Francisella tularensis

Richard W. Titball[1] *and Petra C.F. Oyston*[2]
[1]School of Biosciences, Geoffrey Pope Building, University of Exeter, Exeter, Devon, UK
[2]Defence Science and Technology Laboratory, Salisbury, Wiltshire, UK

OUTLINE

ABSTRACT

Francisella tularensis has four subspecies: *tularensis, holarctica, mediasiatica*, and *novicida*. It is a zoonotic pathogen, capable of infecting a wide range of hosts, from amoebae to rodents and humans. Of the subspecies, *F. tularensis* subspecies *tularensis* is the most virulent for humans. There are diverse presentations of tularemia, depending on the route of infection. The most common is ulceroglandular tularemia, which is acquired by the bite of an infected insect vector, or through infection of skin abrasions. The most acute form of disease is respiratory tularemia, arising from inhalation of the bacterium, for example, through contaminated hay dusts. The pathogen has a very low infectious dose for humans by the inhalational route. Infection responds well to antibiotic therapy, but if left untreated mortality rates can be high. For these reasons, the pathogen has long been of concern as a biothreat agent. An attenuated live vaccine strain, strain LVS, was awarded investigational new drug status and shown to be effective in preventing tularemia. However, this vaccine has never been fully licensed, and its investigational

new drug status has now been revoked. Thus, there is renewed effort underway to develop an effective licensable vaccine against *F. tularensis* infection. The availability of genome sequence data should help in the search for a new vaccine, by facilitating the identification of attenuation targets or potentially protective subunits. However, the immunity required for protection against high-virulence strains of *F. tularensis* requires both humoral and cell-mediated responses to be induced.

INTRODUCTION

Francisella tularensis is one of the most infectious pathogens known and is able to cause the disease tularemia after entering the body via a number of routes. Respiratory tularemia is of greatest concern in humans because of the acute nature of the disease. So infectious is this pathogen by the airborne route that Overholt et al. (1961) stated that "The hazard of infection with *F. tularensis* is well recognized; few persons escape illness if they continue to work with the organism." It is probably the high infectivity by the airborne route and the ease of culture that in the past attracted some to develop this bacterium as a bioweapon. During the middle of the twentieth century, there was a significant effort to devise a vaccine against tularemia. A live vaccine was shown to be effective in laboratory workers, but this vaccine is currently not licensed. Against the background of an increased threat from biological weapons and increased research into the biology of this organism, there is an urgent need for an effective licensed vaccine against tularemia. This chapter reviews past work to devise vaccines against tularemia and assesses the prospect for improved vaccines.

SHORT HISTORY OF THE DISEASE

The first reported isolation of *F. tularensis* was in 1911 in Tulare County, California and followed an outbreak of a plague-like disease in rodents (McCoy and Chapin, 1912). The bacterium was originally named *Bacterium tularensis*, then subsequently placed in the *Pasturella* genus followed by a move to the *Brucella* until finally being assigned to a new genus entitled *Francisella* in 1947 (Dorofe'ev, 1947). Although the bacterium was originally isolated from rodents, naturally occurring tularemia has since been reported in mammals, birds, amphibians, fish, and even in invertebrates (Morner, 1992). Until recently, the only reported cases of tularemia in humans or in animals were in the Northern Hemisphere. However, there has recently been a report from Australia of an infection in humans caused by a strain of *F. tularensis* subspecies *novicida* (Whipp et al., 2003). At this stage it is not clear whether this is an exceptional case of disease, or the bacterium is more widely distributed in the Southern Hemisphere than was previously thought.

ETIOLOGIC AGENT

Tularemia is caused by the etiological agent *F. tularensis*. The bacteria stain weakly Gram-negative. The cells are small, 0.2 to 0.5μm by 0.7 to 1.0μm, single coccobacilli. The organism is fastidious, requiring enriched media for growth, and has a requirement for cysteine. The organism will grow on general microbiological agars used routinely in US clinical laboratories, such as Thayer-Martin, sheep blood, and chocolate agars. Traditionally, the organism has been cultured on cysteine glucose blood agar, but cysteine heart agar supplemented with heated sheep red blood cells to give a chocolate agar has also been used (Anonymous, 2001). *F. tularensis* is slow-growing on solid media, requiring 2–4 days incubation to produce individual colonies at 37°C. On blood agar, a small zone of alpha-hemolysis develops. *F. tularensis* does not grow well in liquid media and requires a heavy inoculum for growth. The organism will not grow in standard laboratory liquid media used by US clinical laboratories, such as brain heart infusion or trypticase soy broth. Growth in aerobic enriched media can take up to a week to produce visible turbidity; static cultures will take a minimum of 10 days. A synthetic, defined medium for the growth of *Francisella* is available (Chamberlain, 1965).

The identification of *F. tularensis* and differentiation of its subspecies has traditionally been accomplished by observing growth characteristics and biochemical analysis. Besides being time consuming and tedious, cultivation results in a high risk of laboratory-acquired infection (Burke, 1977). In view of these problems, the diagnosis of tularemia has relied mainly on clinical picture backed by serology. However, antibodies are usually not detected before the second week of disease (Koskela and Salminen, 1985). Moreover, due to its fastidious growth requirements and slow growth rate,

isolation of the bacterium directly from the environment is hampered since other bacteria can grow more rapidly on most media used to culture *F. tularensis*.

CLASSIFICATION

F. tularensis is a member of the gamma subdivision of the *Proteobacteria*. There are two species in the *Francisella* based on 16S rDNA sequencing and fatty acid composition; *F. tularensis* and *Francisella philomiragia* (Hollis et al., 1989; Forsman et al., 1994). There are currently four recognized subspecies of *F. tularensis*. *F. tularensis* subspecies *tularensis* is the most virulent of the four subspecies and is found primarily in North America (Fig. 61.1), whereas *F. tularensis* subspecies *holarctica* is less virulent and is found mainly in Europe and Asia. *F. tularensis* subspecies *mediasiatica* is isolated in central Asia and *F. tularensis* subspecies *novicida* primarily in North America. Subspecies *mediasiatica* and *novicida* rarely cause disease in humans. The highly virulent *F. tularensis* subspecies *tularensis* strains have infectious doses (IDs) for humans of less than 10 CFU, making this one of the most highly infectious bacterial pathogens known.

Francisella-specific 16S rRNA sequence signatures have allowed the development of PCR-based methods for the identification of *Francisella* strains at the genus level and differentiation at the species level. PCR amplification of the rRNA gene cluster combined with endonuclease digestion has been used for typing of *Francisella* strains, allowing differentiation at the species level but not at the subspecies level. Repetitive extragenic palindromic sequence (REP)-PCR has been applied to identify strains of subspecies *novicida*, but patterns from subspecies *holarctica* and subspecies *tularensis* strains were found to be similar. Recent studies have evaluated the use of PCR based on the use of various arbitrary primers as well as of primers specific to REP and enterobacterial repetitive intragenic consensus sequences (ERIC). It was concluded that the methods were useful for rapid and a technically simple strategy for discrimination of subspecies but not of individual strains. A 30-bp sequence heterogeneity among the genomes of various *F. tularensis* strains was found by the use of PCR and arbitrary priming; by targeting this genomic region a PCR was

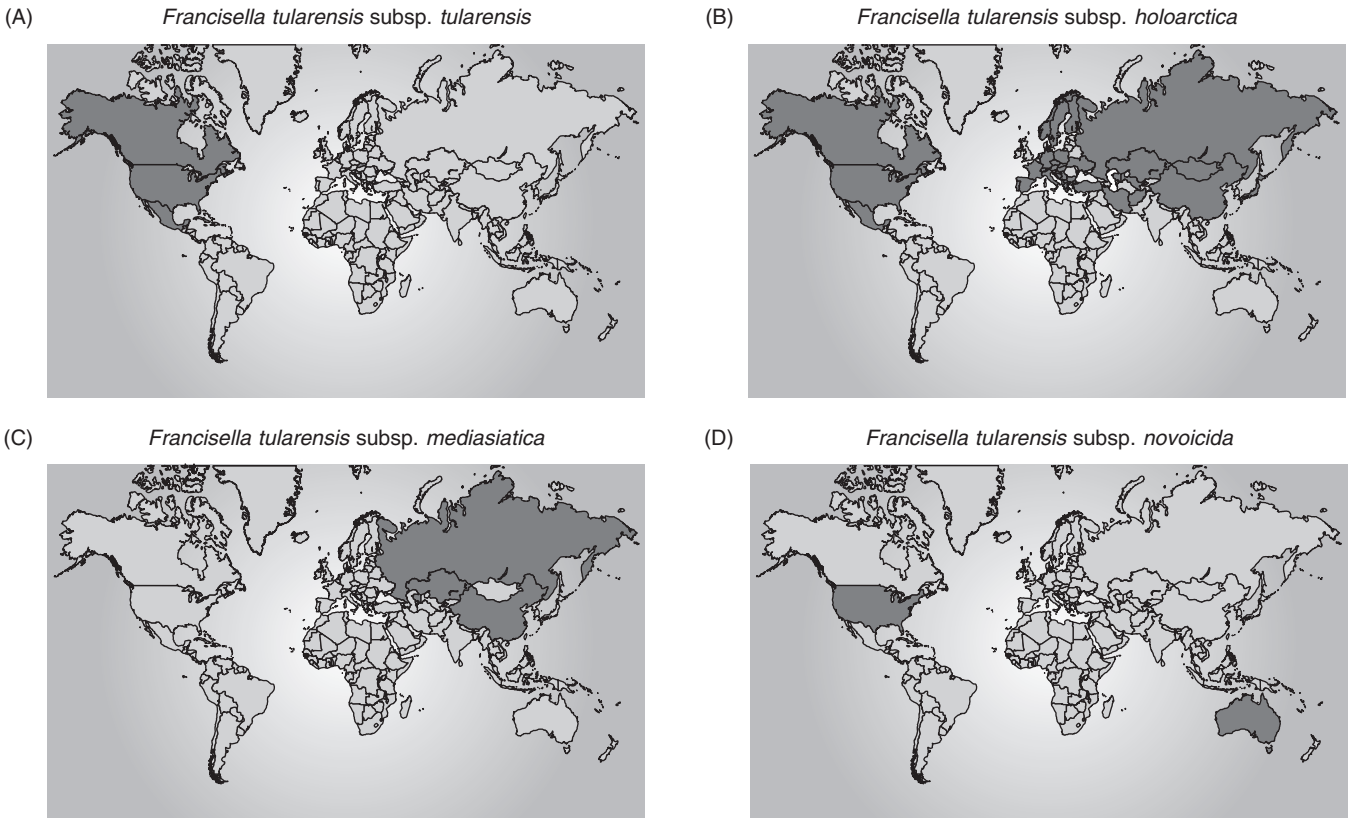

FIGURE 61.1 Worldwide distribution of *F. tularensis* subspecies. Reproduced from Oyston et al. (2004).

developed that distinguished the two clinically most important subspecies, *tularensis* and *holarctica*.

Work to determine the complete genome sequence of a virulent subspecies *tularensis* strain, SCHU S4, also allowed the production of an ordered clone microarray. Hybridization patterns of DNA isolated from a range of strains representing the various subspecies revealed a hyperplastic region different in each subspecies. This allowed the development of a PCR whereby the four subspecies could be differentiated (Broekhuijsen et al., 2003). However, it must be borne in mind that the ordered clone array was developed prior to complete assembly and analysis of the genome sequence data, and as such there may be gaps in the coverage provided by this array.

ANTIGENS EXPRESSED BY THE ORGANISM

The genus *Francisella* is antigenically coherent and the subspecies are almost indistinguishable by serological methods, although the LPS of *F. tularensis* subspecies *novicida* discriminates this subspecies from the others (Prior et al., 2003; Vinogradov et al., 2004). Serological tests for confirmation of tularemia rely on the detection of antibodies produced against LPS.

Several proteins have been identified that are able to induce the proliferation of T cells isolated from LVS vaccinees or convalescent individuals (Table 61.1), two of which were putative surface proteins of 32 and 17 kDa (Sandstrom et al., 1987; Sjostedt et al., 1990a, 1990b; Surcel et al., 1991). The role of these proteins in infection is not known.

Western blotting of outer membrane preparations, with sera from patients who had contracted tularemia during an outbreak in Sweden, showed patient-to-patient variation in immune response (Bevanger et al., 1988). However, one protein of 43 kDa termed FopA appeared to be immunodominant as all 12 patients tested produced antibodies against this antigen. Recently, a proteomic analysis was undertaken to identify the immunologic proteins expressed by strain LVS, recognized by C3H/HeN and C3H/HeJ mice, and naturally infected humans (Havlasová et al., 2005). Strong murine antibody responses were detected to 36 *F. tularensis* proteins, 27 of which were identified for the first time as being immunogenic (Table 61.1). Eight proteins were recognized by both mouse and human: ClpB, an outer membrane protein, malonyl-Co-A-acyl carrier protein transacylase, GrpE, oxidoreductase, a hypothetical protein, 10 kDa chaperonin, and a probable sigma modulation protein.

TULAREMIA AS A PUBLIC HEALTH PROBLEM

Tularemia has been isolated from several parts of the Northern Hemisphere but has only rarely been found in the Southern Hemisphere (Fig. 61.1). The majority of cases of human disease are reported from Scandinavia, Northern America, Japan, and Russia (Boyce, 1975; Ohara et al., 1996; Stewart, 1996; Tarnvik et al., 1996b; Berdal et al., 2000). Although outbreaks of tularemia are rare, they can involve a high number of cases. For example, in a recent outbreak in Bulgaria, 262 cases were confirmed, mainly presenting with oropharyngeal tularemia (Christova et al., 2004). The outbreak was caused by *F. tularensis* subspecies *holarctica*, probably contracted from food and water that had been contaminated by infected rodents. In an outbreak in Sweden, almost 700 cases of respiratory tularemia were reported, and in another more than 500 cases of ulceroglandular tularemia reported. The source of pathogen was most likely either carcasses or secretions of infected animals.

TULAREMIA AS A BIOTHREAT AGENT

F. tularensis subspecies *tularensis* has been an organism of concern since the large state-funded biological weapons programs of the 1950s, when the USA and the former Soviet Union (fSU) first evaluated the organism as a biological weapon. It is a highly infectious organism inducing a potentially fatal disease, but no licensed vaccine is available for prophylaxis.

CLINICAL DISEASE

The typical symptoms of tularemia occur after an incubation period of 3–5 days and the onset of disease is often abrupt with fever, chills, malaise, sore throat, and headache (Evans, 1985; Evans et al., 1985). However, other symptoms of disease are dependent largely on the route of entry of the bacterium into the body. The most common form of the disease, and representing 90% of all cases in Europe, is ulceroglandular tularemia. The disease is acquired following direct contact with an infected animal or is vector-borne (Tarnvik et al., 1996a; Ohara et al., 1998). At the site of the vector bite, a primary ulcer develops (Fig. 61.2a) followed by the development of a pustule surrounded by inflammation (Evans, 1985; Evans et al., 1985). In some cases, the ulcer is inconspicuous and heals within a week

TABLE 61.1 Immunogenic proteins identified from *F. tularensis*

Antigen	Recognition by convalescent antisera?	Recognition by convalescent T cells?

