses rather than highly virulent field strains as a source of antigen for vaccine production could reduce the risks associated with virus escape or incomplete virus inactivation. Moreover, chimeric technology in which capsid-coding regions of difficult-to-cultivate viruses (such as some SAT types) are inserted into other backbones may provide alternative methods for the production of seed viruses for traditional inactivated vaccine manufacture (van Rensburg et al., 2004).

Protein and Synthetic Peptide Vaccines

Early analyses of the FMDV capsid proteins by enzymatic treatment identified a protein on the virus surface, 1D, which was sensitive to trypsin and absorbed neutralizing antibody [see Mason et al. (2003) for a review]. Inoculation of this protein into animals induced both a neutralizing antibody response and protected swine when subsequently challenged with virus [see Grubman and Baxt (2004) for a review]. Soon after these discoveries, Bachrach and coworkers used recombinant DNA techniques to create an *Escherichia coli*-expressed 1D vaccine candidate, and demonstrated that swine and cattle given two inoculations of this purified recombinant protein developed high levels of neutralizing antibody and protection against challenge (Kleid et al., 1981). Subsequent work demonstrated that fragments of 1D, particularly the C-terminal half of the molecule, could elicit a neutralizing antibody response (Strohmaier et al., 1982). Based on the sequence of the 1D protein from a number of FMDV serotypes, Brown and collaborators identified a region of the protein that was highly variable (amino acids 141–160) and, using chemically synthesized peptides, demonstrated that this region could induce neutralizing antibodies and protect guinea pigs against virus challenge (Bittle et al., 1982). Subsequent studies by a number of laboratories have used chemically synthesized 1D peptides in combination with peptides containing T cell epitopes (to enhance the humoral immune response) to produce high-titer antibodies to these 1D peptides (DiMarchi et al., 1986; Francis et al., 1991; Nargi et al., 1999; Pfaff et al., 1982). Other groups have used viral vectors, naked DNA plasmids, transgenic plants, or plants infected with recombinant viruses to express 1D-coding regions (particularly the 141–160 region) to produce vaccine candidates with the ability to generate strong anti-FMDV titers (Kit et al., 1991; Kitson et al., 1991; Wigdorovitz et al., 1999a, 1999b; Wong et al., 2000, 2002). While in some cases these immunogens

induced a significant neutralizing antibody response, they either did not induce protection in livestock species or required multiple inoculations to induce protection (Grubman and Baxt, 2004). All of these approaches present a limited number of viral epitopes that represent only continuous regions on the viral capsid to the inoculated animal. However, some of the antigenic sites on the FMDV capsid are composed of discontinuous epitopes corresponding to regions from more than one structural protein or from different loops on the same protein (Mason et al., 2003). Thus, with the known variability and quasispecies nature of FMDV (Domingo et al., 2003), vaccination of animals with only a subset of epitopes representing a small number of the continuous epitopes present on the virus could result in the selection of antigenic variants that could cause outbreaks if these animals were exposed to an infectious virus. This supposition was supported by the results of a large-scale synthetic peptide vaccination study that revealed limited protection against challenge, with disease in the unprotected cattle arising from antigenic variants with alterations in the regions corresponding to the immunizing peptide (Taboga et al., 1997). Thus, it appears that development of an efficacious FMD peptide vaccine will require: (1) new technology to construct peptides that present discontinuous epitopes and (2) inclusion of peptides that represent multiple epitopes of |the virus.

Empty Capsid Vaccines

An alternative approach to the use of immunogens containing only a limited subset of viral capsid epitopes is the construction of an immunogen that contains the entire repertoire of immunogenic sites present on intact FMDV. Empty viral capsids, virus particles lacking nucleic acid, are naturally produced in FMDV-infected cell cultures, are antigenically similar to infectious virus, and are as immunogenic as virions in animals (Rowlands, 1974; Rweyemamu et al., 1979). Utilizing recombinant DNA technology, FMDV constructs that contain the portions of the viral genome required for empty capsid synthesis, processing, and assembly have been produced (Belsham et al., 1991; Lewis et al., 1991; Roosien et al., 1990). These constructs include the coding region for the viral structural protein precursor (P1-2A) and $3C^{pro}$ (the NS protein required for capsid precursor processing and assembly) but lack the coding regions for most of the other NS proteins (see Fig. 22.2). Furthermore, this immunogen lacks FMDV nucleic acid and cannot synthesize infectious viral nucleic acid when inoculated into animals. Thus, this type of vaccine is not infectious, does not require high-containment facilities for production, and can be produced in the United States. In addition, vaccines derived from such products could be easily used as "marker" vaccines since companion diagnostic assays could be designed to detect antibodies against FMDV NS proteins not present in the vaccine; thus vaccinated animals can be distinguished from infected animals.

A number of approaches to deliver this type of empty capsid immunogen to animals have been examined; these include inoculation of proteins expressed in *E. coli* (Grubman et al., 1993; Lewis et al., 1991) or recombinant baculovirus-infected cells (Grubman et al., 1993; Lewis et al., 1991; Saiz et al., 1994), direct inoculation of DNA encoding the immunogen (Beard et al., 1999; Benvenisti et al., 2001; Cedillo-Barron et al., 2001; Chinsangaram et al., 1998a), or direct inoculation of recombinant viral vectors encoding the immunogen (Abrams et al., 1995; Berinstein et al., 2000; Mayr et al., 1999, 2001; Moraes et al., 2002; Sanz-Parra et al., 1999a, 1999b). Thus far, the most effective delivery system is a recombinant, replication-defective human adenovirus type 5 (Ad5) vector (Mayr et al., 1999, 2001; Moraes et al., 2002). This vector is derived from the replication-competent form of Ad5 by deletion of a portion of the genome; the resulting replication-defective virus has the capacity to incorporate 5–8 kbp of foreign DNA and is only able to grow in cell cultures that provide the missing Ad5 proteins (Graham et al., 1977). This vector has a number of positive features including infectivity in multiple animal species, including swine and bovine (ensuring uptake and expression of foreign genes in these species) (Prevec et al., 1989), a lack of pathogenicity in animals, and a predicted high level of safety in humans (since replication-competent viruses were used extensively to immunize U.S. military recruits) (Couch et al., 1963; Top et al., 1971). In addition, since the empty capsids are produced in the inoculated animal, it can, like FMDV infection, induce both humoral and cell-mediated immune responses.

Despite their inability to productively replicate in animals, immunization of a number of animal species with replication-defective Ad5 vectors containing transgenes from other pathogens has resulted in induction of an immune response against the transgene and protection from challenge (Moraes et al., 2002; Pacheco et al., 2005; Russell, 2000). Furthermore, in the case of FMDV, the faithful replication of Ad5 and transgene DNA sidesteps the problem of selection of antigenic variants during cell passage of FMDV for traditional vaccine production (see Antigenic Variation and Cell Culture-Derived Inactivated Vaccines).

An Ad5-FMDV vector encoding the capsid and $3C^{pro}$ regions of a laboratory strain of FMDV, type A12, induced an FMDV-specific neutralizing antibody response in swine, and after two inoculations, five of six animals challenged by contact were protected from clinical disease (Mayr et al., 1999, 2001). The animal that was not protected had significantly less severe disease than the animals in the control group. It has also been shown that processing of the P1-2A capsid precursor protein was essential for induction of a neutralizing antibody response and protection since Ad5 vectors either containing an inactive $3C^{pro}$ (Mayr et al., 2001) or lacking the $3C^{pro}$-coding region (Sanz-Parra et al., 1999b) did not protect animals from challenge. In subsequent studies, an Ad5 vector was constructed that contained the P1-2A-coding region from an FMDV field strain, A24 Cruzeiro, from South America (Moraes et al., 2002). In these studies, it was demonstrated that a single inoculation of a 10-fold higher dose than in the earlier study induced a neutralizing antibody response. The titers of antibodies obtained were low but detectable at 1 week postvaccination and increased by the second week. When these swine were challenged by direct inoculation at 7, 14, or 42 days postvaccination, all vaccinated animals were protected from clinical disease, and no virus was detected in samples of blood or nasal swabs. Furthermore, there was no evidence of challenge virus replication in the vaccinated animals since none of these animals developed antibodies against the viral NS proteins as assayed by radioimmunoprecipitation.

The Ad5-A24 vaccine was also tested in cattle since these are the most economically important animals susceptible to FMDV (Pacheco et al., 2005). Cattle were administered a single high dose of vaccine and co-housed with animals given the same dose of a control Ad5 vector. Seven days later, all animals were challenged by intradermal inoculation on the tongue. The control animals developed fever, viremia for 3 days, and lesions on all four feet. None of the Ad5-A24-vaccinated animals developed fever or viremia, and only one animal had a single lesion on the dental pad. However, this latter animal showed no evidence of systemic spread of the virus. Sera from these animals were tested post-challenge, and all five animals showed serological evidence of limited challenge virus replication.

In a preliminary study in cattle, animals were inoculated with two high doses of Ad5-A24 9 weeks apart and developed FMDV-specific neutralizing antibody titers of greater than 1000, but no antibodies against viral NS proteins were detected (Grubman, 2005). These results clearly demonstrate that animals inoculated with two doses of this subunit vaccine can be differentiated from infected animals indicating the utility of this immunogen as a "marker" vaccine.

Cytokine-Enhanced Vaccines

To aid in the control of outbreaks of FMD in disease-free regions, it is essential to have vaccines that rapidly protect animals from infection, thus limiting virus spread (see Emergency Vaccines). In these regions, both traditional vaccines and genetically derived vaccine candidates, such at the Ad5-vectored empty capsids, suffer from their inability to induce protective immunity in less than 7 days. The economically devastating FMD outbreaks in Taiwan in 1997, and in the United Kingdom and the Netherlands in 2001, stimulated interest in developing protective measures to rapidly block or limit virus replication during outbreaks in disease-free countries and thereby contain disease spread.

The use of cytokines to modulate responses against immunization with candidate FMD vaccines based on DNA and recombinant virus vectors, as well as traditional vaccines, has been investigated by several groups. Interleukin 1 (IL-1) and IL-2 proteins have been shown to enhance the humoral immune response to inactivated FMD vaccines in a mouse model (McCullough et al., 1992). Cedillo-Barron et al. (2001) demonstrated that the inclusion of the gene for porcine granulocyte-macrophage colony-stimulating factor (pGM-CSF) with a DNA empty capsid vaccine resulted in a significant increase in antibody levels against FMDV and some improvement in protection from FMD challenge. However, in these studies, three DNA inoculations were given prior to challenge. Interestingly, Caron et al. (2005) found that co-delivery of an Ad5 vector encoding pGM-CSF and an Ad5-FMDV empty capsid was less effective than an empty capsid construct alone. However, studies with other immunogens indicate that the adjuvant effect of GM-CSF is most pronounced when this cytokine is co-expressed in the same vector (Wang et al., 2002).

Type I interferon (IFNα/β) is a cytokine that provides one of the first lines of host defense against virus infection (Biron and Sen, 2001) and can rapidly protect cell culture against infection by all FMDV serotypes (Chinsangaram et al., 2003; Grubman and Baxt, 2004). IFN has been used clinically to reduce or block virus replication, most notably in the treatment of patients with hepatitis C or B (Grubman, 2003). However, the half-life of IFN in the blood is approximately 5 h, and thus clinical use requires multiple, high-dose inoculations that can have adverse systemic effects (Grubman,

2003). Thus, Chinsangaram et al. (2003) designed experiments to deliver the IFN gene directly to animals by using a replication-defective Ad5 vector designed to produce IFN endogenously, with the hope that this expression system could deliver the compound in a manner that would overcome rapid clearance. In these experiments, swine were inoculated with a single dose of Ad5-porcine IFNα (pIFNα) (or a control Ad5 vector) and challenged a day later by direct inoculation with virulent FMDV A24. The control Ad5-inoculated animals developed typical clinical signs of disease as well as viremia and antibody response to viral NS proteins. All animals given a low dose of Ad5-pIFNα developed clinical disease, but the disease was delayed and less severe as compared to the control group. All animals given a high dose of Ad5-pIFNα were completely protected from clinical disease, had no viremia, and did not develop antibodies to FMDV NS proteins (Chinsangaram et al., 2003). There was a direct correlation between protection and the level of pIFNα in the blood of these animals. These studies also showed that Ad5-pIFNα produced detectable IFN within 4 h of administration, and subsequent studies have shown that the protection observed at 24 h postinoculation lasted for 3–5 days (Moraes et al., 2003). Furthermore, administration of Ad5-pIFNα a day after challenge was shown to be capable of reducing viremia, virus shedding, and disease severity (Moraes et al., 2003). The combination of Ad5-pIFNα and the Ad5-A24 vaccine appears to afford swine exposed to FMDV shortly after treatment both rapid protection and a more robust FMDV-specific neutralizing antibody response than either approach alone (Moraes et al., 2003). More recent experiments have shown that, in addition to inducing a rapid antiviral response, IFNα can function as an adjuvant and enhance the long-term protective response of the Ad5-A24 vaccine in pigs (de Avila Botton et al., 2006).

In studies in cattle, administration of Ad5-pIFNα did not completely protect animals from FMDV challenge, although the disease was delayed and less severe as compared to control animals (Wu et al., 2003). The incomplete protection in cattle correlated with the reduced levels of IFN detected in their blood and was very similar to the results in swine given the low-dose Ad5-pIFNα that was not protective (see above) (Chinsangaram et al., 2003). Thus, it appears that successful application of this approach to cattle will require an enhancement of the level of IFN activity by: (1) using promoters that produce higher levels of IFN, (2) altering the capsid of human Ad5 so that it can more efficiently infect bovine cells, and/or (3) targeting the Ad5 vector to cells or tissues that would increase the effectiveness of the treatment. Other approaches to enhance early innate or adaptive immune responses to FMD vaccines include the addition of multiple cytokines that can act synergistically or combining vaccine antigens with other immune stimulating products such as CpG or dsRNA mimetics to enhance protection. In support of this latter approach, Moraes et al. (2007) have recently demonstrated that the combination of IFNα and type II IFN (IFNγ) can synergistically inhibit FMDV replication in cell culture and sterilely protect swine from virus challenge.

PROSPECTS FOR THE FUTURE

The natural or deliberate release of FMDV in many areas of the world would be devastating. In developed countries with large naive populations of livestock, an outbreak would have immediate adverse economic consequences, and the application of the current control strategy of large-scale slaughter of infected and in-contact susceptible animals would be met with massive public resistance. Thus, despite the availability of vaccines that can be successfully used to control FMD in long-term eradication campaigns, developed countries have begun to invest in alternative control measures that are better suited to emergency vaccination and vaccination-to-live policies. These latter concerns have refocused FMD vaccine development on the production of immunogens that lack one or more of the virus-encoded antigens that can be use as part of "marker" vaccines, which allow for unequivocal distinction between infected and vaccinated animals during post-outbreak serological surveys required to demonstrate freedom from disease. Vaccines with a higher antigen load or augmented with adjuvants or cytokines that stimulate a rapid immune response are also being investigated. Finally, the demonstration that delivery of IFNα can induce protection more rapidly than a vaccine has produced a push for development of either antivirals that do not have vaccine antigens included in them (and hence eliminate the need for differentiating serological tests post-outbreak) or vaccines that are augmented by cytokines designed to activate the innate immune system while vaccine-induced immunity is being established. The development of this latter technology into a useable combination vaccine product will require a concerted collaborative effort by governments of developed countries and veterinary vaccine manufacturers. Recently, the U.S. Department of Homeland Security and the USDA entered into a collaborative agreement with GenVec, Inc., a U.S. biotechnology company, to produce Ad5-vectored FMD vaccines for the USDA-APHIS National Veterinary Stockpile.

While the focus on new technologies may produce products that can limit the spread of FMD outbreaks in disease-free countries, control of FMD in countries where the disease is enzootic will continue to rely on existing vaccines and the diligence of local veterinary authorities in rapidly identifying outbreaks, ensuring compliance with mandatory vaccination policies, and controlling trade and animal movement. These latter activities are likely to become more difficult, as globalization and economic development increase the number of animals being produced and the speed at which animals and their products reach marketplaces in distant lands. However, increased transparency in trade and sharing of resources could help to control this devastating disease worldwide, improving the economic situation in all countries.

KEY ISSUES

- FMD is the most highly regulated agricultural disease in the world and its presence in countries with active animal-product export economies can be devastating.
- Infections with the etiologic agent of the disease, FMDV, are not usually fatal and can cause difficult-to-detect diseases in certain species, complicating outbreak control.
- FMDV is one of the most rapidly mutating viruses known and exists in the form of multiple subtypes and serotypes.
- FMDV vaccines are currently being manufactured using chemically inactivated cell culture-derived virus. These vaccines prevent disease, but not infection, and have demonstrated utility in campaigns to eradicate disease where the circulating serotypes are known. However, application in an outbreak of unknown origin is more difficult due to the need to match the vaccine to the serotype(s) causing the outbreak.
- Vaccination campaigns in the face of spreading outbreaks are complicated by the fact that the disease spreads so rapidly from host to host that the outbreak can arrive to locations before vaccination has produced immunity sufficient to prevent viral shedding and/or disease.
- Existence of an FMDV carrier state in a portion of vaccinated animals that have been infected with the virus and the ability of vaccinated animals to shed the virus if they become infected have been used as arguments against vaccination, especially in the early stages of outbreaks when it appears that slaughter and quarantine alone can control spread of the disease.
- New vaccines as well as antivirals/cytokines that provide immunity more rapidly and/or can be produced without the need for production of the tremendous amounts of infectious material required for manufacture of the current vaccine are being developed and may provide additional tools to help control FMD.