Single-strand binding protein	Yes (Havlasová et al., 2005)	NR

and may be mistaken for an insect bite. Subsequently the most obvious sign of disease is enlargement of the draining lymph nodes (Evans, 1985; Evans et al., 1985). If appropriate antibiotic therapy is not instituted within 7–10 days, the enlargement may become even more prominent and in 30–40% of cases suppuration eventually results (Helvaci et al., 2000). Recovery from ulceroglandular tularemia can be protracted but the

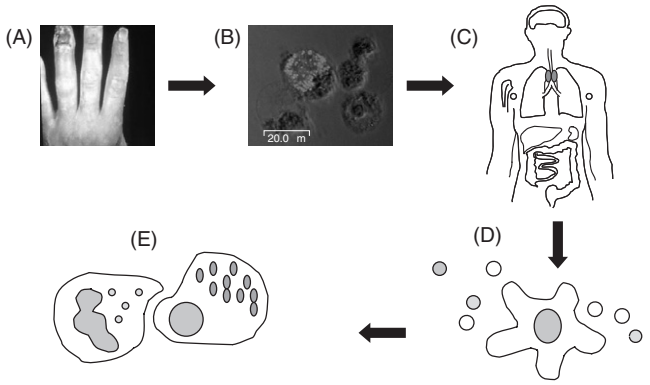

FIGURE 61.2 Pathogenesis of *F. tularensis* infection. (a) In typical human ulceroglandular tularemia, a skin lesion first appears at the site of infection after 3–5 days. (b) The bacteria (shown here labeled with green fluorescent protein) are taken up by macrophages, where they escape killing and multiply to high levels within the cytoplasm of the cell. (c) A transient bacteremia occurs seeding the organism throughout reticuloendothelial tissues of the body. (d) A wide range of cytokines are expressed in the reticuloendothelial tissues; for example, infected hepatocytes produce TNF-α, IL-10, IL12, and IFN-γ. (e) As infection progresses, T cells play a more significant role in protection. Neutrophils also appear to play a role in defence by ingesting and killing microorganisms, lysing infected hepatocytes, and acting as a source of cytokines.

mortality rate associated with this form of disease is typically less than 3% (Evans et al., 1985).

Respiratory tularemia is the consequence of the inhalation of bacteria, and naturally occurring cases of disease are usually the result of farming activities when dusts contaminated with the bacterium are generated (Tarnvik et al., 1996b). Often exposure occurs during the clearing of barns or other storage areas that infected rodents have colonized (Syrjala et al., 1985; Stewart 1996). The symptoms of respiratory tularemia are quite variable and the disease commonly presents as a systemic illness with fever but without obvious signs of respiratory disease (Dahlstrand et al., 1971; Evans et al., 1985). Respiratory infection caused by *F. tularensis* subspecies *holarctica* is often a relatively mild infection. Other common symptoms of disease included headache, myalgia, dry cough, and arthralgia (Syrjala et al., 1985). Respiratory tularemia caused by *F. tularensis* subspecies *tularensis* is a much more acute disease characterized by high fever, chills, malaise, dyspnea, and cough (Evans, 1985; Evans et al., 1985). Pulmonary symptoms, including cough, substernal pain, and tachypnea are more common than in the respiratory disease caused by *F. tularensis* subspecies *holarctica*. Without antibiotic therapy the case fatality rate is typically up to 30–60% but with appropriate therapy this can be reduced to less than 2% (Dennis et al., 2001). The respiratory from of the disease caused by *F. tularensis* subspecies *tularensis* is the most likely consequence of the deliberate release of the bacterium.

Other forms of tularemia are much less common. Typhoidal tularemia is a relatively ill-defined form of the disease in which septicemia develops without lymphadenopathy or the appearance of an ulcer. Oculoglandular tularemia can occur following the contamination of the eye with bacteria (Steinemann et al., 1999). The disease is marked by the development of ulcers and nodules on the conjunctiva, and the infection can spread to the local lymph nodes. Oropharyngeal or gastrointestinal tularemia can develop following the ingestion of bacteria in water of foodstuffs (Stewart, 1996; Tarnvik et al., 1996b). Oropharyngeal disease is characterized by a sore throat with enlargement of the tonsils and the formation of a yellow-white pseudomembrane (Ellis et al., 2002). The severity of gastrointestinal tularemia can range from a mild and persistent diarrhea to an acute fatal disease with extensive ulceration of the bowel (Ellis et al., 2002).

TREATMENT

Following the possible exposure of an individual to *F. tularensis*, chemotherapy should commence immediately and continue for at least 14 days. The isolation of the individual is not necessary since human-to-human transmission of the disease has not been reported. *F. tularensis* is susceptible to a range of antibiotics in vitro, and historically the aminoglycoside streptomycin has been the drug of choice for the treatment of tularemia (Enderlin et al., 1994). Nowadays streptomycin is not the preferred drug of choice because of the associated ototoxicity, but it is an option for the treatment of tularemia meningitis. Gentamicin provides an acceptable alternative. However, because of the need for parenteral administration and the continuous monitoring of serum levels, aminoglycosides are only the drugs of choice for serious forms of tularemia and in cases where there are no alternative efficacious regimens available, such as treatment of children and pregnant women (Dennis et al., 2001).

Tetracyclines have also been used extensively to treat tularemia, and due to its excellent pharmacokinetics, doxycycline is the preferred choice (Tärnvik and Berglund 2003). It is a second-line treatment for uncomplicated forms of ulceroglandular tularemia. To avoid the possibility of relapse, tetracycline therapy should continue for at least 2 weeks.

Other antibiotics might also be of value for the treatment of tularemia, although clinical experience using these drugs for this disease is more limited. In vitro data indicate that *F. tularensis* is susceptible to carbapenems,

ceftriazone, ceftazidime, rifampin, and certain macrolides, but there is a lack of clinical data to recommend any of them for clinical use (Tärnvik and Berglund, 2003). Additionally, there is widespread natural resistance to erythromycin among strains of subspecies *holarctica*. The quinolones have excellent in vitro efficacy against *F. tularensis* (MIC 0.01–0.1 mg/L (Johansson et al., 2002)) and several reports have demonstrated the utility of ciprofloxacin for the treatment of tularemia (Enderlin et al., 1994; Johansson et al., 2000, 2001; Perez-Castrillon et al., 2001). Based on published clinical evidence and microbiological data, ciprofloxacin is becoming the drug of choice for treatment of uncomplicated tularemia and as a second line of treatment for severe infections (Dennis et al., 2001). It may also be of value for treatment of tularemia in pregnant women. Excellent clinical efficacy for treatment of children has been reported (Johansson et al., 2000). In a mass casualty setting, it has been suggested that the oral administration of ciprofloxacin is the drug regime of choice (Dennis et al., 2001).

PATHOGENESIS

F. tularensis is able to infect a wide range of hosts, with a typical ID in humans of only ten bacteria (McCrumb, 1961). Very few classical virulence factors have been identified for this pathogen. It does not apparently produce secreted exotoxins, and the LPS of *F. tularensis* does not exhibit the properties of a classical endotoxin (Sandstrom et al., 1992).

In typical human ulceroglandular tularemia, a skin lesion first appears at the site of infection 3–5 days after infective exposure (Fig. 61.2). During this initial phase, T cells appear to play little role in combating infection, but the cytokines tumor necrosis factor (TNF) and interferon gamma (IFN-γ) play a key role in response to infection (Elkins et al., 1993). A transient bacteremia occurs, during which the pathogen must resist lysis by complement. The capsule is reported to be essential for serum resistance, but not required for survival following phagocytosis (Sandstrom et al., 1988). The bacteremic phase allows the organism to be seeded throughout the body, infecting all reticuloendothelial tissues. As infection progresses, T cells appear to play a more significant role in protection (Conlan et al., 1994; Yee et al., 1996; Fulop et al., 2001). Neutrophils also appear to play a role in defence by ingesting and killing microorganisms, lysing infected hepatocytes, and acting as a source of cytokines (Conlan et al., 1994; Sjostedt et al., 1994).

The pathogenicity of intracellular bacteria depends upon their ability to survive within macrophages, although other cell types such as hepatocytes may play a role (Conlan and North, 1992). The intracellular lifestyle of *F. tularensis* is unique compared to other intracellular bacterial pathogens. The phagosomes containing *F. tularensis* show limited maturation in the endocytic pathway (Golovliov et al., 2003; Clemens et al., 2004). The phagosome matures to a late endosome-like stage, but there is no lysosome fusion. The bacterium then escapes into the cytoplasm by disruption of the phagosomal membrane and multiplies to high numbers.

Little is known about the molecular mechanisms of *Francisella* pathogenesis. The recently published genome sequence of a highly virulent strain revealed a paucity of potential virulence factors (Larsson et al., 2005). However, a genomic island required for intracellular survival and growth has been reported, the *iglC* gene contained therein being responsible for the inhibition of lysosomal fusion (Santic et al., 2005).

IMMUNE RESPONSES TO INFECTION

Following a natural infection with *F. tularensis*, most of the antibody that develops is directed against the LPS. Additionally, several studies (Bevanger et al., 1988; Sjostedt et al., 1990a, 1990b; Ericsson et al., 2001; Havlasova et al., 2002, 2005) have identified at least some of the protein antigens which are recognized by either immune sera or T cells (Table 61.1).

Recovery from natural infection generally provides long-lasting protection against reinfection with *F. tularensis*. However, there have been relatively few studies on the nature of protective immunity to tularemia. In a review published in 1989 (Tarnvik, 1989), and based largely on studies carried out during the period 1940–1960, both humoral and cellular responses were identified as being important for protection, but the relative contributions of these arms of the immune system to protection were different. During the 1930s and 1940s, there were several studies to evaluate immune sera for the treatment of tularemia (Foshay 1934; Foshay 1946). These studies yielded contradictory results. For example, Foshay, (1934, 1946) claimed that antisera was effective in the treatment of tularemia, whereas Francis and Felton (1942) claimed that antisera was of little value in treating disease. Overall, the current consensus is that antibody to *F. tularensis* can play a role in protection or recovery from tularemia caused by low-virulence strains. However, the role of antibody in protection or recovery from disease caused by high-virulence strains is at best minimal (Tarnvik, 1989).

Conversely, the evidence points to cellular responses playing a major role in protection from tularemia

caused by all strains of *F. tularensis* (Tarnvik, 1989). The transfer of mononuclear leukocytes from immune to naive mice or from immune to naive rats provides protection against a subsequent challenge with a virulent strain of *F. tularensis* (Allen, 1962; Thorpe and Marcus, 1965). However, these studies do not clarify the roles of activated phagocytes and committed leukocytes. During the early stages of the disease, T cells appear to play a minor role in the control of the infection (Elkins et al., 1993). However, cytokines such as IFN-γ and TNF-α are important for the resolution of disease (Elkins et al., 1993; Fortier et al., 1994), possibly because they play roles in the activation of phagocytic cells such as macrophages. Later during infection, both CD4+ and CD8+ T cells play a role in protection. Mice devoid of either subset of T cells were capable of controlling but not eliminating infection (Conlan et al., 1994; Yee et al., 1996; Fulop et al., 2001).

Circulating $\gamma\delta$ T cells might also play an important role in protection or recovery from tularemia and the expansion of this subset of T cell has been reported in individuals recovering from tularemia (Poquet et al., 1998; Kroca et al., 2000). Phosphoantigens that are expressed in vivo are strongly implicated in the development of this response (Poquet et al., 1998). It is known that $\gamma\delta$ T cells play a key role in the control of some intracellular infections (Hiromatsu et al., 1992), but the role of these cells in the control of tularemia has yet to be determined.

VACCINES

History

Live Attenuated Vaccines

During the early part of the twentieth century research to devise a vaccine against tularemia was carried out both in the USA and in the fSU. In the fSU, work appeared to be focused on the development of a live attenuated vaccine, and in 1934 El'bert demonstrated proof of principle that a live attenuated vaccine was a realistic prospect (Ellis et al., 2002). Subsequently, a live attenuated vaccine (strain Moscow) was reportedly tested in several thousand human volunteers, before being lost (Tigertt, 1962). Subsequent work resulted in the generation of strain 15, which had reduced virulence in guinea pigs. This strain, given subcutaneously, was tested extensively in humans and it was concluded that this vaccine was safe (Tigertt, 1962). The strain 15 vaccine was used in a number of mass-vaccination campaigns in the fSU, in areas where outbreaks of tularemia occurred naturally. In total, as many as 60 million individuals were immunized. Subsequently, an additional live vaccine termed strain 155 was developed and produced along with strain 15 at the Gamleya Institute. Both of these strains were transferred to the USA in 1956. These strains were propagated and subcultured to provide the so-called "Live Vaccine strain" (LVS), though it is uncertain whether LVS was derived from strain 15 or strain 155.

All of the evidence points towards these live attenuated vaccines as being effective for the prevention of tularemia in humans. In one study in the USA, both individuals immunized with a live attenuated vaccine and naive individuals were exposed to airborne *F. tularensis* (McCrumb, 1961). This study showed that the degree of protection afforded by immunization depended on the challenge dose (Table 61.2). Good protection against a challenge of 10 IDs was reported but when challenged with 1000 IDs the degree of protection was marginal (McCrumb, 1961). In another study, the incidence of laboratory-acquired tularemia at Fort Detrick in Maryland was shown to reduce markedly following the introduction of the LVS vaccine (Burke, 1977). Interestingly, this study also shows that the use of microbiological safety cabinets alone was insufficient to reduce the incidence of disease. Collectively, these findings indicate that a live attenuated vaccine is effective for the control of tularemia.

Although live attenuated vaccines were generally given by the intradermal/subcutaneous route, there is a significant body of evidence that oral, aerogenic, and intranasal immunization also provides protection against tularemia (Eigelsbach and Tulis, 1961; Eigelsbach et al., 1962). Some of these studies suggested that the aerogenic rather than intradermal route of immunization provided a higher level of protection against a subsequent respiratory challenge (Hornick and Eigelsbach, 1966). This finding might be in accordance with more recent studies which have shown that mice immunized with the LVS strain by the intranasal route are better protected against a subsequent challenge than mice immunized by the intradermal/subcutaneous route (Conlan et al., 2005; Wu et al., 2005).

During the selection of the LVS strain in the USA, the phenomenon of blue and gray variant colonies was first highlighted. When grown on certain solid media and viewed under obliquely transmitted light, colonies appeared to have either a gray or a blue tint (Eigelsbach and Downs, 1961). Subsequent studies in mice and in guinea pigs showed that only immunization with blue variant colonies resulted in protection against a subsequent challenge with *F. tularensis* (Eigelsbach and Downs, 1961). During the subsequent manufacture of

[c] ID, human infectious dose; 1 ID = 200 cfu by the airborne route.

batches of the vaccine by the National Drug Company (USA), the control of the proportion of gray variant colonies was an area of significant concern. In addition to the potential for the LVS strain to segregate into different colony variants, there is evidence that marginal differences in cultural conditions can affect the immunogenicity of the vaccine (Hambleton et al., 1974; Cherwonogrodzky et al., 1994). The potential for significant variation in batches of vaccine is highlighted by comparing the properties of different batches. For example, the NDBR101 lot of vaccine contained 1% gray colony variants whereas one of the last vaccine lots produced contained 20% gray cells (Sandstrom, 1994).

Whilst in the past this vaccine has been used in humans as an investigational new drug, currently the LVS vaccine is not available. The potential for batch-to-batch variation of vaccine lots, along with the lack of information on the molecular or biochemical basis of attenuation, has so far precluded the full licensing of this vaccine for use in humans. It has been suggested (Sandstrom, 1994; Ellis et al., 2002) that any future work to license this vaccine should especially focus on characterizing the LVS strain in the following ways. It would be essential to establish a reliable seed-stock and to devise a method for the reliable quantification of blue and gray variant colonies in batches of vaccine. This may then allow methods for the culture of the LVS strain to be established which ensure that the proportion of blue variant colonies is reproducible. Additional work is required to establish the genetic or biochemical basis of attenuation of the LVS strain and identify mechanism of protection.

Killed Whole-Cell Vaccines

Much of the work on killed whole-cell vaccines took place in the USA during the 1930s and 1940s, and was driven by an early observation that immune sera could modify the course of tularemia in humans (Foshay, 1934, 1946). However, the significance of this finding is still debated. As highlighted above, antibody can place a role in protection against low-to-medium virulence strain of *F. tularensis*. The individuals who were involved in these trials of antisera were naturally infected and it is not clear whether they had been infected with strains of *F. tularensis* subspecies *holarctica* or *F. tularensis* subspecies *tularensis*. Without this information it is difficult to make a meaningful judgment on the value of antisera to treat disease.

Notwithstanding this concern, there were a number of reports on the preparation and efficacy of killed whole-cell vaccines during the 1940s, 50s, and 60s. Various methods for killing the bacteria cells and extracting immunogenic components were reported including acetone, heat, and phenol treatments (Foshay et al., 1942; Foshay, 1946, 1950). Some of these vaccines reportedly caused significant side effects in human volunteers, including the development of lesions at the site of immunization (Foshay, 1950). The available evidence does not conclusively indicate that these vaccines are of value in preventing tularemia. In animal models of disease, such as the mouse, guinea pig, or rabbit, killed vaccines failed to increase the level of resistance to infection or to modify the severity of the disease caused by *F. tularensis* subspecies *tularensis* given intraperitoneally, intracerebrally, or subcutaneously (Eigelsbach and Downs, 1961). In monkeys immunized with a killed vaccine, the susceptibility to infection by the subcutaneous or intradermal route was not modified. However, the severity of disease after challenge with 10 organisms (but not after challenge with 750 or 2600 organisms) was reduced (Eigelsbach and Downs, 1961). The phenolized and acetone-extracted vaccines (or the Foshay vaccines) underwent some limited trials in humans. The immunization of laboratory workers or hunters with the Foshay vaccine

provided only slight protection against disease (Eigelsbach and Downs, 1961). Volunteer studies indicated that the vaccine reduced the severity of disease caused after intracutaneous challenge with 10 organisms of *F. tularensis* subspecies *tularensis* (strain SCHU S4), but did not provide any protection against disease caused by the inhalation of 50 organisms (Eigelsbach and Tulis, 1961). Overall, it can be concluded that killed whole-cell vaccines, at least those prepared in the ways reported above, are not tularemia vaccines.

Subunit Vaccines

There have been a limited number of studies to identify protective polysaccharides or proteins from *F. tularensis*, which might be exploited as components of a subunit vaccine. These studies have generally met with limited success. The immunization of mice with purified LPS induced a humoral response that was able to protect mice against low-virulence strains of *F. tularensis* subspecies *holarctica* (Fulop et al., 1995, 2001). However, this immune response served only to extend the time to death following challenge with high-virulence subspecies *tularensis* strains (Fulop et al., 2001; Conlan et al., 2002). This difference in protective efficacy does not appear to reflect differences in the structure of LPS. Other workers have evaluated antigens such as the 17 kDa TUL4 protein (Sjostedt et al., 1992; Golovliov et al., 1995), the FopA protein (Fulop et al., 1995), or heat shock protein 60 (Hartley et al., 2004) as protective antigens, without success.

Current Licensed Vaccines

There is no current licensed vaccine for use in Europe or in the USA.

Vaccines in Development

The history of immunization of humans with live attenuated vaccine strains has shown that an attenuated mutant can induce a protective immune response against virulent strains of *F. tularensis*. However, because these vaccines were all derived from strains of *F. tularensis* subspecies *holarctica*, a much debated question is whether or not an attenuated mutant of *F. tularensis* subspecies *tularensis* would provide improved protection against disease. The main problems associated with developing such defined attenuated strains have been the lack of genetic tools to manipulate *F. tularensis* and the difficulty of transforming subspecies *tularensis* strains. However, methods for producing defined isogenic allelic replacement mutants has been published recently (Lauriano et al., 2003); (Santic et al., 2005) opening the way to the production of attenuated vaccines.

Defined allelic replacement mutagenesis has been used in a variety of bacterial species to produce vaccine strains capable of limited replication in the host. In many cases, the genes targeted are in biosynthetic pathways, such as purine or aromatic amino acid biosynthetic pathways. The genes for these pathways are all present in *F. tularensis*, and the organism can grow in media lacking purines or tyrosine, respectively, showing the pathways to be fully functional (Karlsson et al., 2000). The availability of the *F. tularensis* subspecies *tularensis* SCHU S4 genome sequence (Larsson et al., 2005) will aid the identification of target genes for inactivation, especially when compared to the strain LVS genome once this is completed (http://bbrp.llnl.gov/bbrp/html/microbe.html).

The genome sequence data, supported by proteomic analysis (Lenco et al., 2005; Pavkova et al., 2005), will also help in the search for suitable protective subunits. However, it may be that in order to stimulate a suitable immune response, a protein antigen would have to be delivered with an appropriate adjuvant or using a vector system that would allow induction of a cellular immune response, for example, using a DNA vaccine.

POSTEXPOSURE IMMUNOPROPHYLAXIS

There is no therapy available in the form of vaccination or antibody therapy available for use post exposure. Antibiotics are effective for the treatment of infection (reviewed above).

PROSPECTS FOR THE FUTURE

Efforts are underway to develop an effective licensed vaccine to prevent tularemia. Enhanced funding, especially by US agencies such as the National Institute of Allergy and Infectious Diseases, has resulted in an increased research effort on this pathogen. However, a downside to this is the increased risk of laboratory-acquired infection due to a lack of experience in handling such a highly infectious pathogen. For example, in a recent incident at Boston University three researchers were infected with a highly virulent strain (Dalton, 2005).

KEY ISSUES

- *F. tularensis* is one of the most infectious pathogens known.
- Respiratory tularemia is an acute disease.
- *F. tularensis* has long been of concern as a biothreat agent.
- Antibiotic therapy is effective.
- There is no licensed vaccine available.
- A live attenuated vaccine (LVS) has been shown to be effective in humans, but is probably not licensable.
- Protection appears to be dependent on cellular immunity.
- To date no protective subunits have been identified.

African Trypanosomiasis

Andrew J. Nok
Department of Biochemistry, Ahmadu Bello University, Zaria, Nigeria

OUTLINE

ABSTRACT

African trypanosomiasis, otherwise known as sleeping sickness in humans and Nagana in cattle, is resurgent in Africa. Research suggests that the development of a vaccine is still far away and that existing drugs are becoming ineffective on account of the emergence of drug-resistant trypanosomes. These infections contribute to heavy economic losses and sociopolitical crises in the continent thus underscoring the pressure to intensify research for inexpensive less toxic and affordable trypanocides and effective vaccines. African trypanosomes are transmitted from reservoir hosts to livestock by several species of tsetse flies and other biting insects. In each host the parasite undergoes many life-cycle stages involving forms with discrete morphologies, patterns of gene expression, and proliferation. In each case there developmental changes are precisely programmed.

Infected animals develop fever, weight loss, and progressively become weak and unproductive; breeding animals, if left untreated, may abort or become infertile. Most animals die of anemia, heart failure, or intercurrent bacterial infections as a result of the animal's weakened resistance. Highly productive exotic breeds tend to be susceptible. In human trypanosomiasis, a similar course of events take place with parasites ultimately invading the brain, resulting in the disease syndrome known as "sleeping sickness."

In Africa, trypanosomiasis occurs in 37 countries, extending over 10 million square kilometers which is about a third of the continent. It is recorded in this region that an estimated 50 million cattle, about 30% of Africa's total cattle population, are exposed to the risk of infection. Africa produces about 70 times less animal protein per hectare than Europe, and this is on account of the widespread incidence of trypanosomiasis.

Trypanosomiasis control is focused on the use of insecticide spraying to control the vector tsetse populations and on regular treatment of livestock at risk with trypanocidal drugs. The high cost of regular drug and insecticidal treatment, the limited effectiveness of insecticide application in high-rainfall areas and concerns on environmental pollution, the emergence of parasites resistant to available drugs make tsetse and trypanosomiasis control difficult and expensive.

The development of a vaccine against trypanosomiasis by conventional approaches has been unsuccessful. All African trypanosomes are covered by a thick glycoprotein coat made up of variant surface glycoproteins (VSG), which act as shield for underlying invariant immunogenic proteins. VSG, the predominant surface antigen in African trypanosomes, prevents trypanosome lysis by alternative complement pathway, and enables the organism to avoid adaptive immune responses via the phenomenon of antigenic variation.

In order to pursue chemotherapeutic control of trypanosomiasis, intensive research into several aspects of the basic biology of the parasites, the role of tsetse flies in transmitting disease, and the responses to infection of different breeds and species of livestock are mandatory. This chapter will review developments in trypanosomiasis research and the current progress in vaccine research.

INTRODUCTION

Sleeping sickness, or human African trypanosomiasis (HAT), is an endemic parasitic disease exclusively located in intertropical Africa (Fig. 62.1) where it is transmitted by its unique vector, the tsetse fly or *Glossina* (Fig. 62.2a) (Vickerman, 1985). This vector is exclusive to the African continent. East African trypanosomiasis is caused by the parasite *Trypanosoma brucei rhodesiense* and West African trypanosomiasis by *Trypanosoma brucei gambiense*. East African trypanosomiasis occurs in parts of Eastern and Central Africa, including Uganda, Kenya, Tanzania, Malawi, Ethiopia, Zaire, Zimbabwe, and Botswana. West African trypanosomiasis is found in parts of Western and Central Africa (Fig. 62.2b). The inoculation of trypanosomes into mammalian hosts triggers a series

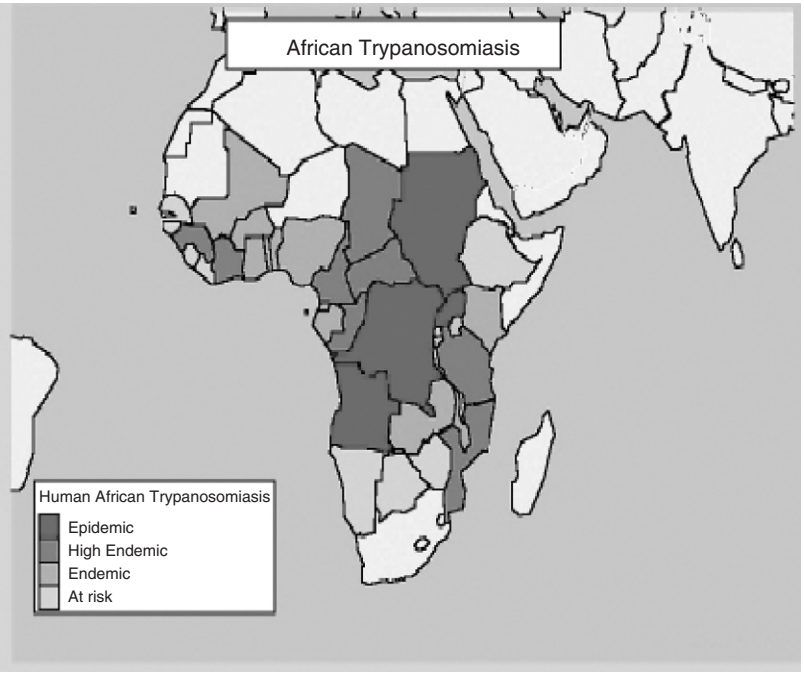

FIGURE 62.1 Geographical distribution of human African trypanosomiasis (HAT).

of events involving, innate and adaptive immunity. The latter requires an efficient presentation of parasitic antigens, activation of T and B cells implying specific antigen receptor recognition, and the development of effector cells and molecules. These mechanisms are highly regulated by multiple signals delivered through a large number of receptors transduced across the plasma membrane and processed.

During co-evolution with their hosts, trypanosomes have learnt to cope with host immune systems, by penetrating, diverting, and altering the numerous steps leading to the generation of an effective immune response. Major modifications of immune systems have been observed in trypanosomiasis: lymphadenopathy, splenomegaly (up to 30 times the normal size) with destruction of lymphatic tissue architecture and hypergammaglobulinemia (Maurice and Pearce, 1987).

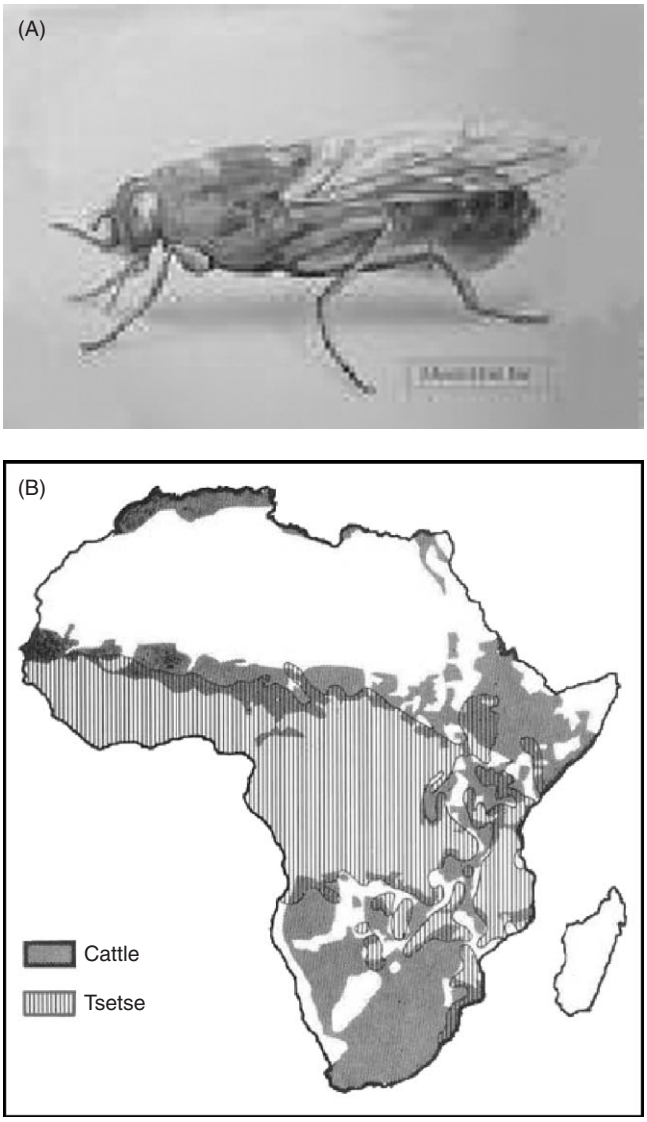

FIGURE 62.2 (a) The tsetse fly, *Glossina morsitans*; (b) geographical distribution of tsetse flies and cattle in the African continent.

Animal trypanosomiasis occurs throughout the tropical regions of Africa and in large areas of Asia and South America. It affects cattle, sheep, goats, pigs, horses, camels, and man. Also, wild animals can be infected with the parasites; however, they seldom suffer from disease. They serve as the reservoir of infection for domestic animals. The most important trypanosome species affecting domestic livestock in Africa are *Trypanosoma congolense*, *T. vivax*, and *T. b. brucei* in cattle, sheep, and goats; *T. simiae* in pigs; and *T. evansi* in camels. *T. vivax* also has a significant impact on cattle production in South America, while *T. evansi* affects camels in Asia and horses, cattle, and domestic buffalo in South America, India, and Southeast Asia.

African trypanosomiasis is transmitted between mammalian host by a variety of *Glossina* species including *Glossina morsitans* and *Glossina* palpalis usually termed tsetse flies (Fig. 62.2). The vector-mediated mode of transmission is relatively inefficient and requires the development of a chronic rather than acute infection to give the parasite sufficient opportunity for reuptake by the vector in order to complete the cycle and sustain the population (Maurice and Pearce, 1987). Therefore, trypanosomes must survive and grow for prolonged periods in their mammalian hosts. This requirement necessitates the existence of a mechanism that regulates parasite growth and ensures the survival of host at least in the short to medium term. Central to this mechanism is the continuous decrease of parasite number.