Hantavirus

Christopher D. Hammerbeck, Victoria Wahl-Jensen and Jay W. Hooper
Virology Division, U.S. Army Medical Research Institute of Infectious Diseases, Fort Detrick, MD, USA

OUTLINE

ABSTRACT

Hantaviruses are known to cause diseases of military and public health concern. The association of hantaviruses and war can be attributed to the fact that these viruses are carried by rodents and are transmitted to humans via rodent excreta. During sustained ground combat operations, human–rodent contact inevitably increases due to an increased number of personnel working and sleeping in the rodents' habitat, environmental disruption, and a

breakdown in hygiene. During the Korean War, casualties caused by hantaviruses impacted military operations and spurred research aimed at identifying the etiological agent responsible for what was then known as Korean hemorrhagic fever, and developing countermeasures to prevent and treat the disease. This research resulted in the identification of multiple hantaviruses responsible for hemorrhagic fever with renal syndrome (HFRS), including Hantaan virus, Seoul virus, Dobrava virus, and Puumala virus. An ongoing effort to develop vaccines against these viruses has resulted in inactivated-virus vaccines that have been licensed in Asia. In addition, efforts to develop safe, effective molecular subunit vaccines against these viruses have shown promise. The only drug to show any clinical efficacy against HFRS is ribavirin used soon after the first symptoms of the disease. Ribavirin has not been licensed by the Food and Drug Administration (FDA) for use as a treatment for HFRS. The viruses associated with HFRS pose a relatively low threat as biological weapons because the viruses are difficult to grow to high titer, HFRS is not contagious, and the case-fatality rates range between 0.1% and 15%. However, starting in 1993, several previously unknown, highly pathogenic hantaviruses were discovered in the Americas. At least one of these viruses poses a substantial bioterrorism threat. Andes virus grows to levels ten times higher than the HFRS-associated hantaviruses, can spread from person to person under close-contact conditions, and is highly pathogenic (30–50% cases are fatal). Andes virus and several other newly emerging hantaviruses in the Americas are associated with rapid onset of pulmonary edema followed by cardiogenic shock. There are no vaccines or effective drugs to prevent or treat hantavirus pulmonary syndrome (HPS). Here, we review the viruses associated with HFRS and HPS with an emphasis on ongoing efforts to develop vaccines against these dangerous pathogens.

INTRODUCTION

Hantaviruses are rodent-borne viruses that cause hemorrhagic fever in humans. These viruses are associated with diverse disease syndromes with varying degrees of severity. Diseases caused by hantaviruses are generally manifested as either hemorrhagic fever with renal syndrome (HFRS) or hantavirus pulmonary syndrome (HPS). The most prevalent and lethal HFRS-associated hantavirus is Hantaan virus (HTNV) (20,000–50,000 cases per year, mostly in Asia) with a case-fatality rate of 5–15% (Fang et al., 2006). The most prevalent hantavirus in Central Europe, northern Europe/Scandinavia, and western Russia is Puumala virus (PUUV); whereas in southern Europe and the Balkans, both PUUV and Dobrava virus (DOBV) cause disease. The most prevalent and lethal HPS-associated hantaviruses are Andes virus (ANDV) in South America and Sin Nombre virus (SNV) in North America. There have been close to 2000 cases of HPS between 1993 and 2007 with an overall mortality rate of approximately 40%, despite state-of-the-art treatment in modern intensive care units. The mechanisms underlying the pathogenesis of the vascular leak syndromes associated with HFRS and HPS remain unknown. There are no vaccines or specific antiviral drugs licensed by the U.S. Food and Drug Administration to treat or prevent HFRS or HPS.

SHORT HISTORY OF THE DISEASE

The Western world became aware of hantaviruses for the first time during an outbreak of HFRS in 1951 during the Korean War. This disease affected nearly 3000 United Nations' troops by 1954 and exhibited a mortality rate of 7% (Johnson, 2001). Despite extensive investigations and reports on this outbreak, the etiologic agent was not identified at that time. Indeed, the mystery agent for what was then called Korean hemorrhagic fever remained elusive until HTNV, named for the Hantaan river that ran near the border between North and South Korea where human cases were endemic, was isolated in 1978 by Lee et al. (1978a, 1978b). Shortly after the discovery of HTNV, other hantaviruses were identified in Eurasia (Brummer-Korvenkontio et al., 1982, 1980; Gresikova et al., 1984). It is widely believed that other wartime epidemics of nephritis and hemorrhagic fever were caused by hantaviruses. For example, 10,000 German troops developed epidemic nephritis in Finland during World War II (Stuhlfault, 1943). More recently, epidemics of HFRS occurred in military units engaged in the conflicts associated with the breakup of the former Yugoslavia (Markotic et al., 2002; Hukic et al., 1996).

Hantaviruses did not burst onto the American scene until an outbreak of fulminate pulmonary illness occurred in the southwest of the United States in 1993 (Nichol et al., 1993). Unlike HFRS, this syndrome largely affected the lungs and was aptly termed HPS. Evidence that cardiac dysfunction plays an important role in the disease caused by the newly discovered hantaviruses led some groups to call the disease hantavirus cardiopulmonary syndrome (HCPS). It is interesting that while it took decades to identify the causative agent of HFRS, the etiology of HPS was determined in approximately 30 days (Johnson, 2001). The agent responsible for this initial outbreak, as well as the majority of disease in North America since

then, is SNV. Retrospective studies have shown that HPS was present but unrecognized in North America before the 1993 outbreak in the Four Corners region (Frampton et al., 1995; Schwarcz et al., 1996; Zaki et al., 1996).

After the discovery of pathogenic hantaviruses in North America, numerous hantaviruses that cause HPS were identified in Central and South America. As was the case in North America, HPS was not recognized in Central or South America until outbreaks of fatal disease occurred. The reader is referred to a review of recent advances in research on hantaviruses of Latin America (Pini, 2004). Unlike HFRS and even HPS in North America, HPS in Chile and Argentina has occurred in clusters, and there is evidence that the causative agent, ANDV, can spread from one person to the other (Lazaro et al., 2007; Toro et al., 1998; Vial et al., 2006; Wells et al., 1997). This development is a serious concern, especially as there have been instances where persons have contracted the disease in South America and then traveled internationally before developing symptoms, and fatal disease (Reynolds et al., 2007). Although person-to-person transmission and the export of cases are relatively rare occurrences, they are important events in the history of hantavirus disease because they demonstrate that the disease is capable of spreading beyond the initial human–rodent interactions.

ETIOLOGIC AGENTS

Hantaviruses represent a diverse group of viruses within a separate genus of the family Bunyaviridae, each carried by a specific rodent host. The viruses that have been associated with human disease are listed in Table 23.1. Viruses not yet associated with disease are listed in Table 23.2. Members of this genus are pleomorphic (70–210 nm), generally spherical particles with a distinctive grid-like appearance (Goldsmith et al., 1995; McCormick et al., 1982; White et al., 1982). Virions possess a host-derived lipid envelope that is studded with oligomers of the surface glycoproteins G1 and G2, now known as G_n and G_c, respectively (Fig. 23.1). The genome of hantaviruses is tripartite, negative-sense, single-stranded RNA that encodes three structural proteins (Schmaljohn and Hooper, 2001). The small RNA segment (S) encodes the nucleocapsid (N) protein, the medium segment (M) encodes the glycoprotein precursor (GPC) that is processed to G_n and G_c, and the large segment (L) encodes the viral RNA-dependent RNA polymerase (RdRp). Each RNA segment is complexed with multiple copies of N protein to form ribonucleocapsids. It is likely that most virions contain single copies of the S, M, and L ribonucleocapsids; however, reassortant studies report that it is possible for virions to contain multiple copies of one or more genome segments (Rodriguez et al., 1998). Hantavirus virions are relatively stable in the environment. For example, PUUV has been shown to remain infectious up to 11 days at room temperature (Kallio et al., 2006).

PROTECTIVE IMMUNE RESPONSES

Humoral Immune Responses

During hantavirus infection, B cells upregulate production of all immunoglobin (Ig) isotypes including IgA, IgE, IgG, and IgM (Alexeyev et al., 1994; Bostik et al., 2000; Groen et al., 1994; Lundkvist et al., 1993). Increases in IgA and IgE antibody titers are typically seen before and during the acute phase of infection, while production of IgM and IgG usually occur during and after the acute phase with IgG titers continuing to increase early into the convalescent phase. While IgM antibodies specific for hantaviral N, G_n, and G_c proteins can be found during infection with both HPS and HFRS viruses, anti-N-protein-specific IgM predominates. Similarly, N-protein is the most common viral antigen recognized by IgG antibodies, which are also the most abundant Ig produced during hantavirus infection. Neutralizing antibodies target the hantavirus surface glycoproteins G_n and G_c, but there is no convincing evidence that antibodies to the N-protein or RdRp neutralize virus. The ability of N-protein-specific Ig to neutralize virus cannot be ruled out entirely, however, as passive transfer of N-protein-specific antibodies delayed time-to-death after experimental infection of suckling mice (Yoshimatsu et al., 1993). High levels of neutralizing antibodies upon hospital admission have been correlated with a milder course of SNV-associated HPS, suggesting that the production of high titers of neutralizing antibodies can mitigate and possibly protect against disease (Bharadwaj et al., 2000). In these cases, mild disease was associated with neutralizing antibody titers less than 1:800 while antibody titers during severe disease were greater than 1:800. The conclusion that neutralizing antibodies are sufficient to protect against hantavirus is supported by numerous passive transfer experiments involving either monoclonal antibodies, convalescent sera, or sera from vaccinated animals (see "Postexposure Immunoprophylaxis"). Still, while vaccine studies in animals indicate that neutralizing antibodies are sufficient to protect, they are not necessary for protection. For example, hamsters

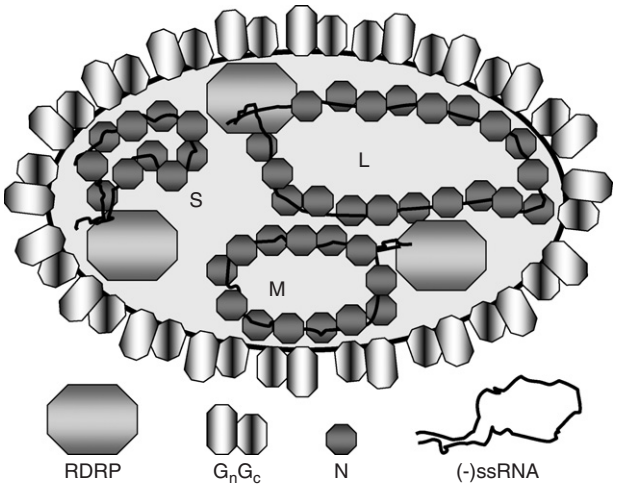

FIGURE 23.1 Hantaviruses are pleomorphic, generally spherical viruses with a diameter of 80–120 nm. They contain a host-derived lipid membrane that contains oligomers of the G_n/G_c glycoproteins. The three single-strand, negative-sense RNA segments are associated with nucleocapsid (N) protein and the RNA-dependent RNA polymerase (RdRp).

previously infected with HTNV, Seoul virus (SEOV), DOBV, PUUV, or SNV were protected against lethal HPS caused by ANDV despite the absence of detectable ANDV cross-neutralizing antibodies (Hooper et al., 2001b). It is likely that cellular responses to the N-protein and/or glycoproteins contribute to protection. In this respect, vaccination with purified N-protein can effectively stimulate T-cell responses and has been shown to protect in several animal models in the absence of neutralizing antibodies (Bharadwaj et al., 2002; de Carvalho Nicacio et al., 2002; Woo et al., 2005). Immune complexes can be found in the sera and on platelets of HFRS patients (Kanerva et al., 1998a) but the role that complement and Fc receptor-bearing cells play in antibody-mediated protection in vivo remains unknown. In vitro experiments have demonstrated that adding complement can enhance the neutralizing activity in sera several fold as measured by plaque reduction neutralization (Takenaka et al., 1985); however, activating complement by the classical pathway has also been correlated with a more severe

course of nephropathia epidemica (NE) after PUUV infection (Paakkala et al., 2000).

Cellular Immune Responses

The role of the human cellular immune response to hantavirus infection is not well defined. During infection in laboratory mice, $CD4^+$ and $CD8^+$ T cells have been shown to protect against HTNV infection in immunocompromised animals (Asada et al., 1987), and in other models, a strong correlation was observed between the number of HTNV-specific, $IFN\gamma^+$ $CD8^+$ T cells and the amount of viral antigen such that mice with large numbers of $IFN\gamma^+$ $CD8^+$ T cells had little to no detectable viral N-protein (Araki et al., 2003). Unlike human infection, however, hantavirus infection of *Mus* species does not cause notable disease (Araki et al., 2004). Hantavirus infection of humans results in the induction of strong immune responses. Elevated numbers of circulating T cells are found during HFRS (Huang et al., 1994), and biopsies of acute PUUV-infected patients reveal high numbers of activated and, predominantly $CD8^+$, T cells (Mustonen et al., 1994; Temonen et al., 1996). Similarly, increased numbers of cytokine-producing cells are seen in the lungs of patients with HPS (Mori et al., 1999). Both cytotoxic $CD8^+$ T cells and helper $CD4^+$ T cells (T_H1 and T_H2) appear important for controlling hantavirus infection in humans. $CD8^+$ T cell epitopes can be found in G_n, G_c, and N-proteins, but like the distribution of serum Ig, N-protein-specific $CD8^+$ T cells appear to be the most abundant (Van Epps et al., 1999; de Carvalho Nicacio et al., 2001; Van Epps et al., 2002). Patients diagnosed with PUUV and HTNV infection have elevated T_H1 (TNFα, IFNγ, and IgG3) and T_H2 (IL-6, IL-10, and IgG1) responses and elevated levels of proinflammatory cytokines such as interferon (IFN)α and interleukin (IL)-1 (Groen et al., 1994; Krakauer et al., 1994, 1995; Linderholm et al., 1996; Lundkvist et al., 1993; Temonen et al., 1996). The same is true during human infection with HPS-causing hantaviruses, where elevated levels of proinflammatory cytokines (IL-1α, IL-1β, and IFNα) and T_H1 (IL-2, IFNγ, and tumor necrosis factor (TNF)) and T_H2 cytokines (IL-4, IL-6, and TNFβ) are seen during fatal HPS cases (Mori et al., 1999). The correlation between the intensity of the immune response and the severity of clinical disease has further led to the suggestion that hantavirus disease pathogenesis is mediated by the immune system (see "Pathogenesis"). A more complete synopsis of all the immunological changes known to occur during hantavirus infection was recently reviewed by Klein and Calisher (2007).

Both T_H1 and T_H2 responses are characteristic of the immune responses elicited during the acute phase of infection of rodent reservoirs such as deer mice (SNV) (Schountz et al., 2007) and Norway rats (SEOV) (Klein et al., 2001; Tanishita et al., 1986). Yet as viral persistence is established, T cells from persistently infected deer mice predominantly expressed TGF-β, and most expressed FoxP3, consistent with inducible and T_H3 regulatory T cells (Schountz et al., 2007), and increased percentages of $CD4^+CD25^+FoxP3^+$ regulatory T cells and TGFβ mRNA expression are found during persistent SEOV infection of Norway rats (Easterbrook et al., 2007), supporting the hypothesis that suppressing the rodent host immune response is necessary to achieve long-term persistence (Meyer and Schmaljohn, 2000). Little is known about the regulatory T-cell response during human hantavirus infection, though. The presence of IL-10, IL-4, and TGFβ during the course of hantavirus infection could indicate a potential role for subsets of regulatory cells (Mills, 2004) in controlling the immune response to and immunopathology of human hantavirus infection. An analysis of acute dengue virus infection revealed increased numbers of $CD4^+CD25^{high}FoxP3^+$ T regulatory cells that are capable of suppressing vasoactive cytokine production, but due to relatively low frequencies, are thought to be insufficient to control immunopathology (Luhn et al., 2007). The extent of regulatory T-cell responses during hantavirus infection is not known, and what role these cells may play in limiting or contributing to hantavirus disease pathology will need to be explored.

Immunologic Memory

Secondary exposures to hantaviruses have not been reported, possibly owing to the formation of long-lived hantavirus-specific humoral and cellular immunologic memory. Studies by Ye et al. (2004) and Valdivieso et al. (2006) demonstrated that convalescent HPS patients maintain neutralizing antibody titers through 11 years postinfection. Similarly, high titers of PUUV neutralizing IgG antibody have been detected in the serum of convalescent patients up through 20 years postinfection (Horling et al., 1992; Lundkvist et al., 1993). Moreover, HTNV- and PUUV-specific memory $CD4^+$ and $CD8^+$ T cells, with frequencies as high as 100–300 per 10^6 for a single epitope, can persist for decades after infection (Van Epps et al., 1999, 2002). Furthermore, given the high degree of cross-reactivity of some T-cell N-protein epitopes (Van Epps et al., 1999) and the suggestion that cross-neutralizing antibody responses can be generated during infection and vaccination (de Carvalho Nicacio et al., 2002;

Hooper et al., 2001a, 2006), it is possible that exposure to one species of hantavirus could afford protection from a subsequent exposure to multiple species of hantaviruses.

EPIDEMIOLOGY

As stated above, hantaviruses that cause disease in humans are carried by rodents. To date, hantaviruses carried by insectivores, such as shrews and moles, have not been associated with human disease, although there is anecdotal evidence that these animals may also harbor pathogenic hantaviruses (Okumura et al., 2007). In general, infection of the natural rodent host results in a chronic carrier state without pronounced pathology or signs of disease. However, in-depth histological studies identified lesions within the lungs of deer mice infected with SNV and white-footed mice infected with NY-1 virus (Netski et al., 1999; Lyubsky et al., 1996). There is also a report that PUUV-infected animals are less likely to survive the winter, suggesting that infection has a negative effect on host fitness (Kallio et al., 2007). Disease in humans occurs when persons are exposed to contaminated rodent feces, urine, or saliva. The most common mode of transmission is thought to be the inhalation of aerosolized rodent droppings; however, contact with open wounds, rodent bites, and ingestion of contaminated material are also possible modes of transmission. Ingestion of virus as a mode of infection is not well documented; however, laboratory hamsters can be readily infected through the gut (gavage needle) with ANDV, supporting the possibility that hantaviruses could be transmitted by the ingestion of contaminated food (Hooper et al., 2008).

In humans, hantaviruses cause disease in the young and old, male and female. In most studies, HFRS and HPS occurred predominantly in working-age males. The preponderance of disease in this population is likely related to occupational exposure. Epidemiologic studies of HFRS and HPS report increased incidence of hantavirus disease in persons working or sleeping in environments inhabited by rodents, which include agricultural workers, forest workers, and soldiers (Mulic and Ropac, 2002; Sinclair et al., 2007; Vapalahti et al., 2003; Abu Sin et al., 2007). In many regions, hantavirus disease has a seasonal peak. For example, most of the cases in the 2005 outbreaks in Europe occurred in June and July (Heyman et al., 2007). The geographic range of hantavirus disease is shown in Fig. 23.2. The geographic range of the rodent hosts of pathogenic hantavirus are shown in Fig. 23.3. Although disease has not been detected in all of these regions, the presence of the rodent reservoir indicates that the potential for hantavirus disease exists. Endemic disease occurs in China, the Korean peninsula, Russia, Europe, and the Americas. A scan of the literature indicates that approximately 40 countries have reported hantavirus disease, the presence of virus, or serological evidence of infection (Figure 23.2 and Table 23.3), while several other countries have reported rare and sporadic HFRS in port cities that can probably be attributed to SEOV infections spread by rats carried port-to-port on ships.