East African trypanosomiasis is usually confined to woodland and savannah areas away from places where people live. Tourists, hunters, game wardens, fishermen, and other persons who work in or visit game parks in East and Central Africa are at greatest risk for illness. The tsetse flies that spread West African trypanosomiasis can be found in Western and Central African forests and in areas of thick shrubbery and trees by rivers and waterholes. The risk of infection increases with the number of times a person is bitten by a tsetse fly. Trypanosomes use two distinct pathways for respiration in the different environments of the tsetse and the mammalian bloodstream. In the bloodstream, respiration is entirely dependent upon the trypanosome alternative oxidase (TAO), a mitochondrial glycerophosphate oxidase, which is unique to trypanosomes and might provide a prime target for trypanocidal drugs (Chaudhuri et al., 1995). Procyclic trypanosomes utilize a mitochondrial cytochrome electron transport system for 70–80% of

respiration and the TAO for only 20–30%. Metacyclic parasites also use both systems, but the relative contribution of each system is reversed with 20–30% derived from mitochondrial cytochrome electron transport and 70–80% from the TAO pathway; this suggests that the metacyclic forms are an intermediate differentiation stage between procyclic and bloodstream parasites (Fig. 62.3).

The current options for trypanosomiasis treatment are poor, making the search for improved drugs essential. Moreover, because those in the lower socioeconomic class are disproportionately affected by the disease, there is a great need for the development of not only less toxic drugs but also less expensive agents.

Another challenging aspect of trypanosomiasis is the parasite's dense glycoprotein coat. The parasite's genome has 1000 different genes encoding antigenically distinct versions of the coat, thus affording protection from adaptive immune responses through antigenic variation (Cross, 1978). This strategy makes the prospect of a vaccine problematic (Pays and Nolan, 1998). The moment African trypanosomes are injected into the bloodstream of the mammalian host by means of the tsetse fly bite, they are exposed to host blood and host immune system. Yet these unicellular eukaryotes live freely in blood dividing by binary fission every 4–6h.

Most of the data concerning African trypanosomiasis have been obtained from naturally infected animals or experimental animal models. Few studies have examined host immune responses to the parasite. Genetic analysis of resistance and susceptibility to infection in inbred and congenic animal strains form the basis for research into equivalent human genes. Introduction of double-stranded RNA (ds RNA) into parasites induces potent and specific gene silencing a phenomenon called RNA interference (RNAi) and is a valuable tool to investigate trypanosome gene functions. The recent sequencing of the entire genome of *T. brucei* is an important breakthrough to investigate immunology and immunopathology (Beverley, 2003).

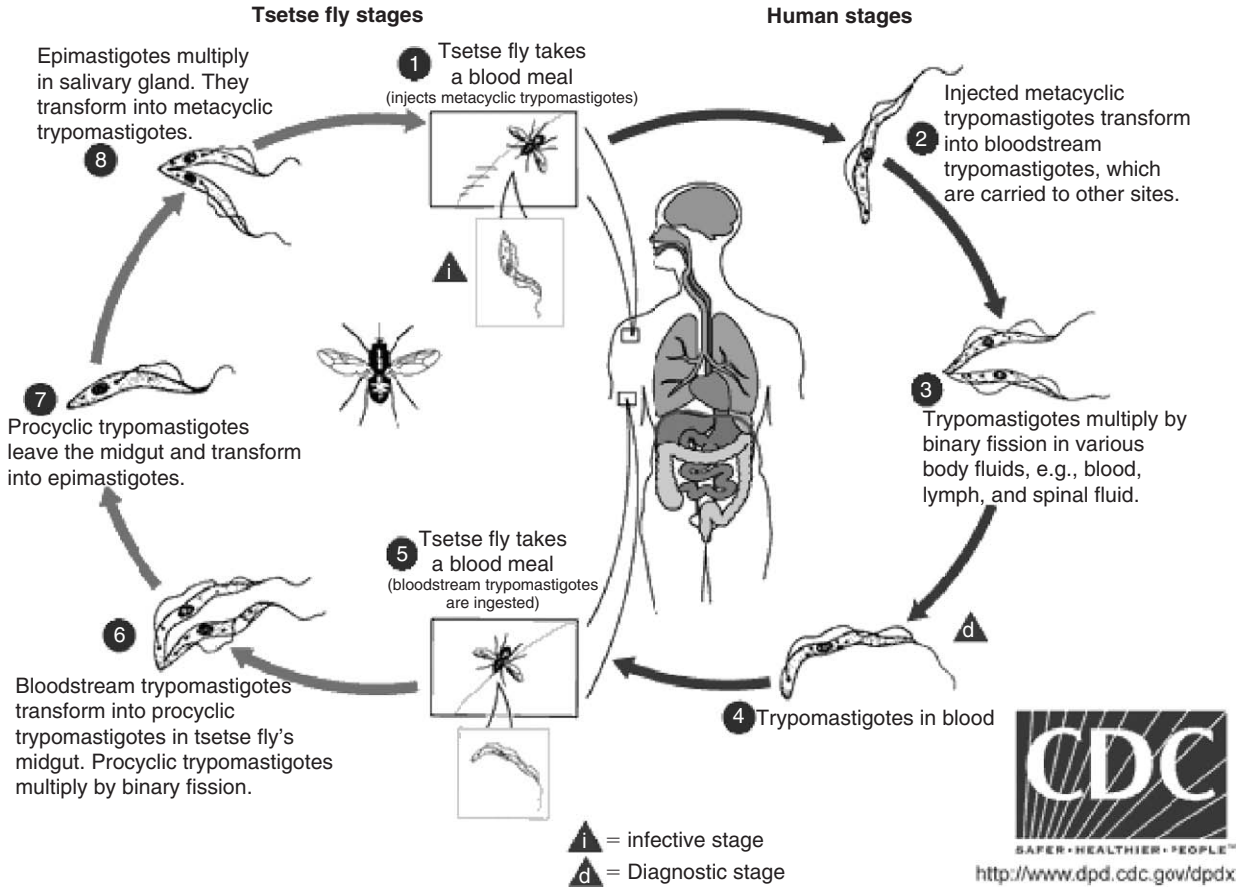

FIGURE 62.3 The developmental stages of trypanosome infection between the insect vector and human host.

CLASSIFICATION

Trypanosoma are of the class kinetoplastida, a monophyletic group of unicellular parasitic protozoa. The name is derived from the Greek *trypaô* (boring) and *soma* (body) because of their corkscrew-like motion. Trypanosomes infect a variety of hosts and cause the fatal disease, sleeping sickness, in humans. Trypanosoma undergo a complex life cycle which includes several different morphological forms (Fig. 62.3). For example, *T. brucei* is transmitted between mammalian hosts through a tsetse fly vector and undergoes a series of morphological and metabolic changes to adapt to these very different environments. In contrast, *T. equiperdum* are sexually transmitted between horses and have no insect part of the life cycle.

Characteristic of this order is the mitochondrial genome, known as the kinetoplast. Structurally it appears as a highly complex series of catenatated circles and minicircles; a set of proteins are required for organization during cell division.

Species of *Trypanosoma* include the following:

- *T. avium*, which causes trypanosomiasis in birds
- *T. boissoni*, in elasmobranch
- *T. brucei*, which causes sleeping sickness in humans and *nagana* in cattle
- *T. carassii*, in freshwater *teleosts*
- *T. cruzi*, which causes *Chagas disease* in humans
- *T. congolense*, which causes *nagana* in cattle, horses, and camels
- *Trypanosoma equinum*, in horses infected by Tabanidae, South America
- *T. equiperdum*, which causes dourine or covering sickness in horses and other *Equidae*
- *T. evansi*, which causes one form of the disease *surra* in certain animals
- *Trypanosoma levisi*, in rats
- *Trypanosoma melophagium*, in sheep infected by *Melophagus ovinus*
- *Trypanosoma percae*, in fish: *Perca fluviatilis*
- *Trypanosoma rangeli*, believed to be nonpathogenic to humans
- *T. rotatorium*, in amphibian
- *T. simiae*, which causes *nagana* in animals
- *T. suis*, which causes a different form of surra
- *T. theileri*, a large trypanosome infecting ruminants
- *T. triglae*, in marine teleosts
- *T. vivax*, which causes the disease *nagana*

The new taxonomy tools used in African trypanosomes (isoenzyme characterization, DNA analysis) have permitted scientists to separate the *T. brucei* class in several subspecies. Two are infective for humans: *T. b. gambiense*, and *T. b. rhodesiense*.

The *brucei* group is made up of *T. b. brucei*, *T. b. gambiense*, *T. b. rhodesiense*, *T. evansi*, *T. simiae*, *T. lewisi*, and *T. congolense*.

Antigens Encoded by Agent

The entire trypanosome surface is covered with a homogenous and dense glycoprotein coat made of approximately five million dimers of single antigen termed variant surface glycoprotein (VSG) that is repeatedly changed in a fraction of population (Fig. 62.4). This allows the trypanosomes to escape antibody-mediated killing and repopulate the host thereby resulting in the development of long-lasting chronic infection (Barry and McCulloch, 2001; Vanhamme et al., 1995; Pays et al., 2004). The VSG constitutes an important molecular interface between trypanosomes and the host immune system. It prevents trypanosome lysis by complement alternative pathway and enables them to avoid the specific immune response via antigenic variation (Fig. 62.5). It also has several effects on immune elements such as induction of autoantibodies and cytokines, in particular tumor necrosis factor (TNF) (Tachado and Schofield, 1994; Okomo-Assoumou et al., 1995a, Magez et al., 2002) (Fig. 62.6).

VSG are immunogenic and are eventually recognized by the host immune system but prior to immune recognition a minority of parasites will switch to an immunologically distinct coat to facilitate the next wave of infection. Despite successful evasion of antibody-mediated clearance by antigenic variation, the parasitemia is attenuated by immune responses

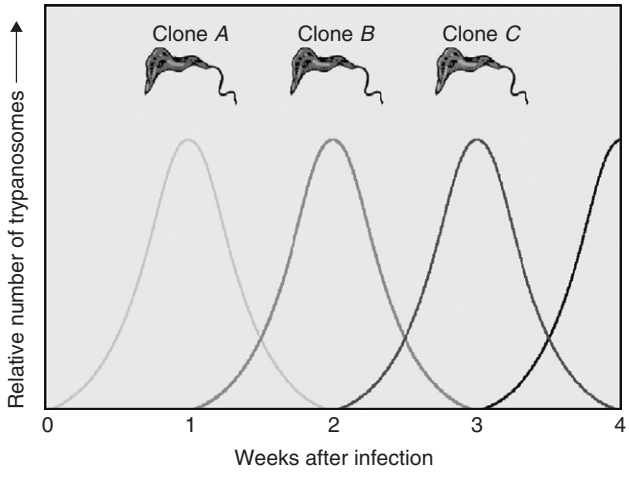

FIGURE 62.4 Schematic representation of the switch to different forms of parasites with varied surface antigens.

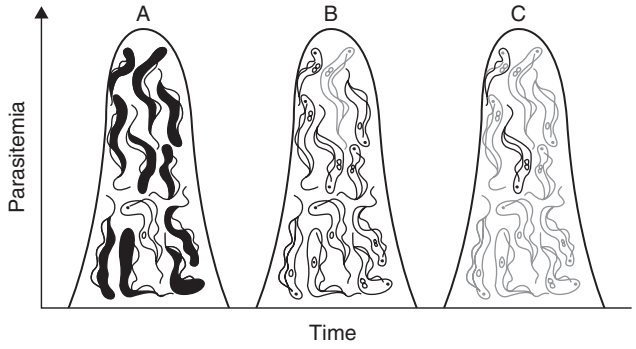

FIGURE 62.5 Schematic representation of the different forms of the trypanosome parasite at the various bouts of parasitemia.

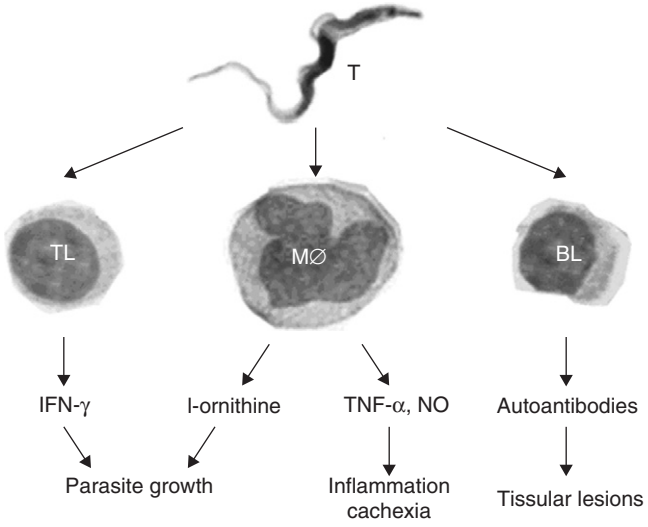

FIGURE 62.6 Trypanosome-induced secretion of various components from immune cells. T, trypanosomes; MØ, macrophage; TL, T lymphocyte; BL, B lymphocyte.

such as TNF (Magez et al., 1997, 1999). The continual release of TNF-α from activated macrophages causes the hallmark chronic wasting disease (cachexia) associated with trypanosomiasis. The parasites invade the central nervous system (CNS) resulting in neurological diseases, coma, and eventual death.

The genes encoding VSGs are located in telomeric expression sites. There are two types of expression sites (ES1) metacyclic ES1 (M-ES1) and bloodstream forms ES2 (B-ES1). The B-ES1 takes over and is used throughout chronic infection (Borst and Ulbert, 2001).

Trypanosomes can change the VSG gene transcribed in a B-ES by replacing the VSG gene in an active expression site by a different one. It is the most important source of VSG antigenic variation and requires DNA rearrangement. Also they can switch expression sites by turning off the active site and activating an earlier silent site. As there are only 20 B-ES1s per trypansosome nucleus, the switching of ES makes a very modest contribution to antigenic variation of the VSG coat. It has been postulated that multiple B-ESs exist to allow expression of different sets of the ESAG1 (Bitter et al., 1998).

Control of Metacyclic Expression

Prior to entry into the mammalian host, trypanosomes that have reached the salivary gland of the tsetse fly acquire a VSG coat. These metacyclic parasites lack functional ESAGs and the VSG gene in this phase are rarely replaced and antigenic variation in metacyclic phase of the life cycle is only accomplished by differential control of the M-ES.

As the wild animals in tropical Africa are chronically infected with trypanosomes, antigenic diversity of the inoculated trypanosome greatly increases incoming trypanosomes gain a foothold within its new host. Up to 27 different M-VATs have been detected in the metacyclic trypanosome population (Turner et al., 1988), hence at least 27 M-ES. Each trypanosome expresses a single VSG gene and continues to express a single VSG gene as long as the metacyclic stage continues. Hence each trypanosome has to decode which M-ES should be activated and how to keep the other 26 silent. The M-ES characterized thus far are all located at the end of large chromosomes and their activation is not associated with DNA rearrangement.