China, Korea, and Far Eastern Russia

HFRS is a major health problem in China. It is estimated that from 1950 to 1997, there were 1.25 million cases of HFRS with 44,300 deaths (Yan et al., 2007; Fang et al., 2006; Kariwa et al., 2007). Liaoning province is one area with a particularly high incidence of HFRS, 141.7 cases/100,000 (Lin et al., 2007). South Korea reported 3039 cases of HFRS between 1997 and 2006 (DisWeb, 2003). During that time, there has been a trend of increased frequencies of cases with more than 400 cases per year for the last 3 years. Based on its geographic location, it is very likely that North Korea has a significant number of HFRS cases; however, as is the case for many countries, the number of recent HFRS cases was not readily available. One review from 1996 reported 316 HFRS cases in North Korea from 1961 to 1997 [sic] (Lee, 1996). In Far Eastern Russia, there were 4442 cases of HFRS between 1978 and 1997 (Tkachenko et al., 1998). Several other countries in Asia, including Australia, Fiji, Hong Kong, India, Indonesia, Japan, Malaysia, Mongolia, Myanmar, Singapore, Sri Lanka, Taiwan, Thailand, and Vietnam, have reported rare or sporadic cases of HFRS, or seroepidemiological evidence that hantaviruses exist and can cause infections (reviewed in Kariwa et al., 2007). The major viruses that cause HFRS in the Far East are HTNV, carried by *Apodemus agrarius* and SEOV carried by *Ratttus norvegicus*. Inactivated-virus vaccines against HFRS are licensed for use in China and South Korea (see "Vaccines").

Western Russia and Eastern Europe

HFRS has been a reportable disease in Russia since 1978. In a review of HFRS in Russia, (Tkachenko et al. (1998) reports that between 1978 and 1997, there were 109,082 cases in western Russia. Specific regions of Russia have reported relatively large outbreaks. For example, the Bashkiria region has consistently

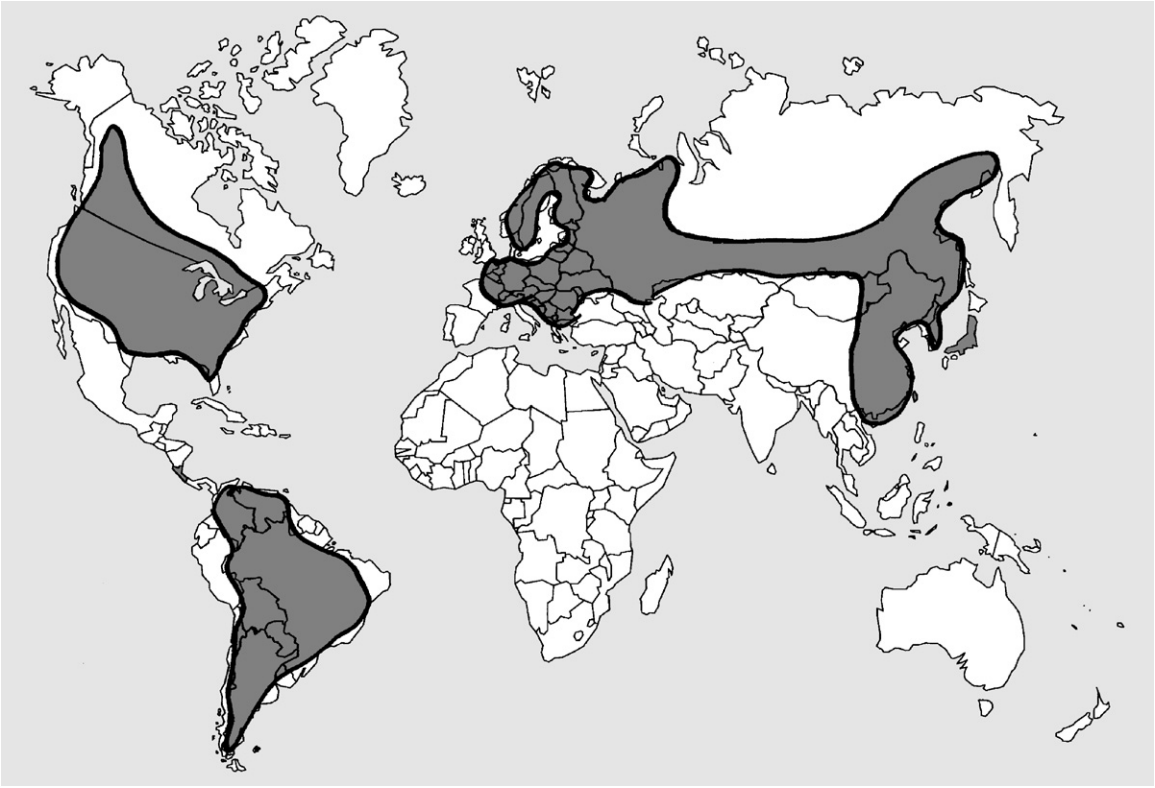

FIGURE 23.2 Distribution of hantavirus disease worldwide. Hantaviruses associated with HPS are found exclusively in North, Central, and South America. HFRS-associated viruses are widespread throughout Europe, the Balkans, Western Russia, China, and the Korean peninsula, Asia.

reported high number of cases, including epidemics in 1993 and 1997, where the number of cases approached 150 and 287 cases/100,000 persons, respectively (Niklasson et al., 1993; Tkachenko et al., 1998). More recently (in 2007), there were outbreaks (more than 3000 cases) in the vicinity of the towns of Voronezh and Lipetsk (Dybas, 2007). As in China and Korea, most of the HFRS cases in Russia occur in rural areas; however, there can be epidemics in urban areas, as was the situation in the 1997 Bashkiria outbreak (Tkachenko et al., 1998). In western Russia, most of the HFRS is caused by PUUV, carried by bank voles, *Clethrionomys glareolus*. Case-fatality rates indicate that strains of PUUV in Russia, such as strain K27 isolated from a fatal human case, cause a more severe form of disease (0.4% case fatality) than the strains of PUUV found in Finland and Sweden (0.1% case fatality) (Tkachenko et al., 1998). Several other countries in Eastern Europe, including Byelorus, Estonia, Georgia, Latvia, Lithuania, Poland, Romania, and Ukraine, have reported rare or sporadic cases of HFRS or serologic evidence that pathogenic hantaviruses are endemic (reviewed in Tkachenko et al., 1999; Vapalahti et al., 2003; Avsic-Zupanc, 1998). There is no HFRS vaccine licensed for use in Russia or Eastern Europe.

Northern and Central Europe/Scandinavia

A review published in 2003 indicated that 12 countries in Europe reported five or more cases of HFRS per year (Vapalahti et al., 2003). Other countries in Europe with rare or sporadic cases of HFRS or seroepidemiologic evidence of infection include Austria, Czech Republic, Great Britain, Portugal, and Switzerland (Lee, 1996; Vapalahti et al., 2003). It is likely that HFRS in Europe is underdiagnosed because the disease is relatively mild as compared to HFRS in Asia or HPS in the Americas. A study in Belgium reported that the seroprevalence was at 3.8%, well above the number of diagnosed cases (van der Groen et al., 1983). Sweden and Finland have the most cases (300 and 1000 per year, respectively) followed by

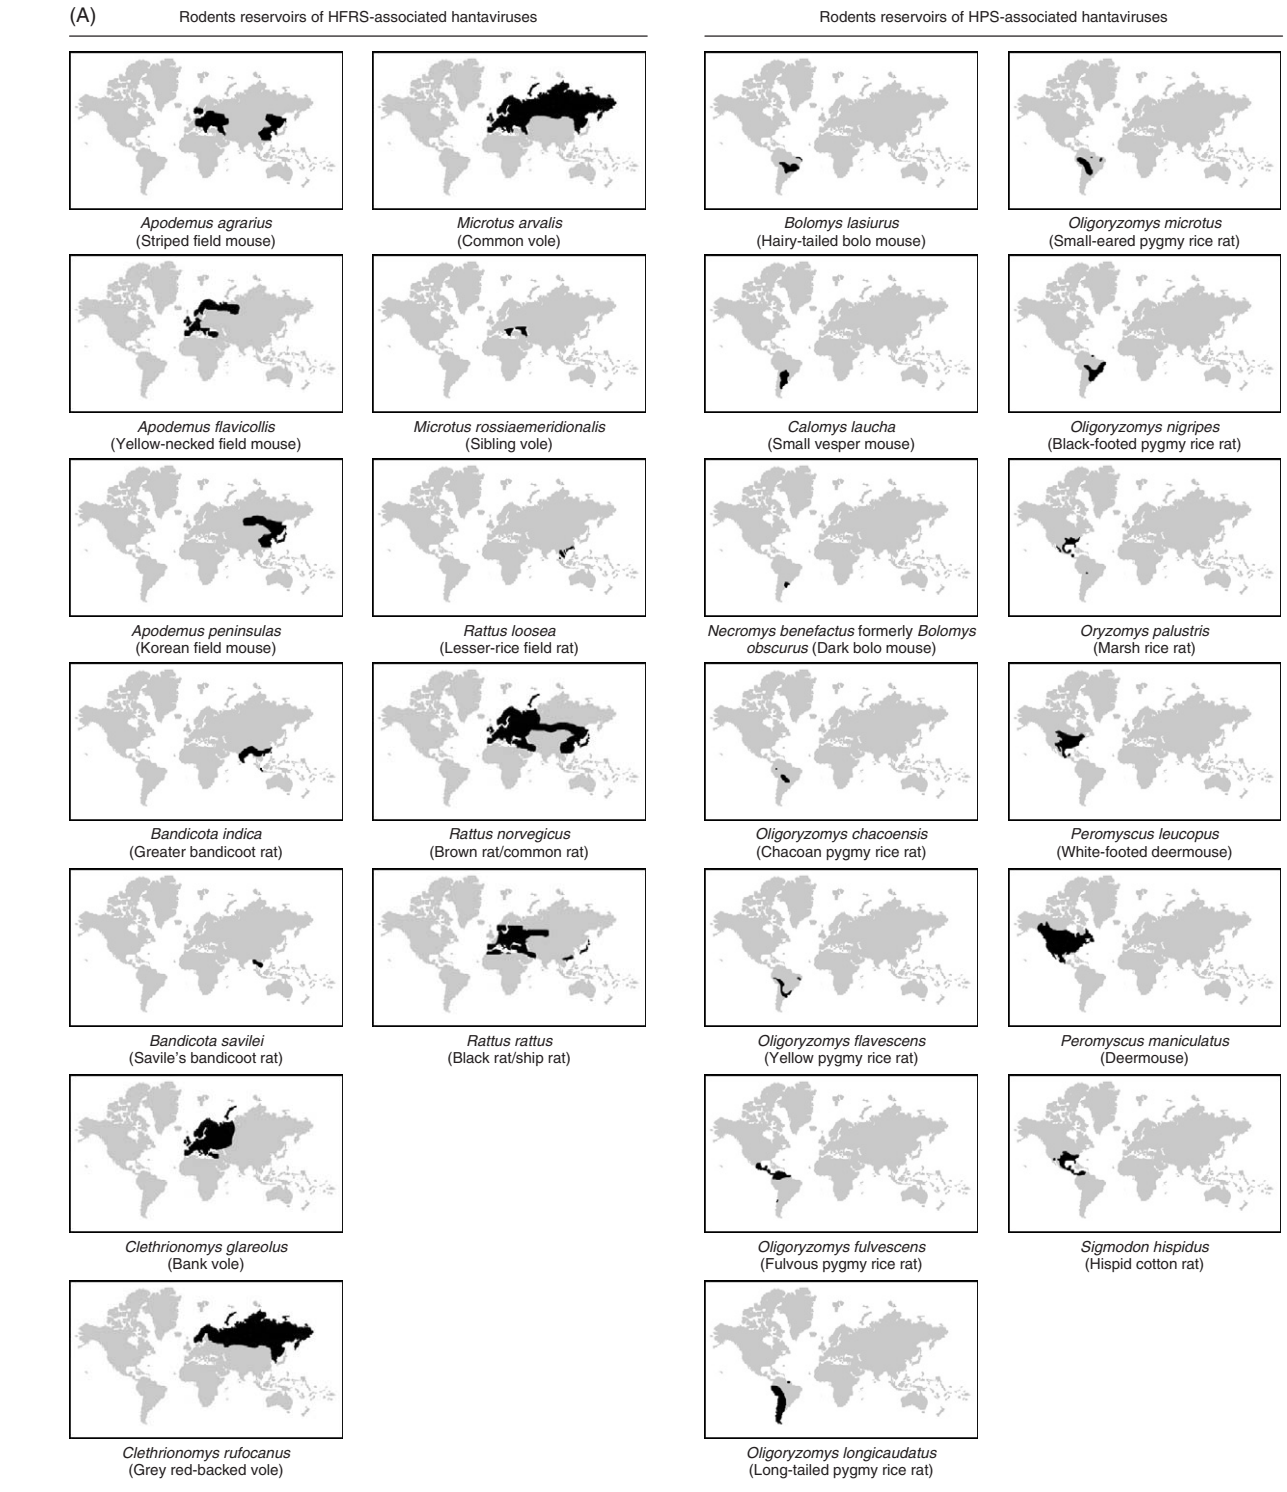

FIGURE 23.3 Distribution of hantavirus rodent reservoirs. (A) Schematic representation of the distribution of individual rodent species that are reservoirs of known pathogenic hantaviruses. (B) Estimate of the number of different rodent species in a given area that are reservoirs for hantaviruses known to cause human disease (see color plate section).

Germany, France, and Belgium, each with ~100 cases per year. These national numbers mask the health problem caused by HFRS in specific geographic regions. For example, the number of cases in northern Sweden is much higher than in the south. Most of the cases are in Vasterbotten County where the incidence is normally ~23.5 cases/100,000 (Settergren et al., 1988). In Finland, the number of cases in the province of Mikkeli was 70 cases/100,000, mostly in farmers (Vapalahti et al., 1999). PUUV is carried by the red bank vole, *C. glareolus*, and DOBV is carried by the yellow-necked mouse, *A. flavicollis*. These viruses are believed to cause most of the cases of HFRS in Northern Europe and Scandinavia.

Recently, HFRS has become more of a health concern in Europe. In 2005, there was a relatively large series of outbreaks in Belgium, France, the Netherlands, Luxembourg, and Germany (1114 cases) caused by PUUV (Heyman et al., 2007). In Germany, many of the cases occurred in relatively large cities, including Osnabuck and Cologne where the annual incidence was 8.5 and 4.2 cases/100,000, respectively (Abu Sin et al., 2007). In 2007, Sweden experienced an almost 10-fold increase in the annual number of HFRS (nephropathica epidemica) cases (Pettersson et al., 2008). Vasterbotten County accounted for 800 of the 2200 cases, with two fatalities. In Europe and elsewhere, there is a suspected link between climate change, food-source production, reservoir population, and incidence of human disease. Climatic conditions that result in increased production of food source (e.g., mast years resulting in high yields of oak and beech nuts) can, in turn, result in increase in reservoir population and incidence of human disease (Heyman et al., 2007; Vapalahti et al., 2003). Although HFRS in Europe has not resulted in high numbers of fatalities, this disease does have a substantial impact on the healthcare system because many patients are hospitalized and some require hemodialysis. There is no HFRS vaccine licensed for use anywhere in Northern and Central Europe or Scandinavia.

Southern Europe/Balkans

A review in 1999 indicated that there were approximately 100 HFRS cases per year in the Balkans (Avsic-Zupanc, 1998). Essentially, all of the countries in the Balkans have reported cases of HFRS (Table 23.3). There is also evidence of HFRS in Albania (Antoniadis et al., 1996). The military conflicts in the former Yugoslavia resulted in increased numbers of HFRS cases, as would be expected based on the increased numbers of personnel working and sleeping outdoors (Avsic-Zupanc, 1998). Severe cases of HFRS in the Balkans are usually caused by DOBV carried by the yellow-necked field mouse, *A. flavicollis* (Avsic-Zupanc et al., 1992). PUUV is also circulating in this region and has been associated with disease (Lundkvist et al., 1997). There is no HFRS vaccine licensed for use in Southern Europe or the Balkans.

North America

HPS in the Americas is relatively rare, but the disease is among the most pathogenic of any acute viral disease. Like HFRS, HPS afflicts mostly working-age males in rural areas (CDC, 2007). Since the first outbreak of HPS in the "Four Corners region" of the southwestern United States, there have been approximately 465 cases of HPS with 35% case fatality. In Canada, there have been ~100 cases. The hantavirus responsible for most of the HPS cases in the United States is SNV carried by deer mice, *Peromyscus maniculatus*. Other hantavirues that have caused disease in the United States include Black Creek Canal virus (BCCV), Bayou virus (BAYV), and New York virus (NYV). There is no HPS vaccine licensed for use in North America.

Central America

HPS is not widespread in Central America. The only country that has reported significant outbreaks is Panama (Bayard et al., 2004). Specific regions, such as the Azuero peninsula, have seroprevalance rates as high as 30% (Armien et al., 2004). A recent serial serosurvey revealed a very high seroprevalence against hantaviruses in certain communities where changes in agribusiness may have brought hantavirus-carrying rodents into more frequent contact with humans. The hantavirus associated with human disease in Panama is Choclo virus, carried by *Oligoryomys fulvescens* (Vincent et al., 2000). There is no HPS vaccine licensed for use in Central America.

South America

Several countries in South America have reported hantavirus disease including Argentina, Bolivia, Brazil, Chile, Columbia, Paraguay, Uruguay, and Venezuela (PAHO, 2004). A list of the viruses that cause HPS in South America is shown in Table 23.1, and a map of the rodent geographic range is shown in Fig. 23.3. ANDV, carried by the long-tailed pygmy rice rat, *O. longicauddatus*, and related viruses cause

[a] Additional countries reporting hantavirus disease, or seroepidemiological evidence of pathogenic hantaviruses, are listed in the text.
[b] Epidemic year.

most of the cases in Chile, Argentina. Juquitiba virus, carried by the black-footed pygmy rice rat, *O. nigripes*, is associated with most of the cases in Brazil. Interestingly, ANDV is the only hantavirus associated with person-to-person transmission, and many of the cases in Chile and Argentina have occurred in clusters (Lazaro et al., 2007; Toro et al., 1998; Vial et al., 2006; Wells et al., 1997). There is no HPS vaccine licensed for use in South America.

CLINICAL DISEASE

HPS, HFRS, and NE are three clinical diseases caused by hantaviruses. The diseases are similar in many respects, and share a number of clinical manifestations which have been the focus of several recent reviews (Jonsson et al., 2007; Mertz et al., 2006; Muranyi et al., 2005). Clinical disease, which is often divided into four to five distinct phases, occurs after an incubation period varying from about 7 to 36 days (Muranyi et al., 2005; Vial et al., 2006; Young et al., 2000) and results from the infection of endothelial cells and subsequent increase in vascular permeability.

Hantavirus Pulmonary Syndrome

After the virus incubation period, the onset of HPS begins with a prodromal, febrile period that typically lasts 3–5 days but can last as long as 10 days (Hjelle and Glass, 2000; Peters and Khan, 2002). Symptoms during the onset of HPS are nonspecific and flu-like and include fever, myalgia, malaise, and may also consist of headache, dizziness, anorexia, abdominal pain, nausea, vomiting, and diarrhea (Enria et al., 2001). Other reported early symptoms included a transient skin rash and conjunctival suffusion. Hantavirus-specific IgG and IgM antibodies can also be detected during this phase. At the end of this phase, however, more serious symptoms may present, such as the abrupt onset of a nonproductive cough, and shortness of breath and tachypnea that mark the beginning of the cardiopulmonary phase (Hallin et al., 1996; Levy and Simpson, 1994). It is at this point that most patients seek medical attention and, in severe cases, may rapidly develop pulmonary edema and respiratory failure, usually within 4–24 h. Whereas chest radiographs of patients may be normal during the prodromal febrile phase, interstitial edema and the presence of bilateral pulmonary infiltrates usually develop within the first few hours of the cardiopulmonary phase (Ketai et al., 1994). A presumptive diagnosis may be made during this phase based on the presence of pulmonary edema and an abnormal peripheral blood smear, including thrombocytopenia, myelocytosis, a lack of significant toxic granulation in neutrophils, hemoconcentration, and >10% immunoblastic lymphocytes (Mertz et al., 2006). Furthermore, the cardiogenic shock syndrome leads to arrhythmias, lactic acidosis, hypotension, and oliguria, while pulmonary edema contributes to tachypnea, exertional dyspnea, and nonproductive cough with hypoxemia as a common feature. Hypovolemia occurs as a result of high-protein-fluid leakage from the blood into the lung interstitium and alveoli, and this further aggravates shock symptoms. The cardiopulmonary phase usually lasts 2–4 days, but in severe cases, approximately half of the patients succumb to hypoxia and circulatory compromise within 24–48 h of developing pulmonary edema. Fatality rates for the most common HPS hantaviruses, SNV and ANDV, range from 30% to 50%, respectively, while deaths from other HPS strains occur in approximately 15% of the cases (Doyle et al., 1998). Patients that survive the cardiopulmonary phase enter the third or diuretic phase, resulting in the rapid clearance of pulmonary edema and spontaneous diuresis followed by cessation of fever and shock. The final convalescent phase may last up to 2 months and may be marked by weakness, fatigue, and abnormal pulmonary function including abnormal diffusion capacity, but usually results in full recovery.

While New World hantaviruses are largely associated with pulmonary dysfunction, cases of renal involvement have been associated with BCCV and BYV, and renal failure was a common feature of Oran-virus-associated HPS infection (Levis et al., 1998; Nichol, 2001). Other clinical symptoms may include conjunctival injection, facial flushing, pharyngeal congestion, petechiae, abnormal urine analysis, and/or frank hemorrhages (Lazaro et al., 2000).

Hemorrhagic Fever with Renal Symptoms

The early clinical manifestations of HFRS are similar to HPS with an initial febrile phase that manifest with acute flu-like symptoms such as high fever, backache, abdominal pain, chills, myalgia, malaise, and bradycardia. The febrile phase, which can last 3–5 days, is also characterized by photophobia, pharynx enathema, diffuse reddening of the face, development of petechia on the palate, hematuria, atypical gross proteinuria, and can include conjunctival hemorrhage and transient visual impairment. After the onset of fever, patients enter a 3–6-day hypotensive phase with symptoms of varying degrees including leukocytosis, thrombocytopenia, elevated serum creatine, tubulinterstitial nephritis, necrotizing glomerulonephritis, IgA nephropathy, petechiae, and nose bleeds to more severe complications that can

include intracranial hemorrhages (Linderholm and Elgh, 2001). Nausea and vomiting with severe clinical shock and hypotension, likely due to massive capillary leakage, have also been reported during the hypotensive phase (Warner, 1996). Renal complications of HFRS, acute renal failure caused by interstitial hemorrhage and interstitial infiltrates (Beers and Berkow, 2005; Sirotin and Keiser, 2001), will typically manifest in the oliguric phase stage of illness. During this phase that begins approximately 8 days after the onset of symptoms, hemorrhagic manifestations become prominent, patients have reported abdominal and/or back pain, and have reduced urinary output. After this, the polyuric or diuretic phase, beginning approximately on day 11, is characterized by a dramatic increase in urinary output, as much as 3–6 L/day, and considerable fluid and electrolyte shifts are observed. The subsequent convalescent phase can last from weeks to several months. Sequelae such as chronic renal failure and hypertension (Makela et al., 2000) can occur during this phase but are rare. Approximately 10% to 15% of HFRS cases are clinically severe with 6–15% of cases becoming fatal. Note that for all phases of HFRS, the overall number of clinical phases and severity may differ considerably on a patient-to-patient basis. Other clinical manifestations that may be involved during the course of HFRS include visual impairment; acute myopia; CNS involvement, resulting in seizures, myocarditis, gastrointestinal hemorrhages; and thyroid, liver, pancreas, and lung involvement.

Nephropathia Epidemica

NE is a less severe form of disease similar to HFRS that is typically caused by PUUV and occurs most commonly in Scandinavia and Central Europe. The majority of NE cases are asymptomatic (~90%), and the overall case-fatality rate of severe NE with acute renal failure is far lower than HFRS (approximately 0.1% to 1% for NE versus 5% for HRFS) (Warner, 1996; Linderholm and Elgh, 2001). Clinically, NE presents similarly to HFRS, while severe neurological complications such as paralysis of the bladder or seizures are reported in approximately 1% of NE patients. After a 3–4-day febrile phase and a 3-day oliguric phase, patients develop polyuria. The convalescent phase may extend over several weeks, and sequelae are rare.

TREATMENT

Treatment of patients with HPS or HFRS remains largely supportive. With respect to HFRS, fluid restriction during the hypotensive and oliguric phases reduced mortality with KHF (Steer, 1955). Nonsteroid anti-inflammatory drugs and any drug that is toxic to the kidneys should be avoided, and close management of electrolyte balance is critical (Linderholm and Elgh, 2001). Dialysis may be appropriate in severe cases of HFRS but is rarely needed in cases of NE.

Intensive care for HPS patients includes careful fluid management, monitoring of cardiac output, and ventilatory support (Castillo et al., 2001; Hallin et al., 1996; Levy and Simpson, 1994). Fluid balance must be vigilantly managed, but not overloaded, due to complication with pulmonary edema (Warner, 1996). Cardiac output and function should be monitored closely and maintained. Supplemental oxygen may be sufficient to treat patients with mild HPS, but in severe cases, disease progression and respiratory failure will occur rapidly and may require venoarterial extracorporeal membrane oxygenation (ECMO) therapy to provide cardiopulmonary support. The efficacy of ECMO therapy during early HPS cases is debatable (Hallin et al., 1996; Crowley et al., 1998; Enria et al., 2001), but more recent studies involving ECMO treatment in the United States (Mertz et al., 2006) and Chile (Tomicic et al., 2005) have been more promising, with a survival rate of approximately 85%. Much of this recent success is attributable to advances in diagnostic tools (e.g., ELISA, PCR, Western blot, strip immunoblot assay) that provide a more rapid diagnosis resulting in more rapid and aggressive treatment.

The use of steroid therapy has also been reported to have some effect in influencing the positive outcome of hantavirus diseases. In two separate cases, patients suffering from PUUV infection improved after extended administration of corticosteroids (Dunst et al., 1998; Seitsonen et al., 2006). The use of steroids to treat hantavirus disease is not without drawbacks, though, as immunosuppression has resulted in the occurrence of secondary infections (Siqueira et al., 2007). Given the apparent relationship between the immune response and pathogenesis of hantavirus disease, the use of methylprednisolone in the treatment of HPS is being investigated in a controlled study in Chile (Mertz et al., 2006).

There is currently no Food and Drug Administration (FDA) approved antiviral drug or immunotherapeutic agent approved for the treatment of hantaviral diseases. The antiviral drug ribavirin has shown success in reducing viral titers, increasing survival rates, and reducing the severity of HFRS in patients in China (Huggins et al., 1991) and in HTNV-infected suckling mice (Huggins et al., 1986). The use of ribavirin as a treatment for HPS has not proved successful (Chapman et al., 1999; Mertz et al., 2004); however, the number of HPS patients to test the efficacy of ribavirin

has been inadequate. In these studies, HPS patients treated with ribavirin did not begin until after the onset of the cardiopulmonary phase of disease. In contrast, the HFRS patients treated with ribavirin began treatment before the onset of renal complications, suggesting that the efficacy of ribavirin treatment may depend largely on the phase of infection and the severity of disease when ribavirin is administered. While ribavirin may not be effective in treating patients after the onset of clinical symptoms, it may be possible to use ribavirin as a prophylactic treatment for people at high risk of contracting disease such as recent household contacts of ANDV index cases where there is the threat of person-to-person transmission (Martinez et al., 2005; Padula et al., 1998). Additionally, evidence that patients with lower titers of neutralizing antibodies often develop a more severe disease (Bharadwaj et al., 2000) had led to the speculation that administration of high-dose neutralizing antibodies as a postexposure immunoprophylatic may reduce disease severity and improve survival (see "Postexposure Immunoprophylaxis").

PATHOGENESIS

In rodents, hantavirus infection results in a largely nonpathogenic, persistent infection (Meyer and Schmaljohn, 2000). In humans, however, clinically productive hantavirus infection results in one of the two diseases, HPS or HFRS, that are both characterized by changes in endothelial cell permeability and vascular edema (Cosgriff, 1991; Lee, 1991; Nolte et al., 1995; Zaki et al., 1995). While the mechanisms underlying the pathogenesis of HPS and HFRS are not completely understood, the direct effects of viral infection of endothelial cells and the immune response to hantavirus infection have been proposed as playing important roles.

Possible Direct Role of Viral Infection of Endothelial Cells on Pathogenesis

Analysis of hantavirus-infected patients (Huang et al., 1994; Zaki et al., 1995; Nolte et al., 1995) and experimentally infected hamsters (Hooper et al., 2001b; Milazzo et al., 2002; Wahl-Jensen et al., 2007) suggests that endothelial cells are the primary targets of hantaviruses; an observation validated by multiple in vitro studies (Gavrilovskaya et al., 1998, 1999; Geimonen et al., 2002; Yanagihara and Silverman, 1990). Infection of endothelial cells appears to be mediated by the expression of β1 and β3 integrins on the surface of endothelial cells as forced expression of these integrins renders cells permissive to hantavirus infection while antibody blockade of these integrins prevents infection (Gavrilovskaya et al., 1998, 1999). Hemorrhagic diseases, in general, are caused by the dysregulation of permeability of the vascular endothelium. Integrins expressed by endothelial cells, such as αvβ3, play key roles in maintaining vascular integrity and regulating permeability (Hynes et al., 1999; Kevil et al., 1998; Leavesley et al., 1993; Sugimori et al., 1997; Tsukada et al., 1995). In this respect, several human hemorrhagic diseases, including Glanzmann's disease and Goodpasture's syndrome, and at least three autoimmune hemorrhagic diseases result from the dysregulation of β3-integrin function (Borza et al., 2003; Gunwar et al., 1991; Hodivala-Dilke et al., 1999; Joutsi-Korhonen et al., 2004; Kalluri et al., 1994; Watkins et al., 2002). Moreover, β3-integrin-deficient mice have vascular permeability defects and mucocutaneous hemorrhage similar to that seen during HFRS (Hodivala-Dilke et al., 1999). Accordingly, infection of endothelial cells by nonpathogenic hantaviruses such as Prospect Hill (PH) virus involves the β1 integrin, whereas infection by pathogenic hantaviruses is associated with β3 integrin (Gavrilovskaya et al., 1998, 1999). Pathogenic hantaviruses bind inactive αvβ3 integrin structures (Raymond et al., 2005), suggesting that infection may interfere with the formation of active αvβ3 conformations which subsequently would inhibit normal β3-integrin function, as seen by Gavrilovskaya et al. (2002). This has lead to the suggestion that virus binding to αvβ3 integrin may disrupt the integrity of endothelial cell junctional complexes leading to increased permeability. Endothelial cells are held together by three major types of junctions, i.e., tight junctions, gap junctions, and adherens junctions, along with numerous other adhesion molecules including PECAM that can interact with αvβ3 integrin (reviewed by Bazzoni and Dejana, 2004; Wallez and Huber, 2007). Inhibition of αvβ3-integrin signaling has been shown to induce the formation of incomplete adherens junctions (Ozaki et al., 2007); however, there is little direct visual evidence that hantavirus infection in vivo results in gap formation between endothelial cells (Wahl-Jensen et al., 2007; Zaki et al., 1995). Nevertheless, in vivo disruption of adherens junctions by targeting VE-cadheren can result in increased permeability without the formation of visible gaps (reviewed by Bazzoni and Dejana, 2004). Still, other in vitro experiments have demonstrated that infection in and of itself does not affect the integrity of adherens junctions (Sundstrom et al., 2001) or increase permeability (Niikura et al., 2004; Sundstrom et al., 2001). Alternatively, hantavirus may influence permeability by altering the function of endothelial

cell cation channels by promoting the influx of Ca^{2+} through αvβ3-integrin signaling (Bhattacharya et al., 2000; Kawasaki et al., 2004). TNFα has been shown to amplify Ca^{2+} influx and endothelial cell permeability by increasing the expression of the TRPC1 Ca^{2+} channel (Paria et al., 2004). Moreover, Ca^{2+} signaling can increase endothelial cell permeability by disassembling VE-cadherin junctions (Sandoval et al., 2001). Intriguingly, TNFα increased the permeability of hantavirus-infected cells and further prolonged permeability even after TNFα was removed (Niikura et al., 2004). Whether this is the result of increased Ca^{2+} signaling is unknown, but it may reflect the importance of endothelial cell and/or adaptive antiviral responses to elicit full hantavirus pathogenesis.

Possible Role of Innate Antiviral Responses on Pathogenesis

Nonpathogenic hantaviruses are not associated with human disease even though, like pathogenic species, they can infect human endothelial cells (Yanagihara and Silverman, 1990). Early experiments demonstrated that HTNV infection of endothelial cells can be blocked by adding exogenous type I IFN (Pensiero et al., 1992), and Geimonen et al. (2002) demonstrated that there is a distinct temporal difference in the induction of the interferon response between pathogenic and nonpathogenic hantavirus strains. Within 24 h of infection, nonpathogenic hantaviruses upregulated numerous interferon-inducible genes (ISG), whereas pathogenic strains largely failed to induce ISG expression. Both pathogenic and nonpathogenic viruses induced IFNβ late after infection (4 days), yet both can inhibit signaling from exogenous type I interferon via STAT-1/2 (Spiropoulou et al., 2007). How pathogenic hantaviruses regulate endothelial cell interferon responses is unknown, but it may relate to portions of the G_n cytoplasmic tail (Alff et al., 2006) and the presence of immuno-tyrosine activation motifs (ITAMs) (Geimonen et al., 2003), as has been demonstrated for other viruses (Beaufils et al., 1993; Dehghani et al., 2002; Lee et al., 1998a; Miller et al., 1995; Willems et al., 1995; Xu et al., 1999).

Aside from forming a barrier within the vasculature and regulating vascular permeability, endothelial cells also secrete cytokines and chemokines, and upregulate adhesion molecules and costimulatory molecules that can prevent infection and can recruit and stimulate cells of the immune system (Choi et al., 2004). Infection of endothelial cells does not appear to directly affect the expression of many cytokines, adhesion and costimulatory molecules (Sundstrom et al., 2001). Rather, expression of these molecules appears to be regulated by inflammatory cytokines such as IFNγ and TNFα. Both pathogenic and nonpathogenic hantaviruses have been shown to induce the translocation of NF-κB and interferon regulatory factors to the nucleus and the subsequent upregulation of leukocyte chemokines such as RANTES, IL-8, and IP-10 (Sundstrom et al., 2001), albeit somewhat species-specifically. At later times after infection, endothelial cells infected by some pathogenic hantaviruses have also been shown to upregulate cytokines such as IL-6, which, along with IL-1 from infected or activated macrophages, may cause increases in endothelial permeability (Kerkar et al., 2006; Maruo et al., 1992; Nooteboom et al., 2006) and have been implicated in the pathogenesis of HFRS (Linderholm et al., 1996). If cytokines mediate vascular permeability during hantavirus disease in vivo, then histological evidence from human cases or experimentally infected hamsters suggests that it does not necessarily involve the restructuring of endothelial gap junctions (Wahl-Jensen et al., 2007; Zaki et al., 1995). Alternatively, IL-1 and IL-6 may synergistically induce vascular endothelial growth factor (VEGF) expression by endothelial cells (Loeffler et al., 2005; Sironi et al., 1989) and the VEGF induced under those conditions could lead to the formation of vesiculo-vacuolar organelles (VVOs) within endothelial cells (reviewed in Dvorak and Feng, 2001; Feng et al., 1999). These cytoplasmic, grape-like clusters provide a direct link between the luminal and ablumenal sides of endothelial cells and have been shown to provide the major route of macromolecular extravasation at sites of increased vascular permeability in veins associated with experimental tumors and in animal models of allergic inflammatory eye disease. Further studies are needed to determine if the plasma leakage in HPS involves a paracellular or transcellular mechanism. Inducible nitric oxide synthase (iNOS), which can be produced by endothelial cells, neutrophils, and macrophages and is known to alter alveolar epithelial and endothelial cell permeability, is upregulated during HPS (Davis et al., 2002). There is further evidence that nitric oxide can upregulate αVβ3-integrin expression on endothelial cells, in vitro (Lee et al., 2000), suggesting a mechanism by which the immune response to hantavirus may propagate hantavirus infection. Additionally, several cytokines produced by lung endothelial cells, epithelial cells, and macrophages are known to influence the deposition of fibrin that is characteristic of HPS pathology in both hamsters (Wahl-Jensen et al., 2007) and humans (Zaki et al., 1995). Permeability of the vascular endothelium is accompanied by an influx of plasma proteins including fibrinogen, which is converted to fibrin at sites of inflammation. TNFα, possibly from

macrophages or T cells, can induce the expression of TGFβ from lung fibroblasts (Sullivan et al., 2005) and epithelial cells (Warshamana et al., 2001), which can subsequently act in concert with TNFα to enhance the formation of fibrin by inhibiting mechanisms of fibrinolysis (Idell et al., 1992). The presence of fibrin can further enhance vascular permeability, possibly by directly inducing the secretion of vasoactive IL-1 from mononuclear cells such as macrophages (Perez and Roman, 1995). Whether regulatory cytokines such as IL-10, which can inhibit the synthesis of inflammatory cytokines and chemokines and decrease fibrin deposition by increasing fibrinolysis (Okada et al., 2000), can improve the course of HPS has not been investigated.