The exact start site for transcription is controversial. Promoter screens using M-ES fragments expressed in procyclic trypanosomes led to the identification of a set of promoters that had some semblance to B-ES promoter (Nagoshi et al., 1995; Vanhamme et al., 1995). Other trypanosome components and soluble factors, such as a trypanosome-released triggering factor (TLTF) which triggers interferon (IFN) production by T cells, are also involved in modulation of the immune system by acting on the synthesis of immune elements (Olsson et al., 1991; Vaidya et al., 1997). Furthermore, increased levels of circulating endotoxins are a feature of human and experimental trypanosomiasis. These endotoxins, potent immunomodulatory molecules, participate to the immune disorders observed in trypanosomiasis. Elaboration of escape mechanisms to host immune defenses and induction of parasite growth factor production are well developed by trypanosomes. In a recently discovered escape mechanism, host arginase induction by trypanosomes decrease immune response efficiency and increase the production of L-ornithine, an essential growth factor (Gobert et al., 2000; Vincendeau et al., 2003).

Flagellar Pocket Antigens

The flagellar pocket of the trypanosome contains receptors that are involved in specific host macromolecule uptake. One example of a flagellar pocket protein is trypanosomal transferrin-binding protein (TFBP), whose gene is present in multiple versions, and to which antibodies are produced in chronic infection. We showed that azanthraquinone coupled to transferrin enhanced the killing effect of the compound on trypanosomes (Nok and Nock, 2002). In a study with organotin palmitate, a known trypanocidal compound, we showed that the flagellar pocket is intrinsically affected by the compound and the topoisomerase of the parasite are equally strongly inhibited (Shuaibu et al., 2004). It has been conjectured that flagellar pocket proteins are highly conserved among flagellated protozoans. For this reason, a vaccine against the flagellar proteins of *T. brucei* may also confer protection against other parasites. In one study a flagellar pocket antigen from *T. b. rhodesiense*, with bovine serum albumin as a carrier and alum as the adjuvant, was used to inoculate 90 cattle in Kenya (Mkunza et al., 1995). The rate of infection was reduced from 13% to 0.9%. This study is of particular note because it was carried out in an environment of natural exposure with a naturally susceptible species.

Congopain

A second approach in vaccine control has been to prevent disease (limit pathogenicity) associated with infection without preventing the infection itself. Cysteine proteases of microorganisms can degrade host proteins such as immunoglobulins and complement factors. They can also modulate cytokine activities, and are suspected of interfering with antigen presentation and processing. Some cattle species in Africa are more resistant to infection than others. Studies have shown that a *T. congolense* cysteine protease (congopain) may play a role in the different levels of tolerance (Lalmanach et al., 2002). The more resistant cattle generate a stronger IgG response to congopain than the less resistant cattle. Attempts are being made to use congopain antigens in a vaccine that would generate antibodies capable of neutralizing the enzyme's activity.

Intracellular Antigens

Members of the Trypanosomatidae family have subpellicular microtubules cross-linked to each other and to the plasma membrane by unique trypanosomal microtubule-associated proteins (MAPs). The trypanosomal MAP (p52) has been used in an antigenic preparation with the enzymes aldolase and GAPDH as a vaccine in mice and rats. The p52 was isolated from *T. b. brucei*, and when the animals were immunized three times over a period of 3 weeks 100% protection was achieved (Rasooly and Balaban, 2004). The serum from immunized animals also cross reacted with *T. b. rhodesiense* and *T. b. evansi*, which gives hope for cross protection at least among trypanome species, and possibly for the whole family.

PROTECTIVE IMMUNE RESPONSE

Host Antibody Production

In infected animals, antibodies directed against trypanosomal VSGs attach to the surface of the parasites and mark them for destruction by macrophages or by the complement system. Previous studies of *T. b. brucei* infection in mice suggested that host antibody responses do not play a role in stimulating trypanosome transformation in the bloodstream, but only becomes effective after most of the parasites have already switched to nondividing forms. In vitro experiments to examine the effects of anti-trypanosomal antibodies on rapidly dividing forms of the parasite show that the polyvalent and monoclonal antibodies raised against trypanosome VSG bound to the surface of rapidly dividing bloodstream forms of *T. b. brucei.* Parasites exposed to moderate levels of the antibody stop multiplying but when the antibody was removed they began multiplying again, indicating that they had not made an irreversible switch to nondividing forms. The antibodies added to the cultures were rapidly destroyed; most likely, they were endocytosed by the parasites (ILRAD, 1994). Mice that are highly susceptible to trypanosomiasis do not produce detectable antibodies against the parasites, although their B lymphocytes are extensively activated and transformed into plasma cells which contain antibody. In vitro analysis of spleen cells from infected susceptible mice show that their activated B cells were defective in their capacity both to synthesize and to secrete antibody. When resistant mice were infected with trypanosomes, they produced antibodies which controlled the first parasitemic wave, but showed similar defective plasma cell function during the second parasitemic wave. However, in resistant mice antibody synthesis and secretion eventually recovered and parasitemia was controlled. At the time of parasite remission, vast amounts of antibody were synthesized and secreted although the number of cells containing antibody did not increase.

Anemia

In most early cases of trypanosomiasis there is an acute onset of anemia corresponding closely with the detection of parasites in the bloodstream. Later, in chronic infections, levels of anemia are observed which appear unrelated to the rise and fall of parasite populations. The N'Dama breed of cattle is known to withstand the pathogenic effects of trypanosome infection better than susceptible breeds (Shugaba et al., 1994). The etiology of anemia in trypanosomiasis has been linked to the enzymes phospholipase A_2 (Nok et al., 1993) and sialidases (Esievo et al., 1990; Nok et al., 2003b, Nok and Balogun, 2003). The PLA_2 is secreted by dying trypanosomes leading to the hydrolysis of red blood cells (RBC) phospholipids, thus generating free fatty acid and lyso-lipid derivative. The latter is a powerful hemolysing agent that induces high rate of RBC hydrolysis leading to anemia. Studies on potential inhibitors of PLA_2-like organotin derivatives of different fatty acids have proved valuable in experimental chemotherapy of the disease (Nok et al., 1993; Shuaibu et al., 2004). Our work has also revealed that the enzyme sialidase is abundant in bloodstream form of the trypanosome parasite. It mediates its pathogenic property by hydrolysis of membrane-bound sialic acid. When the enzyme attacks the sialyl residue on RBC, asialo-epitopes are generated which are easily recognized by macrophages and cleared accordingly, thereby leading to anemia. Interestingly, the *T. evansi* sialidase has capacity to hydrolize gangliosides, providing a link to the pathology of the brain stage of the disease during the chronic phase. Anemia in trypanosome-infected animals maybe due in part to impaired bone marrow function. Undifferentiated stem cells in the bone marrow give rise to both erythrocytes and white blood cells of different types. Trypanosome infection in susceptible animals could have an inhibitory effect on cell production in the bone marrow and/or result in the premature destruction of developing cells.

Endocrine Dysfunction

In susceptible livestock, growth, fertility, and immune responses are all impaired during trypanosome infection. These important functions are influenced by hormones. Previous studies showed that *T. b. brucei* parasites, perhaps when dying, release enzymes into the bloodstream of infected mice which were capable of degrading host proteins. In a recent report, we showed that the modulation of semen α-fucosidase and the attendant sialic acid surged in experimental trypanosomiasis in rams, suggesting a possible role in the loss of reproductive capacity (Okubanjo et al., 2007). Further, histological examination of the testis of rams chronically infected with *T. congolense* showed severe degeneration (Fig. 62.7).

CLINICAL DISEASE

Hemolymphatic Stage

After a painful tsetse bite, a chancre, from several millimeters to centimeters in size, develops at the site of the bite. It is characterized by local erythema, edema, tenderness, and a lack of suppuration. Trypanosomes are present in the inflammatory tissues. The chancre disappears within 2 or 3 weeks. The disease progresses through two distinct successive phases, the hemolymphatic stage and the meningoencephalitic stage (Molyneux et al., 1996;

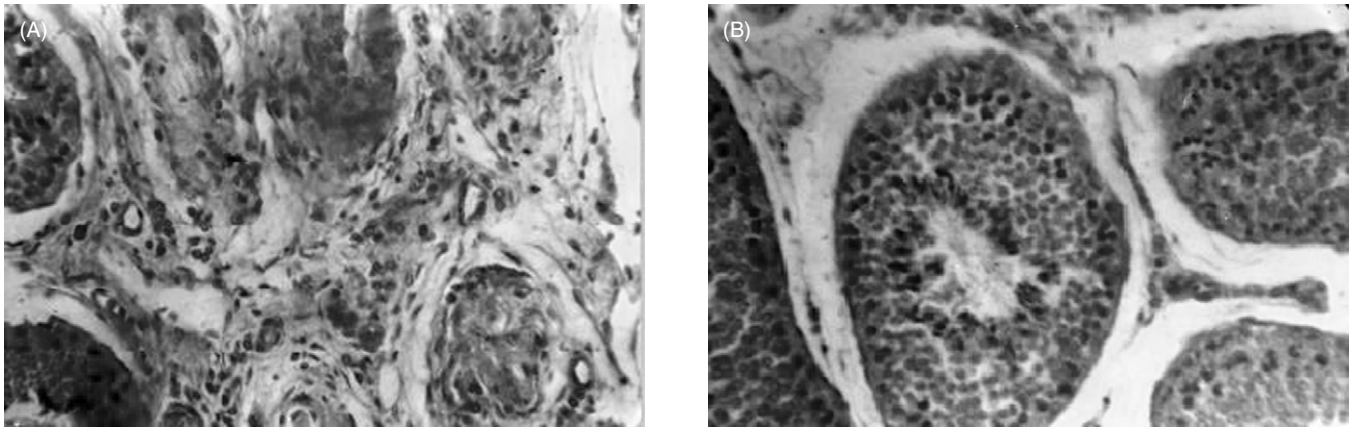

FIGURE 62.7 (a) Severely degenerated testis in *T. congolense*–infected ram (H&E, 400×); (b) normal testis in control ram (H&E, 400×).

Dumas and Bisser, 1999). Systemic signs appear very early. Intermittent fever develops in association with successive waves of parasitemia. Adenopathies, splenomegaly, or even hepatological signs mark the invasion of the reticuloendothelial system. Skin eruptions or trypanides are commonly observed. Severe pruritus can become unbearable for the patient. Cardiovascular alterations are less prominent, especially in the Gambian form. Irregular febrile episodes are accompanied by headaches, malaise, exhaustion, anorexia, extreme thirst, muscle and joint pains, pruritus, anemia, rash, and often deep hyperesthesia. The lymph nodes are generally rubbery and mobile, and painful at the beginning. Palpation of the subclavicular region (Winterbottom sign) is an important part of the diagnostic procedure in the Gambian form. Any adenopathy accompanied by fever should evoke the diagnosis of sleeping sickness in patients from endemic areas. Later, pruritus generalizes. Edema of the face and extremities also develops.

Minor neurological and endocrine findings maybe early indicators of dissemination. Daytime somnolence or nighttime insomnia may develop and electroencephalographic (EEG) tracings may reveal abnormalities. Psychiatric signs, with irritability, changes in personality or mood affecting the daily and professional life of the patients may be an early manifestation of the disease. Endocrine involvement can be marked by a permanent feeling of coldness, lack of appetite, or in contrast hyperphagia, polydipsia and impotence, amenorrhea, or infertility.

Meningoencephalitic Stage

This stage appears over a period of months or years, depending on the trypanosome. The clinical signs remain reversible for a long time with treatment attesting to the predominance of potentially reversible inflammatory lesions over irreversible demyelinating lesions. The general signs of the hemolymphatic stage do not completely disappear: spikes of fever (but sometimes hypothermia), adenopathies and splenomegaly, cardiovascular manifestations, endocrine disturbances, and typical pruritus. The development of the neurological symptoms is progressive. As neurological signs occur, the only means to confirm CNS invasion is based on cerebrospinal fluid (CSF) examination: more than 5 cells/μL and/or the presence of trypanosomes. A range of symptoms may be encountered including daytime somnolence and hence the name, "sleeping sickness." Patient's typically also experience nocturnal insomnia and the patients may be described as being "sleepy by day and restless by night." The sleep–wake cycle disturbances are accompanied by other symptoms including headaches, sensory disturbances with diffuse superficial or deep sensations (muscle and bone hyperesthesia, either spontaneous or provoked; hyperpathia), presence of primitive reflexes (palm-mental reflex, sucking reflex), exaggerated deep tendon reflexes, psychiatric disorders (confusion, mood swings, agitation, aggressive behavior, euphoria, absent gaze, mutism, indifference), and tremor (fine and diffuse without any myoclonic jerk at rest or during movement). Pyram idal alterations revealed by a Babinski sign can also be observed along with alterations in muscle tone, numbness, or sensory deficit.

An abnormal number of monocytic cells are observed in the CSF. The early neurological symptoms correlate with the widespread meningeal inflammation, which occurs in both forms of HAT. The selective CNS locations explain in part the principal clinical neurological signs. Sleep–wake disturbances may result from invasion of the median eminence by parasites, which also accounts for neuroendocrine dysfunctions with the involvement of the suprachiasmatic nuclei. Disorders of the sleep–wake cycle are accompanied by a state of apathy in the patient, the loss of muscle tone especially in the neck muscles and a drooping of the eyelids. Extrapyramidal symptoms signal the involvement of the striatum. Deep sensory disturbances with hyperpathia may result from the involvement of the thalamus and the early invasion of posterior spinal roots. Apart from the disruptions of the circadian rhythm of the sleep–wake cycle, other biological rhythms are disturbed, such as body temperature, cortisol and prolactin, and growth hormone secretion. The invasion of the subthalamic and hypophyseal regions account for the persistence of endocrine disturbances such as impotence, amenorrhea or infertility, and the development of disturbed sensations of hunger and thirst, with often hyperphagia and polydipsia in contrast to the poor general state of malnutrition of the patients. At the terminal phase of the disease, CNS demyelination and atrophy are accompanied with disturbances in consciousness and the development of dementia with incoherence, incontinence, and seizures. The patient dies in a state of cachexia and physiological misery.

TREATMENT

Some of the currently available compounds for the treatment of trypanosomiasis include arsenicals, pentamidines, suramin, isometadium eflornithine, homidium bromide, and nifurtimox. In treating patients who

have progressed to the encephalitic stage, drugs must be used that have the ability to cross the blood–brain barrier and kill the *T. b. gambiense* and *T. b. rhodesiense* parasites that are present in the CSF. Melarsoprol was first introduced in 1949 for the treatment of late-stage trypanosomiasis and has remained the main drug of choice (Denise and Barret, 2001). The administration of melarsoprol to patients is complicated. In *T. b. rhodesiense* infection, it is usually given in three series of four intravenous injections with an interval of 10 days between each series (Denise and Barret, 2001). The treatment of late-stage African human trypanosomiasis with melarsoprol is accompanied by some adverse effects such as cutaneous reactions, polyneuropathy, headache, tremor, fever, abdominal pain, chest pain, skin rash, which affects about 19% of the patients (Barett, 2000). Treatment failures have been reported in late-stage sleeping sickness patients treated with melarsoprol (Burri and Keiser, 2001).

Pentamidine is an aromatic diamine 1,5-bis (4 amidi-) phenoxypentane. It is used for the chemotherapy of African trypanosomiasis, antimony-resistant Leishmaniasis, and *Pneumocytis carini pneumonia* (Sands et al., 1985). It is especially useful in the treatment of early-stage *T. b. gambiense* sleeping sickness. On account of hydrodynamic properties, the role of transporters is central in the mode of action of pentamidine in *Trypanosoma brucei.* Treatment failures and adverse effects such as nephrotoxicity and diabetes mellitus have been reported (Bitonti et al., 1986).

Suramin (Germin, Naganol, Morany Bayer 205) is a colorless polysulfonated symmetrical naphthalene derivative. It has six negative charges at physiological pH as such it cannot cross the blood–brain barrier (Hawking, 1940). Suramin is usually the drug of choice for early stages of African human trypanosomiasis especially *T. b. rhodesiense* infections.