These data suggest that the ability of pathogenic hantaviruses to regulate aspects of the endothelial cell antiviral response may contribute to hantavirus disease pathogenesis. The rapid induction of type I IFN and leukocyte chemokine responses in response to nonpathogenic hantaviruses may contribute to decreased viral replication and dissemination, allowing for more rapid viral clearance which may ultimately lead to a lack of disease. In contrast, the delayed type I IFN responses stimulated by pathogenic hantaviruses may lead to increased viral replication and dissemination, resulting in large numbers of infected endothelial cells secreting vasoactive cytokines and attracting activated leukocytes.

Possible Role of Adaptive Immune Response in Pathogenesis

The noticeable lack of cytopathic effect after hantavirus infection of endothelial cells and the presence of activated T cells during hantavirus disease pathogenesis have led to the speculation that hantavirus disease pathology is mediated, at least in part, by hantavirus-specific effector T cells. Consistent with this idea, increased numbers of activated $CD8^+$ T cells are observed during the acute phase of HFRS (Huang et al., 1994) and acute PUUV infections (Mustonen et al., 1994; Temonen et al., 1996) with disproportionate CD4 to CD8 T-cell ratios (Chen and Yang, 1990). Similarly, large numbers of $CD4^+$ and $CD8^+$ T cells and large numbers of cytokine-producing cells are present in the lungs, spleens, and hearts of HPS patients (Mori et al., 1999; Nolte et al., 1995; Zaki et al., 1995), and the numbers of T cells present in the blood of acute HPS patients can correlate with the clinical severity of the disease (Kilpatrick et al., 2004). In fatal HPS cases, mononuclear cell infiltrates in these tissues were found to include a mixed population of macrophages and T cells which consisted of a disproportionately large number of activated $CD8^+$ T cells. Further studies suggest a genetic linkage between the severity of disease, and MHC haplotype has been observed in patients with NE and HPS, further linking $CD8^+$ T cell responses with disease. Makela et al. (2002) and Mustonen et al. (1996) showed that the HLA-B8-DR3 haplotype was associated with a more severe NE disease outcome) and that the HLA-B27 haplotype was associated with milder disease (Mustonen et al., 1998). Other data suggest a link between the HLA-B35 haplotype and a more severe form of HPS caused by SNV (Kilpatrick et al., 2004).

The extent to which T cells may mediate the pathogenesis of hantavirus infection may also be influenced by infected endothelial cells themselves (reviewed in Choi et al., 2004). Human endothelial cells constitutively express both MHC I and MHC II complexes, allowing them to directly present viral peptides to both activated $CD4^+$ and $CD8^+$ T cells. Moreover, endothelial cells also express a variety of early and late costimulatory molecules and secrete cytokines that can augment or prolong T-cell responses, including IL-6, which enhances T cell–endothelial cell interactions (Watson et al., 1996). $CD8^+$ T cells typically eliminate virus-infected cells using either a perforin/granzyme- or Fas/FasL-mediated death pathway. However, the lungs of HPS patients or infected hamsters reveal little obvious damage to endothelial cells (Hooper et al., 2001b; Nolte et al., 1995; Wahl-Jensen et al., 2007; Zaki et al., 1995), suggesting that if T cells contribute to endothelial cell permeability, then vascular leakage is caused by the release of vasoactive cytokines, rather that endothelial cell apoptosis. Why infected endothelial cells are not subject to elimination by $CD8^+$ T cells and natural killer (NK) cells is still not clear, but elevated levels of perforin, granzyme B, and the epithelial cell apoptosis marker caspase-cleaved cytokeratin-18 in the serum of patients infected with PUUV argues against a global inhibition of perforin and granzyme synthesis. This suggests that infected epithelial cells do not benefit from the same type of protection as endothelial cells (Klingstrom et al., 2006). Increased levels of TNFα and transforming growth factor beta (TGFβ) have been found in kidney biopsies from acute NE patients (Temonen et al., 1996). Moreover, genetic predisposition to produce high amounts of TNF has been associated with severe NE (Kanerva et al., 1998b). Systemic levels of inflammatory cytokines have also been reported in plasma of HFRS patients and include TNFα, soluble TNFα receptor, IFNα, IFNγ, IL-6, and IL-10 (Linderholm et al., 1996). Similarly, Mori et al. (1999) described an increased prevalence of cytokines such as IL-1α, IL-1β, IL-2, Il-4, IL-6, TNFα, TNFβ, and IFNγ in the lungs and spleens of fatal HPS cases. Many of these cytokines are produced by activated T cells,

and all of them are implicated in increased vascular permeability (Beynon et al., 1993; Kerkar et al., 2006; Kotowicz et al., 2004; Maruo et al., 1992; Nooteboom et al., 2006). Consistent with a role for TNFα in immunopathology, mouse models of influenza virus (Xu et al., 2004) and respiratory syncytial virus infection (Rutigliano and Graham, 2004) have shown that the lung injury caused during infection is primarily due to $CD8^+$ T-cell-derived TNFα.

Hantaviral antigens have been detected in the macrophages, dendritic cells, and, to a lesser extent, lymphocytes (Huang et al., 1994; Zaki et al., 1995; Nolte et al., 1995). Whether interactions between T cells and hantavirus-infected, antigen-presenting cells or direct infection of T cells can lead to a dysregulated T-cell responses and overproduction of vasoactive cytokines or can cause the T-cell apoptosis and lymphopenia as was observed shortly after infection in both humans and experimentally infected hamsters (Wahl-Jensen et al., 2007; Zaki et al., 1995) is not known.

Taken together, these data suggest multiple ways that the innate and adaptive immune responses may contribute to hantavirus disease pathology. How these mechanisms contribute to disease will need to be explored further in an animal model that mimics hantavirus pathology in humans (e.g., Syrian hamsters). Ultimately, many of these mechanisms may work synergistically to promote disease, as shown in Fig. 23.4. Endothelial cells infected by pathogenic strains of hantaviruses, likely are unable to upregulate early type I IFN responses, allowing for efficient viral replication and dissemination. As T cells become activated, they migrate to the site of infection in response to endothelial-cell-derived chemokines, and encounter infected endothelial cells expressing viral antigens. The continued interactions between activated T cells and endothelial cells and vasoactive cytokines secreted by both may then act synergistically to induce changes in vascular permeability and edema consistently seen in hantavirus disease pathology.

There is a large body of circumstantial evidence implicating vasoactive cytokines in the pathogenesis of hantaviral diseases. Whether T cells are the primary source of these cytokines has yet to be determined. Still, it is likely that disease pathogenesis is a product of prolonged exposure to these cytokines and not merely the presence of these cytokines. Vaccines are likely to play an important role in limiting the production of these cytokines in the event of subsequent exposure to hantaviruses by either preventing infection altogether by neutralizing antibodies or by stimulating a rapid and robust memory T-cell response that will eliminate virus quickly before prolonged exposure to cytokines can cause disease.

VACCINES

The identification and isolation of the etiologic agent of HFRS by Lee et al. (1978a) provided a target for the development of vaccines to prevent HFRS. In general, two approaches have been used to develop candidate hantavirus vaccines: inactivated-virus vaccines and subunit molecular vaccines. To our knowledge, an attenuated live-virus vaccine approach has not been attempted. Inactivated hantavirus vaccines involve the replication of virus in rodent brains or cell culture. The virus is then chemically inactivated (e.g., formalin or β-propiolactone), combined with adjuvant (e.g., aluminum hydroxide), and delivered intramuscularly. In contrast, the subunit molecular vaccine approach avoids a requirement to replicate, purify, and inactivate highly pathogenic hantaviruses. Rather, modern molecular techniques are used to produce target immunogens delivered as proteins or as genes. Both protein-based and gene-based candidate hantavirus vaccines have been prepared and tested in animals. One gene-based molecular vaccine has been tested in phase 1 and 2 clinical trials, and several candidate gene-based vaccines have been tested in nonhuman primates. A summary of the published candidate inactivated-virus vaccines and subunit molecular vaccines is provided below.

Inactivated-Virus Vaccines

Efforts to produce inactivated hantavirus vaccines to protect against HPS have not been reported. Inactivated-virus HFRS vaccines based on HTNV, SEOV, and PUUV have been produced and tested in humans (reviewed in Hooper and Li, 2001; Cho et al., 2002). Versions of these vaccines are licensed for use in the Republic of Korea and China. The Korean vaccine, marketed as Hantavax®, is produced using formalin-inactivated HTNV grown in mouse brains, precipitated, purified, combined with aluminum hydroxide as an adjuvant, and administered intramuscularly twice at a 1-month interval. Hantavax® and a bivalent vaccine (HTNV and PUUV produced in hamster brains, inactivated with formalin, combined with aluminum hydroxide, and administered subcutaneously three times at 1-month intervals), were able to elicit antibodies in humans, as measured by immunofluorescence and, to a lesser extent, by plaque reduction neutralization test (Cho and Howard, 1999; Cho et al., 2002; Lee et al., 1998b). A vaccine similar to Hantavax®, but produced in Vero cells, was produced and tested in mice (Choi et al., 2003). That vaccine was more immunogenic than Hantavax®, eliciting higher neutralizing antibody responses, and inducing a

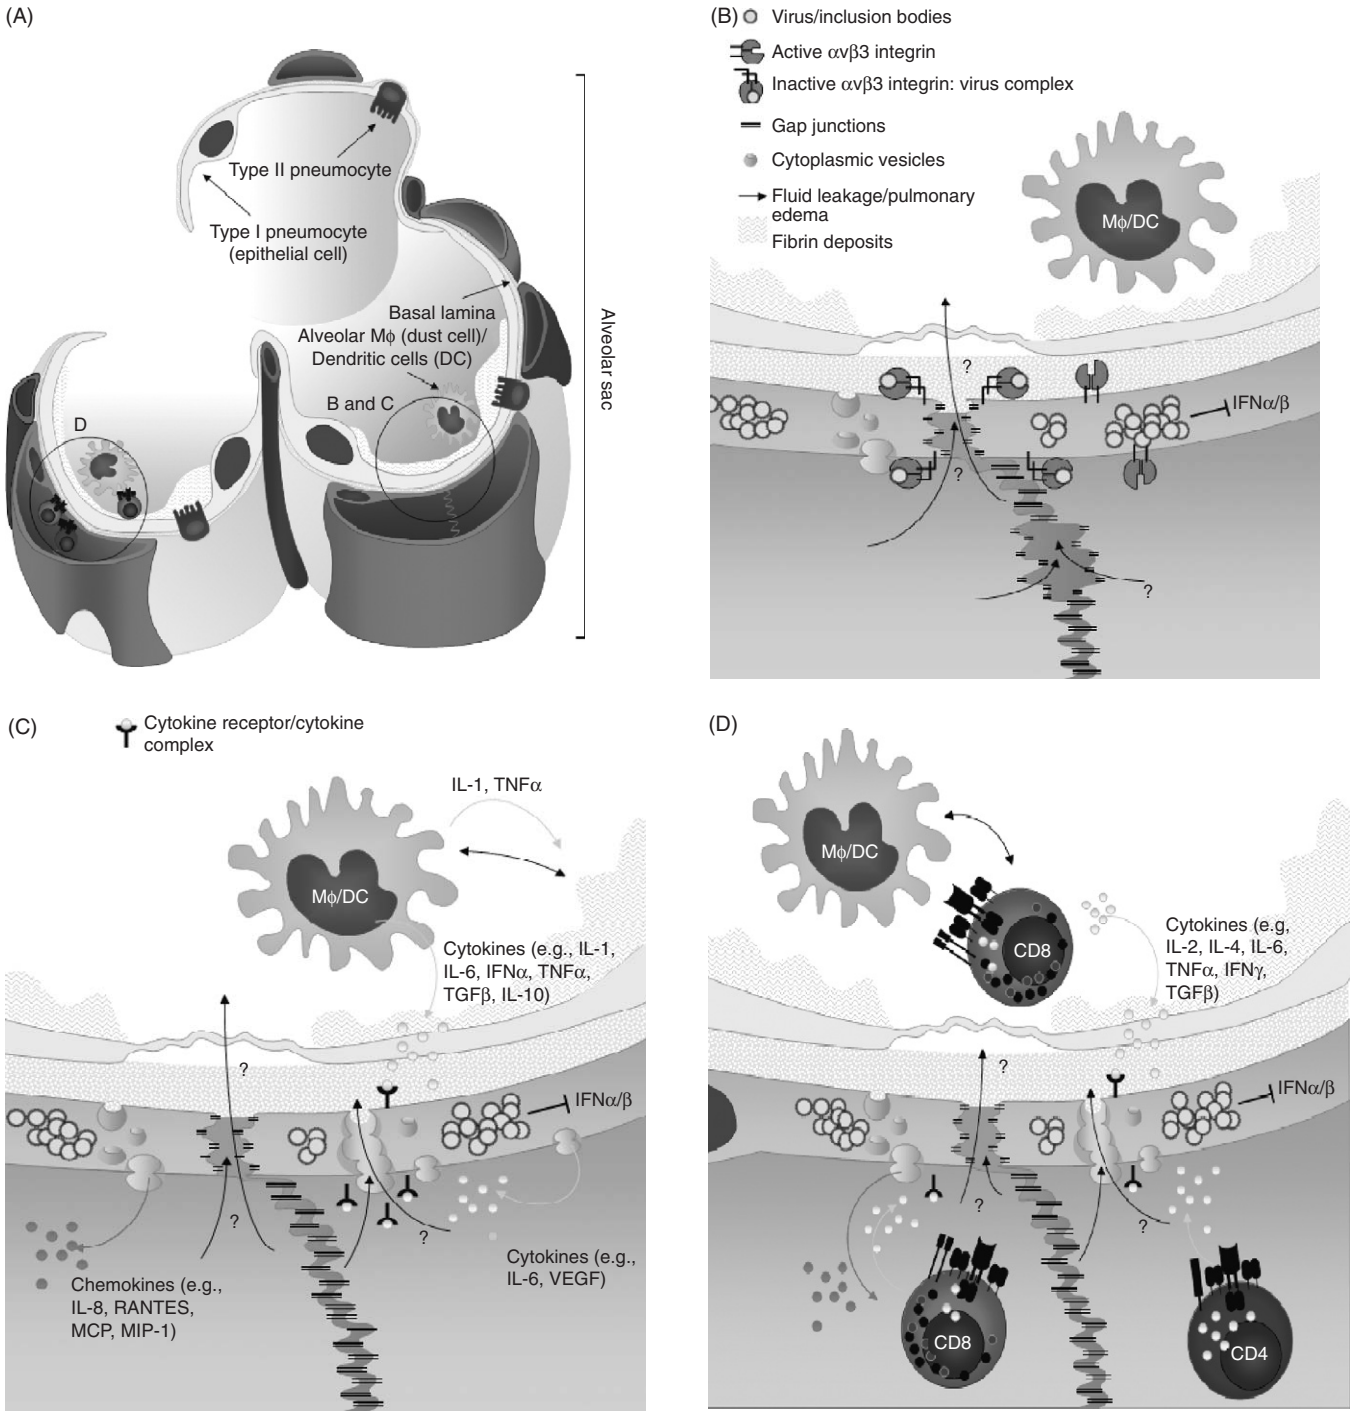

FIGURE 23.4 Possible mechanisms of hantavirus pulmonary syndrome disease pathogensis. (A) Gross schematic diagram of lung alveoli, associated cell types, and vasculature. (B) Vascular permeability as a direct result of virus binding. During infection of endothelial cells, hantaviruses may bind to inactive (bent) $\alpha v\beta 3$ integrin, inhibiting normal integrin function, which may cause endothelial cell junctions to open, allowing fluid to pass between endothelial cells and into the alveolar sac. Viral inhibition of type I IFN responses for efficient viral replication and dissemination. (C) Vascular permeability as a result of endothelial cell responses to infection. Infection of endothelial cells may induce the upregulation of cytokines and chemokines involved in promoting permeability via endothelial cell junctions and/or transcellular pathways, initiating fibrin deposition and attracting leukocytes,. Alternatively, infection may directly interfere with normal endothelial cell processes leading to abnormal regulation of vascular integrity. (D) Vascular permeability as a result of T-cell activation. Chemokines secreted by infected endothelial cells may attract activated $CD4^+$ and $CD8^+$ T cells. As T cells interact with viral antigens presented by infected endothelial cells and macrophages and dendritic cells, they secrete large amounts of cytokines that promote permeability via transcellular pathways or by interfering with the normal function of endothelial cell junctional proteins, contribute to fibrin deposition, and further enhance the activation state of endothelial cells and antigen-presenting cells.

greater level of protection in a mouse infection model when lower doses were administered.

In China, the inactivated-virus vaccines have been produced in cell culture, not in rodent brains. There are at least three vaccines licensed for use in China that are described in the literature. One vaccine involved the growth of Seoul-like virus (strain L99) in golden hamster kidney cells (GHKC) and inactivated using 0.025% formalin (Song et al., 1992). Another vaccine involved the growth of HTNV (strain Z10) in Mongolian gerbil kidney cells (MGKC) and inactivation by 0.025% β-propiolactone. A third bivalent vaccine manufactured by Tianyuan Corporation involved the replication of HTNV (strain Z10) and SEOV (strain Z5) in MGKC and inactivation by β-propiolactone. All of these vaccines included 0.5 mg/ml of aluminum hydroxide as adjuvant (Yongxin et al., 1998). In general, the vaccination schedules were an initial series of three vaccinations at 4- and 2-week intervals followed by a 1-year booster vaccination. All of these vaccines were similar to Hantavax® in that they elicited good antibodies as measured by IFAT and ELISA. Neutralizing antibody responses were detected with lower frequencies than IFAT or ELISA; however, after three vaccinations the neutralizing antibody titers could be detected in up to 100% of the vaccine recipients (Song et al., 1992; Zhu et al., 1994; Yongxin et al., 1998). The inactivated vaccines appear to be safe with minimal adverse effects, and there has been no evidence of antibody-dependent enhancement of disease.

The protective efficacy of these inactivated-virus vaccines remains ambiguous. For example, there are reports that the Chinese MGKC and GHKC vaccines were 94–98% protective in large-scale (tens of thousands) trials (Yongxin et al., 1998). In contrast, there are more recent reports published by Chinese researchers indicating that there is still no effective prophylactic vaccine directed at HFRS (Zhang et al., 2007). Epidemiologic data suggest that there are fewer cases of HFRS in areas where the vaccine has been used; however, there are still 20,000–50,000 cases of HFRS in China per year (Fang et al., 2006). It remains unclear as to how much of a role change in hantavirus-related education and/or changes in living conditions have affected the rates of HFRS in Asia. One epidemiologic study on the efficacy of Hantavax® reports that the apparent protective effects in Korea could be due to chance (Park et al., 2004).

Subunit Molecular Vaccines

Regardless of their efficacy, inactivated hantavirus vaccines have many drawbacks, including difficulty in replicating the virus to high titer, danger of working with high concentrations of a biosafety level 3 or 4 agent, difficulties ensuring complete inactivation of the virus, and the loss of protective epitopes by the inactivation process. To avoid these caveats, researchers around the world have embarked on efforts to identify protective immunogens and use those subunits of the virus as candidate vaccines. A summary of some of the efforts aimed at ultimately developing subunit molecular hantavirus vaccines are provided in Tables 23.4 and 23.5.

Protein-Based Vaccines

Several groups have investigated the immunogenicity and protective efficacy of recombinant hantavirus proteins. Technologies to produce the proteins include recombinant baculovirus, *E. coli*, yeast, and most recently, transgenic plants. In some studies, the N-protein elicited immune responses in vaccinated mice, hamsters, and bank voles (Dargeviciute et al., 2002; de Carvalho Nicacio et al., 2002; Geldmacher et al., 2004a, 2004b; Klingstrom et al., 2004; Lundkvist et al., 1996; Schmaljohn et al., 1990). In most cases, anti-N-protein antibodies were detected by ELISA, while in some studies, the activation of the cellular immune response was detected (de Carvalho Nicacio et al., 2002; Klingstrom et al., 2004). In all of these studies, vaccination with the purified N-protein by the subcutaneous or intramuscular route elicited partial or complete protection against infection. An experiment testing the oral delivery of PUUV N-proteins produced in transgenic plants concluded that N-protein was not immunogenic by that route because it was degraded by proteases in the digestive tract (Khattak et al., 2004). Neutralizing antibodies are not directed at the N-protein; thus, it is likely that cell-mediated immunity plays a critical role in protection afforded by vaccination with purified N-protein.

There is only one published study examining the immunogenicity and protective efficacy of purified recombinant hantavirus glycoproteins as subunit vaccines. In that study, HTNV G_n or G_c or G_n/G_c expressed in insect cells infected with recombinant baculovirus was used to vaccinate hamsters (Schmaljohn et al., 1990). The highest level of neutralizing antibodies, and protection against infection, was elicited when the vaccine consisted of both G_n and G_c. In another report, SNV G_n or G_c peptides plus adjuvant were used as vaccine immunogen in a deer mouse infection model (Bharadwaj et al., 2002). The highest level of protection was elicited by G_n peptides. To date, there are no published reports of protein-based subunit hantavirus vaccines being tested in lethal disease

models, and no studies have been performed in nonhuman primates.

Vaccines with Virus-Like Particles

It is often possible to generate excellent immunity against viruses when the vaccine consists of particles containing protective immunogens in the form of virus-like particles (VLP). One of the most exciting recent examples of a successful VLP vaccine is Merk's Gardasil®, a VLP vaccine against human papilloma viruses (Stanley, 2007; Villa et al., 2006). VLP approaches aimed at hantaviruses have been investigated. Ulrich et al. (1998, 1999) have described animal studies involving chimeric hepatitis B VLP containing N-protein peptides. More recently, a chimeric-polyoma VLP approach was used to elicit anti-N-protein antibodies in mice (Gedvilaite et al., 2004). In another approach, Lee et al. (2006) demonstrated that vesicular stomatitis virus (VSV) pseudotypes with Hantaan G_n/G_c on their surface elicited neutralizing antibodies, and protective immunity, in mice. Hantavirus VLP have not yet been tested in nonhuman primates or in animal disease models.

Live-Virus-Vectored Vaccines

There has been only one candidate subunit molecular vaccine tested in humans. The vaccine is a recombinant vaccinia virus expressing the HTNV S- and M-gene products (i.e., nucleocapsid protein, G_n and G_c). The HTNV G_c/G_n virus-based vaccines, and a similar SEOV-based version, protected against infection in a hamster or gerbil infection model, respectively (Chu et al., 1995; Schmaljohn et al., 1990; Xu et al., 1992). This live-virus vaccine was administered either subcutaneously or intramuscularly in phase 1and 2 clinical trials (McClain et al., 2000). HTNV neutralizing antibodies were elicited in vaccinia-naïve individuals; however, the level of neutralizing antibodies elicited in persons who had previously been vaccinated with vaccinia virus (i.e., the smallpox vaccine) was unacceptably low. Poor immunogenicity in persons previously vaccinated with the smallpox vaccine, coupled with the dangers associated with live vaccinia virus-based vaccines (e.g., progressive vaccinia, eczema vaccinatum) (see Chapter 37), discouraged advanced development of the vaccinia-vectored HFRS vaccine.

A far more experimental live-virus approach involving recombinant cytomegalovirus expressing SNV G_n was tested in a deer mouse model and was shown to elicit a detectable antibody response against G_n (Rizvanov et al., 2006, 2003). To our knowledge, other live-virus-vectored molecular vaccines, including adenovirus-vectored or live-VSV-vectored vaccines, have not been reported.

Packaged Replicons

Vaccine platforms involving viruses that infect but do not replicate have also been used to investigate as putative approaches to develop hantavirus vaccines. Sindbis virus replicons expressing the SEOV N-protein or G_n/G_c were tested in hamsters (Kamrud et al., 1999). These alphavirus replicons elicited antibody responses, and in the case of G_n/G_c, neutralizing antibodies were produced. Hamsters vaccinated with G_n/G_c replicons were partially protected against SEOV infection. Replicons based on another alphavirus, Semliki Forest virus, expressing the PUUV N, G_n, G_c, or G_n/G_c expressed protein in vitro; however, vaccination studies were not reported (Billecocq et al., 2003; Kallio-Kokko et al., 2001).

DNA Vaccines

A great deal of work involving the delivery of plasmid DNA as a vaccine has been performed in recent years. A summary of many of the studies is provided in Table 23.4. In general, DNA vaccines have been delivered as plasmids either by intramuscular injection or by particle-mediated epidermal delivery (gene gun). In addition, there is one report of an ANDV M-gene-based DNA vaccine delivered by electroporation (Hooper et al., 2008).

Vaccines involving the delivery of the S gene as naked DNA or as DNA-launched replicons have elicited antibody responses against SEOV, PUUV, and SNV (Bharadwaj et al., 2002; Bucht et al., 2001; Hooper et al., 1999; Kamrud et al., 1999; Lindkvist et al., 2007). In those experiments, immune responses were detected (e.g., anti-N-protein antibodies by ELISA) and, in some instances, partial protection was observed in rodent infection models (Bharadwaj et al., 2002; Bucht et al., 2001; Kamrud et al., 1999).

Vaccines involving the delivery of the fragments (i.e., peptides) of the M gene have shown some efficacy (Bharadwaj et al., 2002); however, much greater levels of neutralizing antibodies and protection were observed when the vaccine involved delivery of the full-length M gene (Custer et al., 2003; Hooper et al., 1999, 2001a, 2006, 2008). The first DNA vaccine to elicit high-titer neutralizing antibodies against a hantavirus was a gene-gun-delivered plasmid containing the SEOV M gene (Hooper et al., 1999). This was followed by similar vaccines containing the HTNV M gene, ANDV M gene, and a plasmid containing

both the HTNV and ANDV M gene (Custer et al., 2003; Hooper et al., 2001a, 2006). The SEOV and HTNV M-gene-based DNA vaccines elicited immune responses in hamsters that cross-protected against SEOV, HTNV, and DOBV, but not PUUV (Hooper et al., 2001a).

Several of the full-length M-gene-based DNA vaccines have been tested in nonhuman primates (Table 23.5). Rhesus macaques vaccinated with the SEOV or HTNV DNA vaccines by a gene gun produced high-titer neutralizing antibodies that exhibited

cross-reactivity with SEOV, HTNV, and DOBV, but less cross-reactivity against PUUV (Hooper et al., 2001a). Recently, a PUUV M-gene-based DNA vaccine was constructed and tested in nonhuman primates. This vaccine delivered by gene gun elicited neutralizing antibodies against PUUV in nonhuman primates (Hooper et al., unpublished observations). This same vaccine elicited PUUV neutralizing antibodies in hamsters and protected against infection with PUUV. A combined vaccine consisting of the HTNV and PUUV M-gene-based DNA vaccines, theoretically, should cross-neutralize against the full spectrum of major HFRS-associated hantaviruses.

To develop an HPS vaccine, the full-length ANDV M gene was cloned into a DNA vaccine plasmid and tested in animal models (Custer et al., 2003). Interestingly, this vaccine was not immunogenic in hamsters, but was highly immunogenic in nonhuman primates (i.e., rhesus and cynomolgus macaques) and rabbits (Custer et al., 2003; Hooper et al., 2006, 2008). The neutralizing antibody levels produced in the macaques were very high (Table 23.5). In one study, $PRNT_{50}$ titers as high as 1:20,480 were produced (Custer et al., 2003). Sera from the rhesus macaques vaccinated with the ANDV DNA vaccine using the gene gun cross-neutralized SNV and BCCV (Custer et al., 2003); however, sera from the rabbits vaccinated by electroporation failed to cross-neutralize (Hooper et al., 2008). Thus, it might be necessary to construct additional DNA vaccine plasmids (e.g., SNV M-gene-based DNA vaccine) to produce a vaccine that cross-protects against the many different hantaviruses that cause HPS.

A DNA vaccine containing both the HTNV and ANDV full-length M genes, pWRG/HA-M, was not immunogenic in hamsters but was immunongenic in nonhuman primates (Hooper et al., 2006). The reason why DNA vaccines containing the ANDV M gene are poorly immunogenic in hamsters, but are immunogenic in nonhuman primates and rabbits, remains unknown. It is tempting to speculate that this phenomenon could be related to the high virulence of ANDV in hamsters. A more in-depth discussion of the ANDV/hamster lethal HPS model is provided in the "Prospects for the Future" section below.

POSTEXPOSURE IMMUNOPROPHYLAXIS

There is an unquestioned need for the development of hantavirus vaccines for use in regions of the world where there are high numbers of HFRS or HPS cases. Similarly, vaccines are needed for persons in high-risk groups, including soldiers deployed to endemic regions. However, HPS and HFRS outbreaks can occur suddenly in areas previously void of disease where

pretreatment vaccines are unavailable or impractical. In such scenarios (including biological weapons attack), the emergency use of postexposure immunoprophylactic products could be used to prevent disease in potentially exposed individuals, mitigate panic, and contain the spread of disease. Postexposure immunoprophylactic products might also be used in combination with emergency vaccination (e.g., as in the case of rabies), or as part of a therapeutic treatment. Passive antibody has been used to prevent and treat other viral diseases including Argentine hemorrhagic fever (Enria et al., 1984) and has been proposed as a means of defending against biological weapons threats (Casadevall, 2002).

There is reason to believe that immunotherapeutic products could be effective in preventing and treating hantavirus disease. Numerous animal studies have demonstrated that monoclonal or polyclonal antibodies protected rodents from infection with hantaviruses (Arikawa et al., 1992; Medina et al., 2007; Schmaljohn et al., 1990; Xu et al., 2002; Yoshimatsu et al., 1993; Zhang et al., 1989). One study also found passive transfer of neutralizing monoclonal antibodies before challenge could delay the effects of PUUV on the blood chemistry of one of the two infected nonhuman primates (Klingstrom et al., 2005).

We used the ANDV/hamster lethal HPS model (see "Prospects for the Future") to test whether antibodies could protect before and/or after exposure to a lethal dose of ANDV (Custer et al., 2003). Serum from nonhuman primates vaccinated with the ANDV M-gene-based DNA vaccine containing high levels of neutralizing antibodies protected hamsters against an intramuscular challenge with ANDV when given 1 day before challenge. More importantly, passive transfer of the sera up to 5 days after challenge protected the hamsters. This was an exciting finding because it demonstrated that a postexposure prophylactic approach could be a viable way to prevent HPS in persons exposed or potentially exposed to the virus. Recently, we produced ANDV-neutralizing antibodies in rabbits using the ANDV M DNA vaccine and confirmed that pre- or postchallenge passive transfer of the serum could confer protection against a lethal mucosal challenge with ANDV (Hooper et al., 2008).

The aforementioned animal experiments suggest that postexposure use of antibodies could be a way to prevent disease in exposed individuals. There are clinical data supporting this concept. For example, high levels of neutralizing antibodies in HPS patients at hospital admission correlated with higher survival rates (Bharadwaj et al., 2000). Likewise, low levels of viremia at hospital admission are associated with improved clinical outcome (Xiao et al., 2006). Clinical studies testing the capacity of human convalescent serum, or laboratory-derived neutralizing antibodies, to effectively prevent and treat hantavirus diseases are needed. Examples of possible test sites include Chile and Argentina, where HPS can occur in clusters (Lazaro et al., 2007; Toro et al., 1998; Vial et al., 2006; Wells et al., 1997).

PROSPECTS FOR THE FUTURE

As climatic changes affect the environment, we can expect to see changes in rodent populations and distributions. It is likely that these changes will alter the ways in which humans come in contact with hantaviruses, and these changes could result in changes in the rates and distribution of HPS cases in the Americas and HFRS in Eurasia. Moreover, changes in interactions between different species of rodents could, theoretically, increase the possibility that different hantaviruses might coinfect the rodent host and produce reassortant progeny viruses. There is evidence that hantaviruses have reassorted in nature (Henderson et al., 1995; Li et al., 1995). Reassortant viruses could exhibit altered biological properties including virulence, as is the case for influenza virus (genetic shift). Thus, the threat posed by naturally occurring hantavirus disease is dynamic and must be carefully monitored.

The threat posed by unnaturally occurring hantavirus disease caused by their intentional use as biological weapons should not be ignored. ANDV is of particular concern for several reasons including its availability in nature, high lethality, rapid disease onset and progression, transmission properties (e.g., person-to-person transmission), and replication characteristics (e.g., ANDV replicates to titers as high as 10^{7-8} in cell culture and hamster organs).

The threat posed by hantaviruses is of particular concern when one considers the paucity of effective medical countermeasures to prevent and treat HPS and HFRS. There is no HPS vaccine available anywhere in the world. There are no HFRS vaccines, except the inactivated-virus vaccines in China and South Korea. There are no antiviral drugs licensed to specifically treat hantavirus disease. Finally, medical treatments that due exist such as ECMO for HPS and hemodialysis for HFRS are extraordinarily expensive and require a medical infrastructure not available in many parts of the world.

Providing education on steps that can be taken to avoid exposure to hantaviruses (e.g., avoid inhalation or ingestion of rodent excreta) can greatly reduce the incidence of HPS and HFRS; however, medical countermeasures to prevent and treat these diseases remain

desperately needed. The development of animal models that accurately mimic hantavirus disease in humans should accelerate the development of vaccines, treatments, and an understanding of hantavirus disease pathogenesis. Such a model was discovered in 2001. When injected into Syrian hamsters, ANDV causes a lethal vascular-leak disease that closely resembled HPS in humans (Hooper et al., 2001b). Similarities include (1) the incubation time, (2) rapid disease onset after the first symptoms, (3) infection of endothelial cells and the absence of necrosis, (4) severe pulmonary edema and pleural effusion, (5) mild thrombocytopenia, (6) neutrophilia, and (7) cardiogenic impairment and hypotension (Campen et al., 2006; Hooper et al., 2001b; Wahl-Jensen et al., 2007). A second hantavirus, Maporal virus, was reported to cause similar disease manifestations in Syrian hamsters (Milazzo et al., 2002). ANDV is highly pathogenic in adult Syrian hamsters when administered by the intramuscular (LD_{50} = 8 pfu, mean-time-death = 13 days), subcutaneous ($LD_{100} \leq 2000$, mean-time-death = 16 days), intranasal (LD_{50} = 95 pfu, mean-time-to-death = 17.5 days), or intragastric routes (LD_{50} = 225 pfu, mean-time-death = 19 days) (Hooper et al., 2001b, 2008). The sex of the animal does not alter the disease course (Hooper et al., 2008). This lethal disease model of HPS is currently being used to develop candidate hantavirus vaccines, immunoprophylactics, and therapeutics. In addition, experiments using this model are underway to test hypotheses aimed at understanding the pathogenesis of hantavirus vascular-leak syndromes. One limitation on the ANDV/hamster model work is that it requires the highest level of containment (biosafety level 4). This constraint will be alleviated as more high containment laboratories become operational around the world. Another constraint facing the development of medical countermeasures to HPS and HFRS is limited funding. International collaboration and coordination, including cost-sharing, will be a key factor in the future development of vaccines and cures for diseases caused by hantaviruses.

KEY ISSUES

- Pathogenic hantaviruses pose a danger to persons working in environments populated by rodents that carry the virus (i.e., Eurasia and the Americas).
- Certain hantaviruses (i.e., ANDV) pose an increased danger because they are highly pathogenic and can spread from one person to the other (close contacts).
- There is a small animal model for HPS, but there is still no small animal model for HFRS.
- The pathogenesis of HPS and HFRS is not understood; and it remains unclear as to what role the immune response plays in the disease.
- There are no FDA-licensed vaccines or drugs to prevent or cure HPS or HFRS.

OUTLINE

ABSTRACT

Hepatitis C virus (HCV) is a major public health problem, with over 180 million persons infected worldwide and at risk for developing cirrhosis or liver cancer. Current interferon-based treatment options are expensive, often associated with considerable toxicity, and moreover are of limited efficacy. Thus, vaccines capable of either preventing new infections or exerting a therapeutic effect on established infections would be of value. Both types of vaccines remain elusive goals, however, in part because immunity against the virus is very poorly understood. An impressive degree of genetic (and likely antigenic) variation among HCV strains is another barrier to vaccine development. In addition, there are no readily available animal models of hepatitis C, which greatly complicates vaccine development. Protective immunity has been correlated mainly with virus-specific CD4+ and CD8+ T-cell responses, while the role played by antibodies to the virus is less clear but still potentially important. Immunization with recombinant viral envelope proteins induces primarily antibody and CD4+ Th-cell responses. While not preventing acute infection, such a vaccine may have prevented persistent infection in chimpanzees challenged with a virus closely related to the vaccine strain. Other vaccine strategies that have been explored include the use of synthetic peptides, genetic immunization, recombinant vectors, virus-like particles, or combinations of these. While many of these approaches have induced CD8+ T-cell responses, as well as CD4+ Th and B-cell responses, few have shown clear evidence of providing protective immunity against HCV challenge. Other efforts have focused on ex vivo stimulation of dendritic cells, and passive immunization with polyclonal and monoclonal antibodies. This chapter summarizes what is known of the immune responses that control HCV infection and different strategies that have been pursued for HCV vaccine development, and outlines the current status of vaccine candidates in pre-clinical and clinical development.