Isometamidium chloride a conjugate of homidium and is used exclusively as a veterinary trypanocide. It is used for both prophylactic and therapeutic purposes. Isometamidium transport and resistance has largely been studied in *T. congolense*, which together with *T. brucei* and *T. vivax* is the main cause of trypanosomiasis in African livestock. Resistance to the drug is a severe problem in many parts of sub-Saharan Africa. Resistance by parasites with respect to reduced uptake has been reported (Sutherland et al., 1992).

INNATE IMMUNITY

African cattle trypanosomiasis, mainly due to *T. congolense* and *T. vivax*, causes anemia and weight loss, leading to death. Some African cattle breeds (N'Dama), however, are able to live and be productive in endemic areas and are considered to be trypanotolerant. Trypanotolerance is genetically controlled and is an innate character, but can be increased by repeated infections. Trypanotolerant cattle are not less susceptible to trypanosome infection but limit trypanosome proliferation and have lower parasite counts (*Bos taurus*, *B. indicus*). This resistance depends on the nutritional, physiological, and stress conditions of the animal. Studies have revealed that the ability to produce IL-4 plays a role in the susceptibility to *T. brucei* disease (Bakhiet et al., 1996). Recently, mouse strain susceptibility to trypanosome infection has been correlated with an increase in host arginase production (Duleu et al., 2004). Evidence of human trypanotolerance is suggested by case reports (Lapeyssonnie, 1960) and results from immunological screening (Lemesre et al., 1988; Authié et al., 1992). Subjects with a positive card agglutination trypanosomiasis test (CATT) have been reported to be asymptomatic despite having evidence of blood parasites. Moreover, although many Bantou people from Mbomo foci in the Congo were infected with *T. b. gambiense*, none of the pygmy population was infected. This effect, present before infection and unrelated to antibody production, is dependent on innate immunity factors. Moreover, in a recent study in the HAT focus of Sinfra (Côte d'Ivoire), single nucleotide polymorphisms within TNF-α and IL-10 promoters and genes were associated with susceptibility to HAT (Courtin et al., 2006).

Natural Immunity

Normal human sera injected into *T. b. brucei*–infected mice has been shown to reduce parasitemia. This phenomenon cannot be reproduced with the human trypanosome strains *T. b. gambiense* and *T. b. rhodesiense.* Trypanolytic factors (TLF) contained in normal human serum were identified as high-density lipoproteins. Recently, two TLFs have been characterized in human serum, the first one (TLF1) is inhibited by haptoglobin, while the second factor, TLF2, is not inhibited by haptoglobin (Raper et al., 1996). The main trypanolytic effect is thought to be due to TLF2. The trypanocidal effect of Cape buffalo serum has been attributed to xanthine oxidase (Muranjan et al., 1997). Recently a trypanosome lysosomal protein (SRA) was found to be associated with resistance to normal human serum. SRA is a truncated form of VSG and interacts with serum apolipoprotein L-I in the parasite lyzosome (Vanhamme and Pays, 2004).

Complement

Both in humans and animals, complement activation by two pathways occurs in HAT. The alternative pathway, independent of specific antibodies, was studied by the induction of trypanosome lysis (*T. congolense* and *T. b. brucei*) observed after the addition of fresh serum. Serum could induce trypanosome lysis only on uncoated VSG trypanosomes, as observed during the cycle of this parasite (procyclic forms). However, the appearance of VSG on parasites prevents trypanosome lysis by this alternative pathway (Ferrante and Allison, 1983). In another strain of *T. b. gambiense*, it was demonstrated that the alternative pathway was incompletely activated without generation of the terminal complex (C5–C9) able to induce membrane lysis (Devine et al., 1986). The classical pathway, mediated by specific antibodies against trypanosomes, has also described and may be involved in parasite clearance by antibody-mediated lysis and/or opsonization. The coated stages of *T. b. brucei* are lysed by antibodies with activation of complement by the classical pathway. Nevertheless, during these complement activations, the appearance of soluble fragments, including C3a and C5a anaphylatoxins and the C567 complex, could induce, on the one hand, the chemoattaction of neutrophils and monocytes and, on the other hand, the release of amines involved in vasoconstriction and an increase in vascular permeability participating in the initial inflammatory response in the chancre. Immune complexes can also activate complement. These immune complexes are constituted by antibodies specific to trypanosomes (e.g., anti-VSG antibody) leading to a rapid elimination of complement-fixing immune complexes (Russo et al., 1994) or by autoantibodies, such as rheumatoid factor or anti-nucleic acid antibodies. These immune complexes with complement activation are also involved in some adverse effects, especially in tissue damage mediated by immune complex deposits (Nielsen, 1985), such as thrombosis and glomerular involvement (Bruijn et al., 1988; van Velthuysen et al., 1994).

Natural Killer (NK) and T Cells

In *T. brucei*–infected mice, NK activity was not modified in the early stages of infection, but was severely reduced from day 9 onwards (Askonas and Bancroft, 1984). By contrast, NK cells were activated in mice infected with a natural extracellular trypanosome (*T. musculi*) and their critical role was demonstrated by the effects of their depletion by antiserum against asialo GM_1 or their activation by polycytidylic copolymer (Albright et al., 1997). Initial studies have evidenced alterations in T cell functions in trypanosomiasis, both in vivo and in vitro (Mansfield and Wallace, 1974). Histological examination show massive B cell expansion in the lymph nodes and spleen that replaced the thymus-dependent area in *T. b. brucei* TREU 667–infected mice. These changes persist from 7 days postinfection to at least 70 days. Trypanosome antigen-specific T cell response was difficult to identify. In several studies, a transient proliferative T cell response to trypanosome antigens was noted in the first days of the infection followed by loss of the response (Gasbarre et al., 1980). The kinetoplastid membrane protein 11 of African trypanosomes is a potent stimulator of T lymphocyte proliferation (Tolson et al., 1994). In *T. b. brucei*–infected mice, an increased proliferation of T cells was noted in the first days of infection in spleen and bone marrow, T blasts disappeared very rapidly. Th1 cells expressing a functional T cell response directed to VSG are generated in *T. b. rhodesiense*–infected mice. VSG-specific T cells were found predominantly in the peritoneum. These cells did not proliferate but made a substantial IFN-γ and IL-2 cytokine response (Schleifer et al., 1993). The cellular phenotype of VSG-responsive T cells ($CD4^+$ $CD3^+$) indicates that the VSG appear to preferentially stimulate a Th1 cell subset during infection. Analysis of lymphocyte subsets in regional lymph nodes of *T. congolense*–infected N'Dama (trypanotolerant) and Boran (trypanosusceptible) revealed a significant decrease in the percentage of $CD2^+$ and $CD4^+$ T associated with increase in the percentage of $CD8^+$ T cells, B cells, and $\gamma\delta$T cells. VSG and two invariant antigens (33 kDa cysteine protease and 66 kDa antigen homologous to immunoglobulin heavy chain binding protein hsp70/Bip) induced in vitro proliferation and synthesis of IL-2 and IFN-γ (Authié et al., 1992).

B Cells

In African trypanosomiasis, a dramatic increase in IgM is a main feature (Shoda et al., 2001). In *T. b. brucei*–infected mice, B lymphocytes display an aberrant activation phenotype (Sacco et al., 1994). Antibodies specific to trypanosomes are induced by several parasite antigens, including variant and invariant glycoprotein epitopes, as well as membrane, cytoplasmic, and nuclear antigens (Reinitz and Mansfield, 1990). Antibodies directed against trypanosome VSG components appear in sera and their binding to the surface coat of the trypanosomes induce a decrease in parasitemia, both in the blood and extravascular

spaces, specifically by immune lysis of parasites and their destruction by the Kupffer cells in the liver. Only heterologous antigenic variants (<0.1%) remain to repopulate the blood and tissues. Parasites are eliminated due to VSG-specific IgM (appearing at high levels, 3–4 days after infection). During infection, B cell nonspecific stimulation is enhanced as T-independent B cell responses to the VSG successive parasitemias. In contrast, specific trypanosome B cell response, depending on T cell regulation, is depressed. Several factors may contribute to this immunosuppression. Macrophages may become unable to present antigens to T cells (by defects in antigen processing and association of epitopes with MHC Class II) and produce immunosuppressive factors as nitric oxide (NO), prostaglandins (PG), and cytokines. An increase in immunosuppressive cytokines, such as IFN-γ and transforming growth factor (TGF)-β, is observed during infection. However, TGF-β is known to inhibit the production of IL-4, IL-5, and IL-6, the major cytokines implied in B cell proliferation and differentiation (Fargeas et al., 1992). Autoantibodies directed against components of CNS myelin have also been reported. They are specific for the major glycosphingolipids of myelin, the galactocerebrosides, and are detected in the sera of experimentally infected animals (Jauberteau et al., 1991) and patients from the Ivory Coast (Amevigbe et al., 1992). Other autoantibodies directed against not yet characterized proteins have been described in HAT patients (Asonganyi et al., 1989) as well as antibodies directed at myelin basic protein in experimentally infected animals (Hunter et al., 1992). Other antibodies were raised against an epitope containing L-tryptophan, a precursor to the neurotransmetter serotonin (Okomo-Assoumou et al., 1995b), or recognized some neuronal components of the cytoskeleton, neurofilament proteins. In some cases, these autoantibodies (antigalactocerebrosides and antineurofilaments) are associated with the neurological stage of the disease and their detection in sera and CSF could contribute toward defining the neurological involvement of HAT (Courtioux et al., 2005). In vivo demyelinization has been produced by purified antibodies to galactocerebroside (Saida et al., 1979).

Macrophages

Macrophages may play an important role in protection against trypanosomes, particularly in the presence of homologous antiserum. The immunological clearance of [75Se]-methionine-labeled *T. brucei* in mice was studied to investigate the respective roles of antibodies, macrophage activation, and complement in the removal of circulating parasites. The clearance was largely accomplished by antibody-mediated hepatic phagocytosis. C3 is necessary for the full opsonic activity present in murine clearance in passively immunized mice (MacAskill et al., 1980). These in vivo studies extend previous studies on the in vitro phagocytic function of macrophages in the presence of immune serum (Takayanagi et al., 1992). Macrophages from trypanosome-infected mice also synthesize reactive nitrogen intermediates (RNI). Trypanosomes are highly sensitive to the cytostatic/cytotoxic effects of these compounds (Vincendeau and Daulouède, 1991; Vincendeau et al., 1992). It has been shown that *T. b. gambiense* are highly sensitive to S-nitroso compounds, which are new effector molecules synthesized by activated human macrophages in vitro (Mnaimneh et al., 1997). Nitrosylated compounds could represent new effector molecules with a potent effect on targets distant from macrophages. In a recent study, DNA from *T. b. brucei* have increased macrophage production of IL-12, TNF-α, and NO (Shoda et al., 2001). Macrophages are also active in secreting PGs which modulate lymphocyte and macrophage functions. During a *T. b. brucei* infection, the ratio of PGE2/PGF1a is reversed, with an overproduction of PGE2. Macrophages are involved in immunosuppressive mechanism, and VSG also inhibits macrophage functions (Schleifer et al., 1993). Macrophages respond to, and synthesize, a large number of cytokines and the production of IL-1 is increased in *T. b. brucei*–infected mice, but this increase may be due to release rather than synthesis. Human monocytes can also be induced by trypanosomes and secreted factors from trypanosomes to express TNF-α RNA transcripts and secrete TNF-α in culture supernatants (Daulouède et al., 2001). Classical and alternative states of macrophage activation are observed in trypanosomiasis. Classical activation precedes alternative activation in murine trypanosomiasis. However, both activation states are expressed in these mice. By inducing alternative macrophage activation, trypanosomes induce host arginase which both decrease trypanocidal nitrosylated compound synthesis and increases L-ornithine production (Gobert et al., 2000). L-ornithine is the first step of polyamine synthesis, essential for parasite growth and trypanothione synthesis (Vincendeau et al., 2003).

Cytokines and Chemokines

A dysregulation of the cytokine network occurs in trypanosomiasis. The first evidence of overproduction of TNF-α/cachectin was reported in *T. b. brucei*–infected rabbits (Rouzer and Cerami, 1980). TNF-α is known to induce fever, asthenia, cachexia, and

hypertriglyceridemia. High levels of TNF-α are associated with potent inflammatory signs in the early phase of human trypanosomiasis and major neurologic signs in the late phase (Okomo-Assoumou et al., 1995). Initial control of parasitemia in *T. b. brucei*–infected mice was diminished by the injection of anti-TNF-α antibodies (Lucas et al., 1993). VSG can trigger TNF-α production by macrophages. Moreover, TNF-α production can be stimulated by IFN-γ and TGF-β and can be produced by CD8 T cells activated by TLTF released by *T. b. brucei* (Vaidya et al., 1997). Mice chronically infected with *T. b. brucei* develop inflammatory lesions of the CNS after treatment with subcurative doses of a trypanocidal agent (Hunter et al., 1991). Chemokines favor macrophage and lymphocyte recruitment to the CNS of *T. b. brucei*–infected animals. Such recruitment to selected areas of the CNS may be associated with sleep and endocrine disorders.

Nitric Oxide

NO induced by dysregulation of the cytokine network may lead to alteration of immune response and may also be involved in pathophysiological mechanisms. Nitrotyrosine, a marker of peroxynitrite formation, and iNOS are detected in the brains of *T. b. brucei*–infected mice. Nitrotyrosine-positive cells are associated with the development of neurological signs (Keita et al., 2000). In HAT, nitrite production is increased at first and detection of antibodies against nitrosylated antigens indicates the presence of NO-adducts (Semballa et al., 2004). However, in trypanosome-infected mice, a decrease in plasma L-arginine leads to a decreased NO production. By inducing arginase, trypanosomes bypass NO production and facilitate growth factor production. Arginase induction by parasites might be considered as a new strategy elaborated by parasites to escape host defense.

Immunoprotection

The resistance of mice to African trypanosomes can be nonspecifically increased by immunomodulators such as Calmette–Guérin bacilli and *Propionibacterium acnes* (Murray and Morrison, 1979; Black et al., 1989). These immunomodulators activate macrophages. *P. acnes*–treated macrophages inhibit *T. brucei* growth in vitro (Black et al., 1989). In a 10-year study, in Zaire, of adults previously diagnosed and treated for HAT, the risk of a second episode of HAT was greatly reduced compared to the risk of a first episode (Khonde et al., 1995).

VACCINE

Induction of protective immunity by vaccination is an important goal, but in the case of trypanosomiasis the vaccine will need to induce immunity to a large number of antigenic variants. An important feature of the trypanosome parasite is the dense glycoprotein coat covering the entire surface of the parasite. With 1000 different genes encoding antigenically distinct versions of the coat, the parasites have the capacity to engage in an immune escape through the process of antigenic variation. This has proven particularly problematic in the development of a vaccine against trypanosomiasis. However, previous studies have shown some promise in the use of other parasite surface proteins. Scott et al. (1978) reported protection in zebu cattle following double vaccination with 11 isolates of *T. congolense* given either as live or dead organisms and trypanocidal therapy when the cattle were challenged with nine of the original isolates. Neither the live or killed organism regimen prevented the animals from becoming parasitemic nor eventually succumbing to the infection, however, the mean survival times were greater in the live vaccine group compared to the killed vaccine and control groups. Whitelaw et al. (1979) reported that in mice immunized with louping-ill virus vaccine and challenged with *T. brucei* or *T. congolense*, the antibody response was completely suppressed, while in immunized Ethiopian cattle experimentally infected with *T. congolense* or *T. vivax* the antibody response to the vaccine was only 10% of that observed in uninfected animals. In contrast, the response of cattle infected with *T. brucei* was not significantly reduced, and this was attributed to their relatively light and transient parasitemias. Trypanocidal chemotherapy (diminazine aceturate) administered on the same day as vaccination largely restored the competence of the immune response of both mice and cattle infected with *T. congolense*.