INTRODUCTION

Hepatitis C virus (HCV) was identified and shown to be the cause of almost all cases of post-transfusion "non-A, non-B" viral hepatitis in the late 1980s (Choo et al., 1989; Kuo et al., 1989). The virus has a unique capacity to establish long-term, persistent infections in the majority of acutely infected persons, placing such individuals at significant risk for progressive hepatic fibrosis, cirrhosis, and liver cancer. This occurs despite the activation of virus-specific CD4+ and CD8+ T cells and the presence of virus-neutralizing antibodies in infected persons. HCV has the capacity to disrupt early events in the innate immune response to infection, but the specific mechanisms underlying viral persistence and the failure of virus-specific B- and T-cell responses to eliminate the infection remain incompletely defined. HCV infection currently accounts for less than 15% of acute viral hepatitis cases within the United States. However, it is by far the leading cause of chronic viral hepatitis and is present in over 40% of persons with chronic liver disease. Efforts at vaccine development, yet to succeed despite almost two decades of work, are thus aimed at both prevention of infection (prophylactic vaccines) and treatment of established infections (therapeutic vaccines).

HEPATITIS C VIRUS

Genome Organization and Virus Structure

HCV is classified within the genus *Hepacivirus* of the family *Flaviviridae*, and it shares a distant phylogenetic relationship with yellow fever virus and other classical flaviviruses. However, HCV has many features that distinguish it from other members of this virus family, including the organization of its polyprotein that contains two envelope glycoproteins, E1 and E2 (Fig. 24.1). Much has been learned about the molecular virology of HCV and its interactions with host cells since the discovery of the virus. A complete description of the agent is well beyond the scope of this chapter, and for this the reader is referred to detailed reviews elsewhere (Lemon et al., 2006; Lindenbach and Rice, 2005). Only a brief summary is provided here.

Similar to other members of the *Flaviviridae*, the HCV genome is comprised of a single RNA molecule that is single-stranded and messenger sense (Choo et al., 1989). The genomic RNA has a relatively lengthy 5′ nontranslated region of approximately 342 bases, containing an internal ribosome entry site (IRES) that directs the 5′ cap-independent initiation of viral translation (Lemon and Honda, 1997) (Fig. 24.1). This is followed by a long open reading frame encoding a single polyprotein that undergoes co-translational processing events directed by both host cell and virus-encoded proteases resulting in the production of ten mature proteins (Fig. 24.1). Proteolytic cleavages directed by host cell signal peptidases produce a series of structural proteins which include the core, and E1 and E2 envelope proteins, as well as a small membrane-associated viroporin, p7. Virus-encoded proteases are responsible for additional processing events that generate the nonstructural proteins of HCV.

There is no high-resolution model of the structure of the envelope proteins, and only a rudimentary

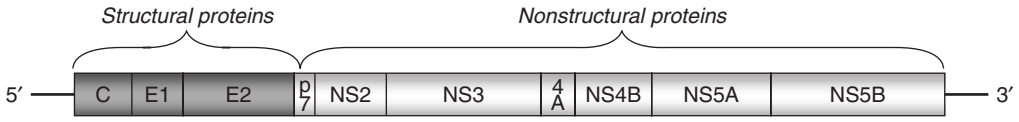

FIGURE 24.1 Organization of the positive-sense RNA genome of HCV. The noncoding RNA sequences are shown as solid lines, while the polyprotein coding region is shown as a box. The 5′ nontranslated segment of the genome contains an IRES that controls translation of the polyprotein. The segment of the polyprotein that contains structural proteins (core, E1, and E2) known to be present within the virus particle is heavily shaded, while nonstructural proteins are lightly shaded; p7 and NS2 are presumed to be not present within the virus particle, but are also not required for replication of virus RNA.

understanding of their membrane topology. Signal sequences at the carboxy termini of the core and E1 coding regions direct the secretion of E1 and E2 into the lumen of the ER; both remain anchored to the membrane by hydrophobic C-terminal sequences as type 1 transmembrane proteins. The core protein is released from the membrane by an intramembranous cleavage carried out by signal peptide peptidase (McLauchlan et al., 2002), and remains within the cytoplasm where it associates with lipid droplets and mitochondria. E1 and E2 are massively glycosylated within the ER and the Golgi, with about 50% of their mass made up of sugars in their mature form. This is reminiscent of the "glycan shield" presented by human immunodeficiency virus (HIV), and may contribute to the relatively poor effectiveness of virus neutralization by antibodies in vivo. It also poses challenges for vaccine development. E1 and E2 proteins have strong ER retention signals, and details of the secretion process remain obscure (Penin et al., 2004; Dubuisson and Rice, 1996). However, the recent advent of cell culture-infectious virus systems is providing much new information about viral assembly, which appears to be dependent upon the association of the core with lipid droplets and involves multiple nonstructural proteins (Miyanari et al., 2007; Gastaminza et al., 2008).

At least six nonstructural proteins are derived from the remainder of the polyprotein, each of which likely has multiple functions, many only partly understood. These include NS2, which contains in its C-terminal half a unique cysteine protease activity that spans the NS2/NS3 junction and cleaves in *cis* at this site. Crystallographic studies suggest that NS2 functions as a dimer with composite active sites (Lorenz et al., 2006). The NS3 protein contains in its amino terminus residues that function as part of the *cis*-active NS2/NS3 protease and, after cleavage from NS2 and the intercalation of NS4A, form the mature NS3/4A serine protease that is responsible for all of the other downstream cleavage events within the polyprotein (Kim et al., 1996). The carboxy two-thirds of the NS3 protein folds into a separate functional domain-containing NTPase and RNA helicase activities that are essential for virus replication (Yao et al., 1997). In addition to its role as an NS3 protease accessory factor, NS4A contains a membrane anchor that fixes the NS3/4A complex to cellular membranes (Lin et al., 1995). NS4B is a hydrophobic protein; it appears to be responsible for reorganizing intracellular membranes into a "membranous web" that appears to be the site of replication of viral RNA (Moradpour et al., 2003). NS5A is a multi-functional protein that contributes to interferon (IFN)-resistance and also plays an essential role in replication of viral RNA as well as assembly of the virus particle (Enomoto et al., 1996; Miyanari et al., 2007; Tellinghuisen et al., 2005); Finally, NS5B, which is derived from the carboxy terminal portion of the polyprotein, is an RNA-dependent RNA polymerase that forms the catalytic core of the replicase (Bressanelli et al., 1999).

Many, if not all, of these proteins have important interactions with cellular proteins that contribute directly or indirectly to viral RNA replication (Lemon et al., 2006). Prominent among these interactions is the ability of the mature NS3/4A protease to proteolytically target key cellular signaling molecules required for the induction of IFN-mediated antiviral cellular defenses through both the Toll-like receptor 3 (TLR3) and retinoic acid-inducible gene I (RIG-I) pathways (Li et al., 2005a; Meylan et al., 2005).

Virus Structure

Little is known about the structure of the virus particle, and only a few reliable images of HCV particles obtained from infected humans or chimpanzees exist (Kaito et al., 1994). These show a rather ill-defined amorphous membrane enveloping what appears to be a more ordered nucleocapsid structure. Evidence suggests that the E1 and E2 glycoproteins form a noncovalent heterodimer that is presented on the surface of the virion. E2 contains a highly variable domain near its amino terminus (HVR-1 domain), which is likely to form an immunogenic loop on the surface of the virion and which may interact with neutralizing antibodies (Kato et al., 1993; Bartosch et al., 2003a).

As such, it may be analogous to the V3 loop of HIV-1. It may also play a role in determining the interaction of the E2 protein with SR-B1, a putative co-receptor important for viral entry into cells (Bartosch et al., 2003c; Roccasecca et al., 2003). However, this loop can be deleted without complete loss of infectivity (Forns et al., 2000b). E2 is considered to be the major target of neutralizing antibodies. Further details of the interactions of antibodies with the virus are described below.

Growing evidence supports the involvement of apolipoproteins (ApoB and ApoE) produced within the hepatocyte as an integral component of the viral structure. Virus found in the serum of infected chimpanzees or humans generally demonstrates a significantly lesser buoyant density than infectious virus produced in cell culture (see below) (Lindenbach et al., 2006). Moreover, serum-derived virus can be precipitated efficiently with antibodies to ApoB and ApoE, and progressive detergent disruption of these particles has shown that ApoB remains tightly associated with the virus even after treatment with 0.5% deoxycholic acid or 0.18% NP-40 (Nielsen et al., 2006; Diaz et al., 2006). In addition, the production of virus particles by infected Huh7 cells is blocked by siRNA knockdown of ApoB as well as inhibition of microsomal transport protein, which participates in the secretion of triglyceride-rich very-low-density lipoproteins from liver cells (VLDL) (Huang et al., 2007; Gastaminza et al., 2008). Thus, HCV particles have been described as "lipoviroparticles" based on a high content of host lipoproteins and the possible involvement of the apolipoprotein secretory apparatus in their assembly and release. The implications of this feature of the virus structure for the success of vaccines remain uncertain. However, the immunoprecipitation of virus from an infected patient was notably less efficient with antibodies to E2 (~25% precipitation) than antibodies to ApoB or ApoE (>95%) (Nielsen et al., 2006). Further studies are needed to understand the significance of this finding, but it is possible that the ability of neutralizing antibodies to access E2 might be limited by the association of infectious virus particles with host lipoproteins.

Cell Culture Replication of Virus

Wild-type HCV replicates inconsistently in cultures of primary chimpanzee or human hepatocytes; it has also been shown to be capable of very low level, persistent replication in some B- and T-cell derived lymphoid cell lines (Shimizu et al., 1992; Shimizu and Yoshikura, 1994; Shi and Lai, 2001; Lanford et al., 1994). More permissive in vitro cell culture systems supporting the replication of HCV would be helpful for gaining a better understanding of the virus, as well for vaccine development. However, such systems remain generally elusive.

Infectious cDNA clones of the genome were constructed following identification of HCV, and the infectivity of RNA transcribed from several of these was established by direct intrahepatic injection of synthetic RNA in chimpanzees (Kolykhalov et al., 1997; Yanagi et al., 1997). These early clones benefited many aspects of HCV research, including the development of subgenomic HCV RNA replicons in many laboratories. These RNAs encode selectable markers and a minimal polyprotein segment extending from NS3 to NS5B. They contain authentic 5′ and 3′ termini, and undergo efficient autonomous amplification following transfection into permissive cell cultures, typically human hepatoma (Huh7) cells (Lohmann et al., 1999). Replicons propelled the field forward and led to many studies that have usefully characterized various aspects of viral RNA replication. In general, efficient replication of these replicon RNAs is associated with the acquisition of specific cell culture-adaptive mutations, often involving the NS5A protein. Importantly, these mutations may be highly attenuating when introduced back into the wild-type virus (Bukh et al., 2002).

In recent years, a limited number of HCV strains that are capable of reproducing the entire replication cycle in cultured cells have become available (Lindenbach et al., 2005; Yi et al., 2006; Wakita et al., 2005; Zhong et al., 2005). Most notable among these viruses is the JFH-1 strain, a remarkable genotype 2a virus that for reasons still unknown is capable of moderately efficient replication in Huh7 cells (Wakita et al., 2005). These cell culture-produced viruses are referred to as "HCVcc." Important from the perspective of vaccine development, the JFH-1 strain has been used to construct chimeric viruses with envelope proteins from different virus genotypes, opening up new approaches to assessing the presence of serum neutralizing antibodies (Yi et al., 2007; Pietschmann et al., 2006).

Sequence Diversity among Different HCV Strains

Different strains of HCV have been classified into six distinct major "genotypes" based on nucleotide sequence divergence (Simmonds, 2004; Simmonds et al., 2005). The genetic distance between some genotypes is large enough to suggest that there are likely

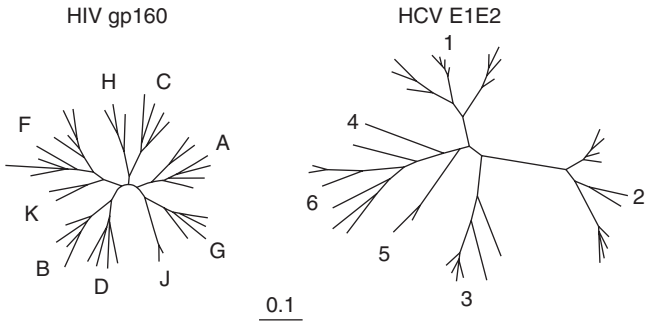

FIGURE 24.2 Comparative phylogenetic analyses of sequence diversity in the envelope protein sequences of HCV and HIV. Trees, displayed here on the same scale, were generated separately for both viruses using a maximum-likelihood search method and amino acid sequences translated from aligned nucleotide sequences available in the Los Alamos databases. HIV subtypes and HCV genotypes are labeled. The figure is provided courtesy of Dr. Stuart Ray, Johns Hopkins University.

to be significant serotypic differences. This is reflected in substantial differences in the amino acid sequences of the E1 and E2 glycoproteins of different genotypes, which are considered to be the major, if not exclusive, target for neutralizing antibodies. The extent of diversity among these envelope protein sequences exceeds that existing among the gp160 proteins of different subtypes of the HIV (Fig. 24.2). Nonetheless, although this presents a very large hurdle to be overcome for the development of a successful vaccine, monoclonal antibodies have been isolated which are capable of broad recognition of viruses from different genotypes (Owsianka et al., 2005).

Genotype 1 HCV is considerably more refractory to IFN therapy than nongenotype 1 strains, with sustained response rates of only about 50% with the best-available therapy, a combination of pegylated IFN and ribavirin. In addition, spontaneous resolution of acute infection appears to occur with greater frequency in genotype 3 infections than in infections with other genotypes (Lehmann et al., 2004). Otherwise, there is little evidence for differences in the pathogenicity of various genotypes.

CLINICAL DISEASE AND PATHOGENESIS

Most acute HCV infections are associated with minimal symptoms and only rarely with identifiable jaundice (Feinstone et al., 1975). Thus, patients presenting to physicians with acute hepatitis C are much more likely to be icteric but represent only a small fraction of all acute infections (Alter et al., 1992). The incubation period extending from exposure to onset of acute liver disease, when it occurs, is of the order of 8 weeks. Virus replication is maximal shortly after infection. The level of viremia declines subsequently with the appearance of antibody to viral proteins and T-cell mediated immunity to HCV, and in most persons remains constant at a relatively fixed level for many years thereafter (Alter et al., 1992; Thimme et al., 2002). However, in as many as 20–40% of infected persons, these immune responses clear the infection and viral persistence is not established.

Approximately two-thirds of persons who progress to persistent infection go on to develop persistent or intermittent elevations in serum alanine aminotransferase (ALT) levels, a marker of hepatic inflammation (Alter et al., 1992). At liver biopsy, these individuals may have fibrosis, the extent of which does not correlate with the magnitude of serum enzyme elevations. As many as a third of these patients will ultimately develop cirrhosis (Kage et al., 1997; Alter et al., 1992; Seeff et al., 1992). Cirrhosis may develop within as little as 5 years of the initial infection, but typically is found in persons who have been infected for several decades. Factors associated with disease progression include an older age at infection, regular alcohol consumption, coinfection with HIV or hepatitis B virus, and obesity and insulin resistance (Strader et al., 2004; Consensus Development Panel, 2002). Once cirrhosis is established, there is a substantial risk (perhaps as high as 3–4% per year) of developing primary hepatocellular carcinoma (Saito et al., 1991). In one US series, 42% of patients with hepatocellular carcinoma had detectable HCV genomic RNA in liver tissue (Abe et al., 1998). Liver injury most likely results from the direct action of virus-specific cytotoxic T-cells, as well as from secondary mediators of inflammation, such as IFN-γ, and other cytokines and chemokines, that are released as a result of a virus-specific T-cell response (Rehermann and Nascimbeni, 2005; Thimme et al., 2002). CD8+ T-cell mediated responses may suppress virus replication and lower the magnitude of viremia, as described below. However, in the absence of eliminating the virus altogether, these T-cell responses may be destructive and result in significant inflammation within the liver.

Extrahepatic manifestations of HCV infection are relatively common, and include glomerulonephritis and type II mixed cryoglobulinemia associated with vasculitis (Johnson et al., 1993; Palekar and Harrison, 2005; Agnello et al., 1992; Marcellin et al., 1993). Such individuals have circulating immune complexes containing viral RNA. Other potentially associated clinical conditions include porphyria cutanea tarda, sicca

syndrome, and a variety of autoimmune diseases as well as B-cell lymphoma. The pathogenesis of these conditions is poorly understood (Lemon et al., 2006).