Studies have shown that the immunization of animals and humans with trypanosome tubulin protein protects against trypanosomes. A vaccine consisting of a tubulin extract from *T. brucei* has been reported to protect animals and humans against heterologous strains of different species of *Trypanosoma*. Recent studies examining a vaccine containing the trypanosome microtubule-associated protein p15 (MAP p15) in mice found that p15 (native or recombinant) provided up to 100% protection from an otherwise lethal challenge of a heterologous strain of *T. brucei* (Rasooly and Balaban, 2004).

Vaccine Development

DNA vaccination is a relatively recent development. DNA vaccines are generally less costly to produce than peptide or protein vaccines, and are chemically stable under a variety of conditions. There has been some promising work with a related trypanosome family, *Leishmania*. Recently, we reported the protection of mice immunized with a DNA plasmid encoding parasite gamma-glutamylcysteine synthetase and experimentally challenged with *Leishmania donovani* (Carter et al., 2007). The DNA vaccine induced specific IgG1 and IgG2a antibodies and resulted in significantly lower liver parasite burdens compared to controls. Protection was also associated with a significant increase in cell-mediated immunity, demonstrated as an increase in nitrite production by ConA-stimulated splenocytes, an increase in the percentage of splenic $CD3^+$ $CD4^+$ cells, and enhanced granuloma maturation, compared to control values. It is hoped that similar DNA vaccine strategies can be developed for control of African trypanosomiasis. One strategy currently being explored is the development of a DNA vaccine encoding sialidase, an enzyme implicated in the etiology of anemia during trypanosomiasis (Esievo et al., 1990; Nok et al., 2003a; Nok and Balogun, 2003).

Based on the current state of the field it is clear that progress in developing an effective vaccine will likely require complex strategies that may include the use of trypanocidal drugs.

KEY ISSUES

- In Africa, trypanosomiasis occurs in 37 countries extending over 10 million square kilometers.
- An estimated 50 million cattle, about 30% of African total cattle population, are exposed to the risk of infection.
- Trypanosomiasis control is focused on the use of insecticide spraying to control vector tsetse population and on regular treatment with trypanocidal drugs.
- Toxicity of existing drugs, high rate of treatment failures, and the emergence of drug-resistant trypanosomes make the development of alternative control measures mandatory.
- Development of a vaccine by conventional methods has been unsuccessful due to antigenic variation by the parasite.
- The trypanosome parasite has at least 1000 different genes encoding antigenically distinct versions of the surface coat and has been a major obstacle toward the development of a vaccine.
- MAP p15 tested as a vaccine in mice generated 100% protection against lethal *T. brucei*.
- Current effort on the control is focused on the development of DNA vaccines.

OUTLINE

ABSTRACT

Leishmania parasites are transmitted by phlebotomine sand flies and can cause diverse clinical manifestations known as leishmaniasis. Drug resistance/toxicity and *Leishmania*/HIV coinfection call for a safe, effective vaccine. Recent research focuses on generating vaccines targeted on parasite- or sand fly-derived components. Defining the optimal combinations of antigens and adjuvants that elicit durable cellular immunity is critical for the control of leishmaniasis.

INTRODUCTION

Leishmaniasis contains a group of (mainly) zoonotic diseases transmitted to humans and animals by the bite of phlebotomine sand flies (Fig. 63.1A). Leishmaniasis is currently considered the third most important vector-borne parasitic disease after malaria and lymphatic filariasis. It was estimated recently that leishmaniasis was responsible for 1.8 million disability-adjusted life years and 59,000 deaths annually. Leishmaniasis is widespread in 22 countries in the New World and 66 nations in the Old World (but is not found in Southeast Asia). Human infections are found in 16 countries in Europe, including France, Italy, Greece, Malta, Spain, and Portugal (Fig. 63.2) (http://www.who.int/tdr/diseases/leish/default.htm).

Over the past 10–20 years, there has been a dramatic increase in the number of reported human leishmaniasis cases. This trend is partially due to improved diagnostic methods and reporting systems and due to changes in transmission epizoology, failure of vector and reservoir control campaigns, emergence of *Leishmania* as an opportunistic infection in HIV-infected people, increase in drug-resistant parasite strains, and the massive relocation of susceptible individuals to leishmaniasis-endemic areas because of war or economic pressures (Reithinger and Davies, 2002). For example, during August 2002–February 2004, the Department of Defense staff identified 522 parasitologically confirmed cases of cutaneous leishmaniasis (CL) in military personnel who were deployed to three countries (Afghanistan, Iraq, and Kuwait). Following isoenzyme electrophoresis of cultured parasites, *Leishmania major* was found to be the etiologic agent for all 176 cases for which species data were available (http://www.cdc.gov/ncidod/dpd/parasites/leishmania/default.htm).

Given the public importance of *Leishmania* infection, extensive studies aimed at understanding the cellular and molecular basis of protective immunity and disease pathogenesis have been conducted over the past several decades. Despite the wealth of information gained from murine models of leishmaniasis, and much effort by the scientific community to develop an anti-leishmanial vaccine, there is yet no efficient vaccine for any of the forms of leishmaniasis. Current control measures rely on chemotherapy and vector control and the control of reservoir host populations. The chemotherapeutic agents used presently are inadequate, expensive, and often associated with side effects. This chapter will emphasize recent advances in vaccine development for the control of leishmaniasis and the particular difficulties encountered in generating efficient vaccines.

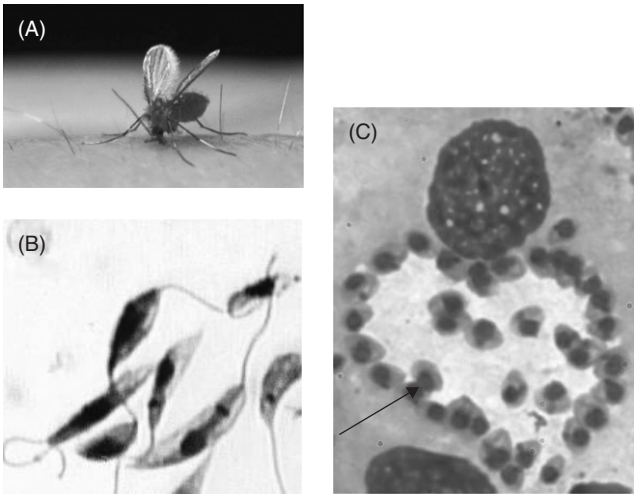

FIGURE 63.1 The vector and parasites that cause leishmaniasis. (A) Phlebotomine sand flies transmit *Leishmania* parasites to the vertebrate hosts, while they take blood meals. (B) The mobile, elongated promastigotes replicate extracellularly in the midgut of the sand fly. Metacyclic promastigotes are injected together with sand fly saliva to the skin, where they enter target cells and establish infection in macrophages and dendritic cells. (C) Nonmobile amastigotes replicate within the phagolysosomal compartment of an infected macrophage. The arrow indicates amastigotes within the parasitophorous vacuole.

BIOLOGY OF *LEISHMANIA* PARASITES

Leishmania parasites are named after W.B. Leishman, who identified and generated one of the earliest strains of the *Leishmania* parasite in 1901. The genus *Leishmania* is taxonomically classified as belonging to the order of Kinetoplastida and the family Trypanosomatidae because of the presence of the kinetoplast-mitochondrion and other trypanosomal features. *Leishmania* parasites have a dimorphic life cycle characterized by a free-living promastigote form and an intracellular amastigote form. Metacyclic promastigotes (Fig. 63.1B) replicate extracellularly in the sand fly midgut and are transmitted to the mammalian host by the bite of infected female sand flies. Once inside the host, the promastigotes are phagocytosed by macrophages or dendritic cells (DCs), where they differentiate into nonmotile amastigotes and replicate within the amino acid-rich phagolysosomal compartment (Fig. 63.1C) (McConville et al., 2007). The promastigote form can be maintained in vitro in cell-free cultures (at 23°C, pH 7.0), whereas the amastigote form can be isolated from mouse lesions or infected macrophages or, for some species, maintained in vitro by the differentiation of promastigotes using defined pH and temperature conditions (32°C, pH 5.0). The doubling time

for *Leishmania* parasites in culture media is around 16 h. Given the technical difficulty in generating large quantities of amastigotes, the vast majority of immunological, biochemical, and vaccine studies have been conducted using the promastigote forms.

The genome of Old World *Leishmania* (*L. major* and *Leishmania donovani* groups) is spread over 36 chromosome pairs (0.28–2.8 Mb in size), yielding a total genome size of about 34 Mb. The genome sequence projects for *L. major* Friendlin (http://www.genedb.org/genedb/leish) and *Leishmania infantum* (http://www.genedb.org/genedb/linfantum) were completed in 2005, revealing 8272 protein-coding genes, only 36% of which can be ascribed a putative function (Ivens et al., 2005). Therefore, the function of the majority of the open-reading frames is still under investigation. In comparison, New World *Leishmania* species have only 34 or 35 chromosome pairs, with chromosomes 8 + 29 and 20 + 36 fused in the *Leishmania mexicana* group and 20 + 34 in the *Leishmania braziliensis* group, respectively (Stiles et al., 1999). Gene order and sequence are highly conserved among the ~30 *Leishmania* species. Little is known about the mechanism of transcription initiation and functional promoters in *Leishmania* and other related trypanosomatids (*Trypanosoma cruzi* and *Trypanosoma brucei*). Trypanosomatid mRNA processing is distinctive: Almost all mature mRNAs have a trans-spliced leader RNA added to their 5′-ends, and all protein-coding genes are transcribed polycistronically by RNA polymerase II in a divergent or convergent manner on DNA strands of the different chromosomes (Myler et al., 2000).

Developmental regulation of gene expression in *Leishmania* is mediated almost exclusively at the posttranscriptional level and often involves the 3′-untranslated region of the RNA, which determines RNA stability and translational efficiency (Rochette et al., 2005). In addition, infectivity of the parasites is also dependent on extensive posttranslational modifications (Ilgoutz and McConville, 2001). Often mRNA abundance does not reflect protein levels in *Leishmania*, and methodologies to globally analyze gene expression at the protein level are especially useful for this organism. Recently, global analyses

FIGURE 63.2 Map of geographic distribution of leishmaniasis. Major forms of leishmaniasis are endemic in 88 countries on four continents. According to the World Health Organization reports, more than 90% of cutaneous leishmaniasis cases occur in Iran, Afghanistan, Syria, Saudi Arabia, Brazil, and Peru, while more than 90% of visceral leishmaniasis cases occur in Bangladesh, Brazil, India, and Sudan.

of *Leishmania* gene expression indicate that the vast majority (>95%) of genes are constitutively expressed in all life stages, and among differentially expressed genes between amastigotes and promastigotes, most are species specific (Cohen-Freue et al., 2007). For example, among two dozen amastigote-specific genes identified each in *L. major* and *L. mexicana*, none are present in both species (Cohen-Freue et al., 2007). This limited amastigote-specific gene expression obviously posts additional challenges to identify the contribution of parasite molecules to diverse host immune responses, following infection with various *Leishmania* species. Although molecular technologies such as targeted gene disruption (see the vaccine section below) and RNA interference (Robinson and Beverley, 2003) have been successfully applied in the study of *Leishmania* biology and host–parasite interactions, they have not been widely used as in the study of bacteria and viruses. Because of its importance, *Leishmania* has been heavily studied and continues to be investigated in numerous areas, such as cell differentiation, host–parasite interactions, and new drugs and vaccine targets.

CLINICAL MAGNIFICATIONS AND EPIDEMIOLOGY

About 30 *Leishmania* species have been identified, and of these, approximately 20 species and subspecies can infect humans (Banuls et al., 2007). The diverse clinical magnifications are determined by the species of the parasite involved, as well as the host immune and nutrition status. Human leishmaniasis ranges from simple, self-healing skin ulcers to severe, life-threatening disease and can be classified into four main forms (http://www.who.int/tdr/diseases/leish/default.htm):

1. Visceral leishmaniasis (VL) is the most serious form and is fatal if left untreated. This form is mainly due to *L. donovani* infection in the Old World, and *L. infantum/Leishmania chagasi* infection in European countries and South America. More than 90% of VL cases occur in five countries—India (especially near the Ganges and in the Brahmaputra plains), Bangladesh, Nepal, Sudan, and northeastern Brazil. In most areas, children under 10 years of age account for 80% of the cases. In India, VL is often referred as kala-azar because it is associated with a characteristic darkening of the skin. VL is characterized by fever, splenomegaly, hepatomegaly, hypergammaglobulinemia, and pancytopenia, with a high mortality (up to 36%), especially in late-stage cases and individuals with severe malnutrition (Guerin et al., 2002). During the active stage of VL, patients display an antigen-specific suppression of cellular immune responses and nonresponsiveness to leishmanin and other antigen-stimulated skin tests.
2. CL is the most common form among the four clinical forms. While skin lesions in most individuals can heal spontaneously within a few months, they leave unsightly scars. More than 90% of CL cases occur in seven countries—Afghanistan, Iran, Syria, Algeria, Saudi Arabia, Brazil, and Peru. Parasites in the *Leishmania tropica* complex, including *L. major* and *Leishmania aethiopica*, are responsible for CL in the Old World, and lesions are mostly limited to the skin. Two *Leishmania* subgenera (*L. Leishmania mexicana* and *L. Viannia braziliensis*), with up to 11 species of parasites, are responsible for American (or New World) CL (Reithinger et al., 2007). While a majority of American CL patients can mount adequate cell-mediated immunity to parasites and heal the primary lesion(s) spontaneously, some progress into other forms of the disease.
3. Mucocutaneous leishmaniasis (MCL) is the hyperergic form, mainly due to infection by parasites in the *L. braziliensis* complex. It begins with skin ulcers that spread, causing dreadful and massive tissue destruction, especially of the nose and mouth. About 5% of CL cases will eventually develop into MCL, and most of these are found in Brazil (Silveira et al., 2004) and Andean countries (Bolivia, Peru, Colombia, Ecuador, and Venezuela) (Davies et al., 2000). The time of conversion from CL to MCL varies greatly, ranging from a few months to more than 20 years. The mucosal lesions usually contain scanty parasites, but massive cellular infiltrates, suggesting an excessive, uncontrolled response to the involving parasites. The cellular and molecular basis underlying this conversion remains largely unknown (Reithinger et al., 2007).
4. Diffuse cutaneous leishmaniasis (DCL) is the anergic form and is mainly associated with *L. mexicana* and *Leishmania amazonensis* infection in the Amazon basin. This rare form of the disease is characterized by multiple, non-ulcerative nodular skin lesions that resemble those of lepromatous leprosy. The lesions are filled with heavily parasitized macrophages. These patients have a profound impairment of parasite-specific responses and are often refractory to currently available treatment (Reithinger et al., 2007; Silveira et al., 2004).

Leishmania parasites have been recognized as an opportunistic pathogen in immunosuppressed individuals, including those infected with HIV-1. Leishmaniasis and AIDS overlap in several subtropical and tropical regions around the world, including the Mediterranean region, Europe, Brazil, India, and Africa (Desjeux and Alvar, 2003; Reithinger et al., 2007). Since *Leishmania* and HIV-1 can infect cells of myeloid or lymphoid origin (e.g., macrophages and DCs), probably through the binding of the same host receptor on the cell surface (e.g., DC-SIGN) (Garg et al., 2007), this coinfection is of special concern: (1) It changes the epidemiology of leishmaniasis (especially VL) because of an increased risk of human-to-human transmission of parasites, probably due to needle sharing (Molina et al., 2003); (2) it reduces accuracy of immune-based diagnosis because of a compounding immunosuppression associated with each infection (Deniau et al., 2003); (3) it reduces the efficiency of therapeutic treatment for leishmaniasis (Laguna, 2003) and poses a new challenge for those seeking to develop live, parasite-based vaccines.