ANIMAL MODELS OF HEPATITIS C

In addition to the limited availability of fully permissive cell culture systems that are capable of supporting the entire HCV life-cycle, the lack of a small animal model has bedeviled the field since its inception. Chimpanzees remain the only well-validated animal model for HCV infections in humans (Lanford et al., 2001). Chimpanzees recapitulate many features of hepatitis C in humans (Fig. 24.3), but there are significant differences in the course of infection in chimpanzees and humans. Persistent infections develop in only 30–50% of experimentally challenged chimpanzees, less than the 60–80% persistence rate in humans, and moreover are not usually associated with significant liver disease (Bassett et al., 1998). Chimpanzees also demonstrate a very restricted antibody response to the envelope proteins

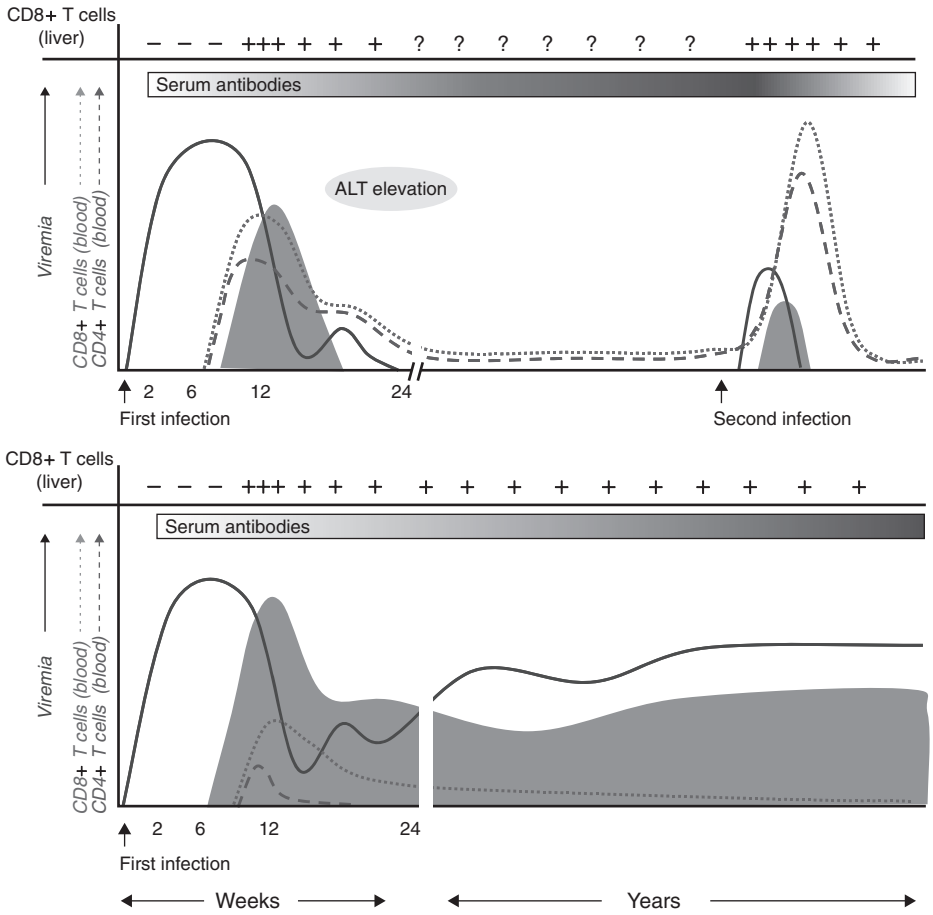

FIGURE 24.3 Typical course of acute resolving and persisting HCV infections in humans and chimpanzees. Top panel: Viremia usually peaks at 8–12 weeks after infection in acute resolving hepatitis C. Expansion of virus-specific CD4+ and CD8+ T cells in blood and their infiltration into liver is temporally associated with a decline in viremia and rise in serum ALT. Successful T-cell responses fully contract only after apparent resolution of infection. Whether memory T cells reside in the liver is unknown (indicated by "?"). Serum antibody responses to structural and nonstructural proteins develop within the first month of infection and titers decline in the years following virus clearance; the kinetics of neutralizing antibody are not known. Spontaneous resolution of acute hepatitis C generally confer only partial protection against re-infection. Second infections are more likely to resolve and are of shorter duration, at least in part due to rapid expansion of memory CD4+ and CD8+ T cells. Bottom panel: HCV infections that persist are characterized by variable T-cell responses that often target fewer epitopes and reach lower peak frequencies. HCV-specific CD4+ T-cell responses either never develop or fail before virus is cleared. CD8+ T cells are sometimes detected in blood for weeks to months following infection but can persist in the chronically infected liver for decades. Durable serum antibody responses to viral proteins develop early in infection. Neutralizing antibodies also appear but at least initially have a limited capacity for recognition of rapidly emerging HCV variants.

compared to humans (Bassett et al., 1999), which should raise concerns regarding their use for evaluation of vaccines. Moreover, the availability of this endangered animal species is limited, and its use in vaccine studies extraordinarily expensive. As an alternative, mice with chimeric human livers have been created by transplanting human hepatocytes into SCID mice bearing a lethal plasminogen activator transgene (SCID-Alb-uPa) (Mercer et al., 2001). While difficult to produce, such animals are susceptible to infection with HCV. However, their underlying immune deficiency makes them unsuitable for most studies of vaccine immunogenicity or protective immunity.

TREATMENT

Current treatment options are limited to recombinant IFN-α-based therapies, which are suboptimal. The best-available therapies, combinations of pegylated IFN-α and ribavirin, result in sustained viral clearance in only ~50% in those infected with genotype 1 viruses, which are most prevalent (Davis et al., 1998; McHutchison and Fried, 2003). Cures are possible, and sustained clearance of the virus is associated with improved clinical outcomes. However, a recent multi-center, NIH-sponsored study (HALT-C) indicated that attempts at long-term suppression of infection with IFN are not beneficial in those who fail to clear the virus. A number of candidate antiviral compounds with specific activity against HCV are currently under development. Many of these target the NS3/4A protease or NS5B polymerase enzymatic activities that are required for viral replication. Early emergence of resistance has been documented in phase I/II clinical trials of such compounds, however, and current concepts call for IFN-α to remain a major component of therapy in the foreseeable future (Chung et al., 2008).

EPIDEMIOLOGY

Worldwide, over 170 million people are estimated to be infected with HCV, reflecting the unique capacity of this virus to establish long standing, persistent infections. The overall prevalence of active infection is approximately 2.2% (Fig. 24.4) (Global Burden of Disease for Hepatitis C, 2004). Within the United States, HCV infection is the leading cause of chronic hepatitis and cirrhosis, and an increasingly important factor in the etiology of hepatocellular carcinoma (Alter et al., 1999; El Serag, 2004; Vong and Bell, 2004). The age-adjusted risk for liver cancer increased by 226% between 1993 and 1999 among Americans over 65 years of age, most likely reflecting prior increases in prevalence of HCV infection (Davila et al., 2004). Liver cancer is increasingly found in younger individuals, with African-American and Hispanic males at particularly high risk. This disparity closely mirrors racial and gender differences in HCV infection prevalence (Alter et al., 1999). Nonetheless, the incidence of new HCV infections is relatively low. Only 671 confirmed cases of acute hepatitis C were reported to the US Centers for Disease Control in 2005, leading (after corrections for under-reporting) to estimates of about 20,000 new infections nationally. This low estimated

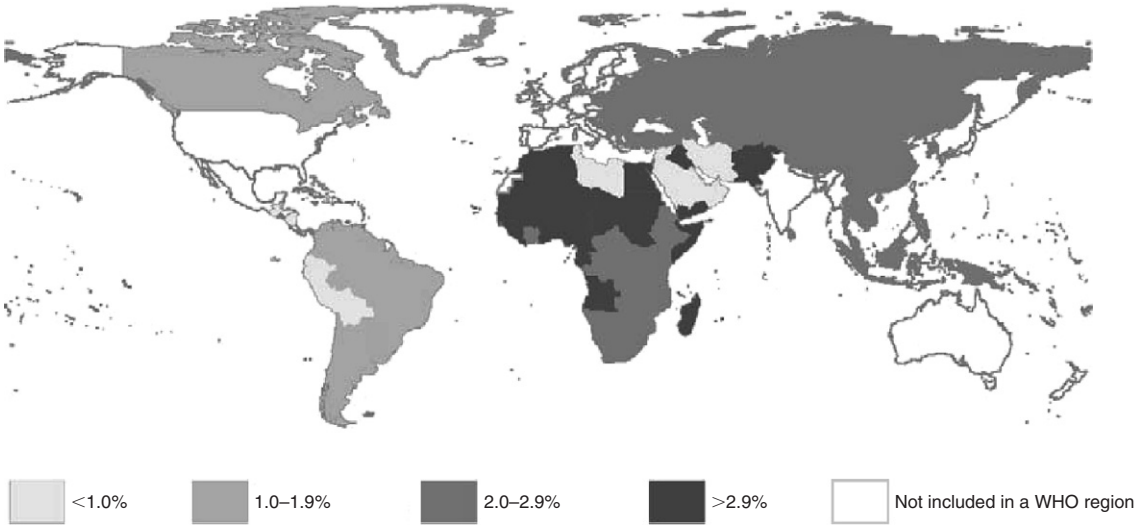

FIGURE 24.4 Global prevalence of HCV infection. Prevalence is based on serological reports available to the World Health Organization (Global Burden of Disease for Hepatitis C, 2004).

incidence rate has led some to question the need for preventive vaccines.

Transmission occurs primarily by percutaneous exposure. While relatively common previously, transmission by blood and plasma-derived products has been virtually eliminated by donor testing and chemical inactivation procedures in well-developed countries. However, patient-to-patient transmission of HCV can result from unsafe therapeutic injections and other health-care procedures, and contributes substantially to the disease burden in the developing world (Hauri et al., 2004; Williams et al., 2004). In contrast, the overwhelming risk factor in industrialized nations is illicit injection drug use (Shepard et al., 2005). Active HCV infections are highly prevalent among injection drug users, and transmission is facilitated by sharing paraphernalia for the preparation of drugs as well as syringes and needles. Percutaneous exposures are a minor source of infection among health-care workers in industrialized nations, and do not result in an increased prevalence of infection in this group above the general population. Sexual activity appears to be an inefficient means for transmission of this virus. However, some studies have shown correlations between sexual practices or numbers of sex partners and the risk of infection with HCV. Recent outbreaks of hepatitis C have been identified among homosexual males who were co-infected with HIV (Gotz et al., 2005; Rauch et al., 2005). Maternal–infant transmission of HCV also occurs at very low rates, but is increased when the mother is co-infected with HIV (Mast et al., 2005; Roberts and Yeung, 2002).

Importantly, HCV can remain viable on surfaces under ambient environmental conditions for at least 16 h (Kamili et al., 2006). For a variety of reasons, however, HCV poses little risk as an agent of bioterrorism.

ANTIGENS EXPRESSED BY HCV

Antibodies directed against many of the mature HCV proteins develop during the course of infection with the virus, including most notably NS3, core, and E2. Current diagnostic assays use recombinant antigens derived from the core and nonstructural (NS3, NS4, and NS5) regions of the HCV genome (Centers for Disease Control and Prevention, 2003). These tests do not measure immunity to the virus, but are rather indicators of previous infection with HCV. Antibodies to E2, the larger of the two envelope glycoproteins, may possess substantial neutralizing activity (see below), while there is no evidence that antibodies to core or to any of the nonstructural proteins are capable of providing protection.

A number of epitopes recognized by virus-specific T cells have been identified. These map in a distributed fashion across the polyprotein in a class I histocompatibility antigen-restricted manner. A compendium of these epitopes is maintained on the web by the Immune Epitope Database and Analysis Resource (http://www.immuneepitope.org/). No single HCV protein has been implicated as dominant in stimulating either CD4+ or CD8+ T-cell subsets (Ward et al., 2002).

HOST IMMUNE RESPONSES

While early reports suggested the absence of protection against rechallenge in chimpanzees that had been experimentally infected with HCV (Farci et al., 1992), the existence of protective immunity following the resolution of HCV infection is now well established in the chimpanzee model (Lanford et al., 2004; Bassett et al., 2001; Weiner et al., 2001). Such immunity is typically not sterilizing in nature, but can broadly extend across genotypes, last for many years, and lead to prevention of long-term viral persistence if not short-term, acute re-infection. Protection from persistent infection is associated with a vigorous T-cell response, and has been shown to be dependent upon both memory CD4+ T cell and CD8+ T-cell subsets (Bassett et al., 2001; Grakoui et al., 2003; Shoukry et al., 2003). As indicated below, the role of antibody in such protection is less certain. Rechallenge of previously infected chimpanzees leads to marked increases in serum antibodies to the envelope proteins, but these responses generally do not correlate well with the outcome of the infection (Bassett et al., 2001). The existence of this nonsterilizing protective immunity, and in particular its ability to protect against persistent infection, provides perhaps the best evidence that it might be possible to develop broadly protective vaccines.

Innate Immune Responses to Infection

The disruption of innate immune signaling pathways that regulate induction of IFN, cytokine, and chemokine responses could be an important factor underlying the failure of virus-specific T cells to control the infection. The NS3/4A protease disrupts signal transduction pathways that normally lead to the synthesis of type 1 IFN α/β and hundreds of IFN-inducible genes (ISGs) in response to virus infection. TLR3 is expressed on the surface of cells, or within intracellular vesicles, activates IFN regulatory factor 3 (IRF-3), and induces IFN-β synthesis when bound by extracellular dsRNA. Signaling through this pathway is

abrogated by NS3/4A-mediated cleavage of the TLR3 adaptor protein, TRIF (Toll-IL1 receptor domain-containing adaptor inducing IFN-β, otherwise known as TICAM-1), which links TLR3 to a TRAF3 complex containing noncanonical and canonical kinases of the IKK complex that are responsible for activation of IRF-3 and NF-κB (Li et al., 2005a; Ferreon et al., 2005). In contrast to TLR3, RIG-I is expressed within the cytoplasm. Upon binding its viral RNA ligand, RIG-I is recruited to mitochondria, where it interacts with MAVS (mitochondrial antiviral signaling protein, also known as IPS-1, VISA, or Cardiff), and initiates formation of a signalosome complex leading to activation of IRF-3 and NF-κB (Seth et al., 2005; Kawai et al., 2005; Meylan et al., 2005). The RIG-I pathway is also disrupted by NS3/4A, which directs the specific cleavage of MAVS (Loo et al., 2006; Meylan et al., 2005; Li et al., 2005b). The disruption of these signaling pathways may serve to delay or prevent the synthesis of IFNs and other cytokines in response to HCV infection. Hypothetically, this could both impair T-cell activation as well as reduce the recruitment of virus-specific CD8+ cells to the liver (Lang et al., 2006; Kabelitz and Medzhitov, 2007; Schulz et al., 2005). However, despite these findings, microarray studies of liver tissues from infected chimpanzee and humans show abundant expression of a large number of ISGs (Bigger et al., 2001, 2004; Su et al., 2002; Lau et al., 2008). The cell type(s) expressing these ISGs remain undefined, and many questions remain concerning the disruption of these innate signaling pathways and how this might contribute to the lack of host control of HCV infection.

Adaptive T-Cell Responses

Studies in chimpanzees and humans suggest that a sustained T-cell response targeting multiple HCV epitopes is usually associated with a successful outcome of infection. The importance of the T-cell response is also supported by a temporal relationship in the kinetics of virus-specific T-cell expansion and reductions in the abundance of circulating virus during acute infection (Cooper et al., 1999; Shoukry et al., 2003; Lechner et al., 2000; Thimme et al., 2001). In addition, antibody-mediated depletion of memory CD4+ helper or CD8+ cytotoxic subsets prior to rechallenge with HCV leads to prolonged viremia in chimpanzees (Shoukry et al., 2003; Grakoui et al., 2003). Other studies have documented substantial reductions in the magnitude of the primary viremia in chimpanzees immunized with nonstructural HCV proteins that are not thought to be targets of neutralizing antibodies (Folgori et al., 2006). Interestingly, the T-cell response to virus challenge is typically delayed in acute infections in chimpanzees. Even when the infection is ultimately cleared, expansion of virus-specific T-cell subsets and the intrahepatic expression of IFN-γ does not occur until 6–8 weeks after acute infection (Thimme et al., 2002; Woollard et al., 2003). Similar delays in acute phase adaptive T-cell immunity have also been described in humans (Shoukry et al., 2004).

Despite a great deal of research over the past 20 years, no clear cut explanation has yet emerged for the failure of host T-cell responses to clear HCV infections. It is likely that the high frequency of persistent virus infections results from a combination of several distinct mechanisms affecting CD4+ helper and CD8+ cytotoxic T-cell subsets. Failure to sustain a CD4+ T-cell response past the point of apparent resolution of infection is perhaps the most reliable predictor of HCV persistence (Shoukry et al., 2004). An inability to generate a durable CD4+ or CD8+ T-cell response may be caused at least in part by disruption of innate signaling pathways, as described above, and consequently impaired cytokine responses to infection. The liver is a classic, immunoprivileged organ, and studies in animal models show that even well-primed liver-specific cytotoxic T-lymphocyte responses may result in little if any liver damage in the absence of TLR3 signaling and appropriate cytokine and chemokine expression in the liver (Lang et al., 2006).

Beyond the possibility of weak antigen priming, reasons for impaired CD4+ T-cell immunity are still poorly understood, in part because these cells are difficult to visualize or detect using functional assays in chronic hepatitis C. Defects underlying failed CD8+ T-cell responses are better defined. HCV can persist despite acute phase CD8+ T-cell responses that are sometimes robust (Lauer et al., 2005). The abundance of circulating IFN-γ secreting CD8+ T cells recognizing HCV-specific peptides can peak as late as 6–12 months after acute infection, and is eventually followed by the loss of some or all epitope reactivities from blood (Cox et al., 2005a). Nonetheless, HCV-specific CD8+ T-cell populations can survive for decades in the persistently infected liver. Failure to recognize and eliminate HCV-infected hepatocytes is probably caused in part by the accumulation of amino acid substitutions within MHC class I-restricted HCV epitopes (Bowen and Walker, 2005; Cox et al., 2005b). These mutations may lead to viral escape from cytotoxic T-lymphocyte responses, thereby compounding potentially inadequate T-cell priming or memory responses. The capacity of the virus to escape from these controlling T-cell responses represents a significant challenge for vaccine development. However, it is important to emphasize that escape mutations do not emerge within all MHC class I epitopes even

when cognate CD8+ T cells are visualized within the liver with MHC class I tetramers.

HCV-specific T cells are frequently defective in proliferative responses, as well as IFN-γ production and cytotoxic effector functions (Wedemeyer et al., 2002). Markers associated with T-cell memory can be reduced or absent, including the interleukin-7 receptor alpha (CD127) receptor required for IL-7 driven homeostatic proliferation. Impaired function may be associated with expression of molecules like programmed death-1 (PD-1) that can transmit inhibitory signals to antigen-specific CD8+ T cells upon engagement of PD-1 ligand(s) (Radziewicz et al., 2007). Strategies to interrupt PD-1 signaling, perhaps in combination with an HCV vaccine, represent promising new approaches for restoration of T-cell function and therapy of chronic hepatitis C (Grakoui et al., 2006).

Humoral Immune Responses

The role of B-cell immunity in resolution of acute infection and prevention of re-infection also remains incompletely defined. Neutralizing antibodies are typically delayed in appearance in acute HCV infection, generally do not confer sterile immunity, and are usually present in chronically infected persons (Farci et al., 1992; Netski et al., 2005; Helle et al., 2007; Lai et al., 1994; Prince, 1994). Nonetheless, substantial data suggest that virus-specific antibodies exert a level of control over HCV infection. This has been demonstrated in chimpanzee challenge studies in which antibodies isolated from a patient with chronic hepatitis C were able to neutralize the infectivity of an inoculum collected from the same subject 2 years previously (Farci et al., 1994). Replication of HCV has also been blocked in chimpanzees by prior in vitro neutralization of an inoculum with antibodies directed against a hypervariable region located near the amino terminus of the E2 protein (HVR-1, see Fig. 24.5, Farci et al., 1996), or by incubation with pooled immunoglobulins prepared from infected individuals (Yu et al., 2004). In other studies, infection was delayed, but not prevented, by passive transfer of the immunoglobulin preparation to animals prior to challenge with infectious virus (Krawczynski et al., 1996). Human monoclonal antibodies (HMAbs) that are capable of broadly neutralizing genetically diverse HCV strains, and protecting against infection with heterologous HCV in transgenic mice possessing chimeric human livers have been also generated recently (Law et al., 2008).