A presumptive diagnosis of leishmaniasis can be made based on clinical signs, epidemiologic data, and laboratory tests; however, a definitive diagnosis requires demonstration of the parasite. Serological diagnosis for VL can be accomplished using a direct agglutination test, ELISA, or immunofluorescence. Testing with a commercially available immunochromatographic strip that uses recombinant leishmanial antigen K39 has proven highly specific and sensitive (98–100%) (Singh and Sivakumar, 2003). The leishmanin skin (Montenegro) test, which measures the cutaneous cellular responses to *Leishmania*-derived antigens, is still frequently used for clinical diagnosis and in epidemiological surveys on the prevalence of leishmanial infection. However, these tests fail to distinguish between current and past leishmanial infections. The detection of parasites by examination of smears from bone marrow, lymph nodes, or splenic aspirate, or detection of parasite kinetoplast DNA in biopsy materials, remains an essential part of any definitive diagnosis (Reithinger et al., 2007). In chronic cases of CL and MCL, a definitive diagnosis is sometimes difficult because of the paucity of parasites in lesions.

TREATMENT AND PREVENTION

Most cases of CL heal without treatment, leaving the person immune to further infection. Other forms of leishmaniasis are extremely difficult to treat, often requiring a long course (20- to 28-day regimen) of intravenous (i.v.) pentavalent antimony drugs, such as meglumine antimonate (e.g., Glucantime) or sodium stibogluconate (e.g., Pentostam) (Vanlerberghe et al., 2007). Recently, resistance to these drugs has been reported, requiring the use of more toxic drugs, such as amphotericin B. Most available drugs are costly, require long treatment regimens, and are becoming more and more ineffective, necessitating the discovery of new drugs. Several new drugs, including Miltefosine and Sitamaquine (both of which can be given orally), are in the pipeline; however, their efficacy needs to be evaluated further (Olliaro et al., 2005; Vanlerberghe et al., 2007). Leishmaniasis, as a complex of diseases, is as yet impossible to control with a single approach or tool, although a vaccine has potential to be a cost-effective exception. In cases in which the reservoir is infected humans, control depends on early case detection and drug treatment. Vector and reservoir host control measures are expensive, requiring good infrastructure and maintenance—often giving results that are short lived. Vector control, based on spraying with residual insecticides, can be effective where transmission occurs in and around the home. In areas known to be the site of transmission, individuals should use some form of protection, such as insect repellent or insecticide.

REGULATION OF HOST PROTECTIVE IMMUNITY AND PATHOGENESIS

Although the clinical manifestations of leishmaniasis are determined by the species of *Leishmania* causing the infection and the host immune responses, the results of most studies indicate that the outcome of *Leishmania* infection seems dependent on regulation of the balance between the parasite and reactive T cell populations. The murine models of *L. major* infection have been extremely helpful for understanding the genetic mechanisms of protection conferred by T cells (von Stebut, 2007). Most inbred mouse strains (e.g., C57BL/6, C3H, CBA/J, and B10D2) are genetically resistant to *L. major* infection, mainly due to the production of high levels of IL-12, IFN-γ, TNF-α, IL-1, and Th1-promoting chemokines (e.g., IP-10/CXCL-10) at early stages of the infection. In vitro studies have confirmed that these cytokines promote macrophage effector activities by stimulating the expression of inducible nitric oxide (NO) synthase (iNOS) and the production NO and, consequently, the killing of intracellular parasites (Fig. 63.3). Suppression/alteration of these Th1 responses by the targeted depletion of cytokine genes or their corresponding receptors,

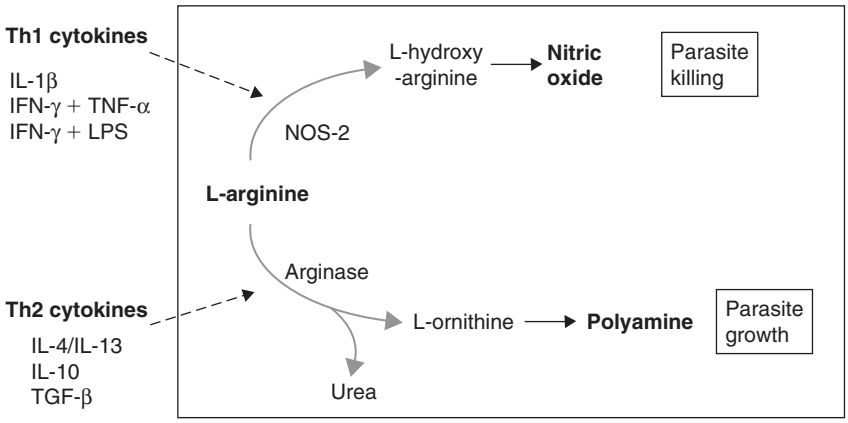

FIGURE 63.3 The arginine metabolism pathways in macrophage determine the fate of intracellular *Leishmania* parasites. Th1 cytokines preferentially stimulate the inducible nitric oxide synthase (iNOS), and the resulting nitric oxide (NO) mediates the killing of intracellular amastigotes. Th2 cytokines preferentially activate arginase, and the resulting polyamines are essential components for replication of amastigotes because parasites are incapable of making their own polyamines.

administration of neutralizing antibodies to block the action of these cytokines, or adoptive transfer of $CD4^+CD25^+$ regulatory T cells (Treg, derived from infected skin tissues or spleen of naive mice) can render these otherwise resistant mice susceptible to the infection (Belkaid et al., 2002).

In contrast, BALB/c mice are highly susceptible to *L. major* infection, developing extensive skin lesions and metastasized infections in the liver, spleen, and bone marrow, mainly due to the uncontrolled production of IL-4, IL-10, and TGF-β. At the cellular level, these Th2-type cytokines suppress macrophage activation by stimulating the arginase-expression-polyamine-production pathway and, consequently, the growth of intracellular parasites (Fig. 63.3). Suppression/alteration of these Th2 responses by targeted gene depletion, injection of neutralizing antibodies to block the action of these cytokines, or adoptive transfer of Treg cells can render these otherwise susceptible mice resistant to infection (Belkaid et al., 2002; Ji et al., 2005). Thus, a fine regulation/balance among Th1/Th2 effector T cells and Treg cells at the local site determines the outcome of the infection.

However, this Th1/Th2 paradigm learned from murine *L. major* infection cannot fully explain healing/nonhealing infection models associated with other *Leishmania* species (Alexander and Bryson, 2005; McMahon-Pratt and Alexander, 2004). First, mice infected with parasite species responsible for different forms of CL in South America (e.g., *L. amazonensis*, *L. mexicana*, *L. braziliensis*), or species responsible for VL (e.g., *L. donovani*, *L. chagasi*), do not show a clear Th1 or Th2 dominancy. Likewise, leishmaniasis patients usually mount a Th1/Th2-mixed response. Second, a given cytokine can display diverse functions, depending on the time and magnitude of its production, as well as the presence of other cytokines/chemokines in the microenvironment. For example, while Th2 responses can be induced in the absence of IL-4, under certain circumstances, IL-4 can prime for IL-12 production and a type-1 response. On the other hand, while IFN-γ and TNF-α synergistically activate macrophage's leishmanicidal activity, IFN-γ alone can actually enhance the growth of parasites within macrophages (Qi et al., 2004) by promoting the arginase pathway with no activation of the iNOS pathway (Wanasen et al., 2007).

Regardless of the mechanism underlying the pathogenesis associated with different models of *Leishmania* infection, what we have learned from animal studies is critical for designing an efficient vaccine for the control of leishmaniasis. First, since Th1 responses favor resistance to leishmaniasis, antigens that preferentially stimulate Th1 cells may not necessarily be good vaccine candidates. Second, immunization with antigens that preferentially stimulate Th2 cells would counterbalance Th2 responses and provide protection in mice (see LACK antigen below) (Campos-Neto, 2005). Recently, Zaph et al. have demonstrated distinct requirements for generating and maintaining different subpopulations of $CD4^+$ memory T cells after infection with *L. major* in mice: short-lived, pathogen-dependent effector cells and long-lived, pathogen-independent central memory cells. Therefore, central memory T cells should be the targets for non-live vaccines against infectious diseases requiring cell-mediated immunity (Scott et al., 2004; Zaph et al., 2004).

VACCINE DEVELOPMENT FOR THE CONTROL OF CL AND VL: TARGETING PARASITE-SPECIFIC COMPONENTS

In endemic areas, a significant number of individuals acquire subclinical infections associated with the development of parasite-specific T cell responses and resistance to leishmaniasis. The acquisition of protective immunity after resolved CL suggests that vaccination, if it induces an appropriate cellular immune response, is a feasible approach toward the control of leishmaniasis. Vaccination against leishmaniasis has passed through many developmental stages, beginning with the ancient practice of "leishmanization" (use of live parasites) as far back as in 1911, during the Iran–Iraq war. However, this practice has been largely discontinued due to the inherent danger of developing disease in a more exaggerated form following immunization with live parasites. Rather, the first-generation vaccines include killed or attenuated parasites whose virulence has been reduced by long-term culture, γ-irradiation, chemical mutagenesis, or gene inactivation/replacement. While injection with a small dose of attenuated organisms is sometimes more efficient in stimulating a protective Th1 response than in natural infection, the spread of HIV infections and use of immunosuppressive drugs in organ transplantation or cancer chemotherapy pose some concerns for the potential of sudden outburst of otherwise latent *Leishmania* infection in these immune-compromised individuals.

During the past few years, significant efforts have been directed toward developing second-generation vaccines that are composed of defined antigenic components and designed to induce potent cellular immunity against *Leishmania* infections (Coler and Reed, 2005; Kubar and Fragaki, 2005; Sukumaran and Madhubala, 2004). Since there are no suitable murine models for the study of MCL caused by *L. braziliensis* infection, or DCL caused by *L. amazonensis* infection, the majority of vaccine studies have been centered on CL caused by *L. major* infection or VL caused by *L. donovani* infection.

Vaccine Studies for CL in Mouse Models

Several approaches have recently been taken to identify vaccine candidates for the control of CL. The first one focused on live virulent *L. major* with a targeted deletion of the dihydrofolate-thymidylate synthase gene locus (*DHFR-TS*). Since these knockout parasites can invade target cells but are deficient for replication within infected macrophages, they are much safer than live parasite vaccines that are generated via long-term in vitro cultivation or chemical mutagenesis (Titus et al., 1995). Targeted gene deletion has been used to generate other mutant lines. The surface of the promastigotes is coated with a variety of interrelated glycoconjugates, including lipophosphoglycan (LPG) and glycosylphosphatidylinositol (GPI)-anchored proteins, such as gp63 and gp46 (Naderer et al., 2004). In the sand fly, stage-specific modifications of LPG are responsible for parasite attachment to, and release from, the sand fly midgut. In the mammalian host, LPG is considered a virulence factor, enhancing the parasite's resistance to complement-mediated lysis and oxidative stress but suppressing the macrophage's effector and antigen-presentation functions (Olivier et al., 2005). The Beverley and Turco groups have generated an *L. major* *lpg1*$^-$ mutant by deleting a gene involved in the biosynthesis of the LPG core glycan and found that this attenuated parasite still induced disease in mice (Spath et al., 2000). However, *L. major* *lpg2*$^-$ mutants, which are deficient in assembly of disaccharide–phosphate repeats of LPG and other phosphoglycan-containing molecules (Spath et al., 2003), are highly attenuated parasites. These *lpg2*$^-$ mutants persist in mice without causing any overt cutaneous lesions and provide protection in susceptible BALB/c mice against challenge with wild-type *L. major* (Uzonna et al., 2004). While deleting the genes involved in the synthesis of LPG results in attenuated *L. major* parasites, similar manipulation does not yield attenuated *L. mexicana* strains (Turco et al., 2001). Mice infected with parasites in the *L. mexicana* group do not show classical Th1/Th2 polarization, as seen in *L. major* infection (Ji et al., 2003), and evidence from biochemical and in vivo studies collectively indicates discernible differences in the biology of the parasites and their associated disease pathogenesis (Xin et al., 2007) and the need for additional vaccine studies for New World CL.

When live parasites are used as candidate vaccines for control of *L. major* infection, the route of vaccination can greatly influence the type, strength, and duration of the memory responses. In the C57BL/6 mouse model (which more closely resembles immune responses seen in *L. major*-infected humans than the BALB/c model), subcutaneous (s.c.) immunization with live parasites in the footpad provides superior protection to that seen with intradermal (i.d.) immunization in the ear (Tabbara et al., 2005). The high level of protection achieved by footpad vaccination was correlated with efficient expansion and recruitment of IFN-γ-producing CD4$^+$ T cells, but delayed recruitment of IL-10-producing Treg cells, to the infection site. This study indicates that a delicate balance

between effector T cells and Treg cells at the site of injection can influence the efficacy of a live leishmanial vaccine.

Based on the Th1/Th2 paradigm defined in murine models of *L. major* infection, leishmanial antigens that preferentially activate type-1 responses (Th1 cells and $CD8^+$ cytotoxic T lymphocytes) are referred to as "protective antigens" and actively investigated as vaccine candidates, whereas antigens that fail to stimulate Th1 cells and/or preferentially activate Th2 responses are not considered favorably as vaccine candidates. The antigens investigated include subcellular (soluble or membrane-enriched) fractions, purified antigens, poly-subunits, mosaic subunits, as well as cDNA expression libraries that express leishmanial proteins. These antigens (or DNA) are usually co-injected with a Th1-promoting adjuvant (rIL-12 or BCG) or constructed into viral vectors (e.g., vaccinia viruses or adenovirus) for prolonged antigen release (Gabaglia et al., 2004).

Among the 15–20 defined *Leishmania* vaccine candidates that have been investigated in detail (Coler and Reed, 2005; Kubar and Fragaki, 2005; Sukumaran and Madhubala, 2004), the 36-kDa LACK antigen (*Leishmania* analogue of the receptors of activated C kinase) has attracted the greatest attention, due to its high conservation among *Leishmania* species and presence in both developmental stages of the parasites. The LACK antigen was initially identified via the use of a T cell expression cloning strategy (Mougneau et al., 1995). The rapid production of IL-4 by LACK-reactive $V\beta4V\alpha8$ $CD4^+$ T cells is known to be responsible for Th2 development and susceptibility of BALB/c mice to *L. major* infection (Launois et al., 1997). Mice made tolerant to LACK by transgenic expression of the antigen in the thymus exhibit both a diminished Th2 response and a healing phenotype (Julia et al., 1996). Vaccines composed of the LACK antigen mixed with an adjuvant or DNA encoding LACK antigen provided satisfactory protection in mice against *L. major* infection; however, these types of vaccines fail to show protection in New World CL caused by *L. mexicana* infection or VL caused by *L. donovani* infection (Dumonteil et al., 2003; Melby et al., 2001). Interestingly, mice intradermally primed with DNA encoding the LACK antigen and then intraperitoneally boosted with vaccinia viruses expressing the LACK antigen developed protective immunity against *L. infantum* infection (Dondji et al., 2005). Therefore, the heterologous prime-boost vaccination strategy, which involves the sequential administration of vaccines that contain different antigens, appears to be a promising approach toward the development and maintenance of a strong cellular immune response for the control of leishmaniasis. To date, there have been relatively limited vaccine studies conducted for New World CL caused by *L. amazonensis* (Armijos et al., 2004; Hernandez et al., 2004) and *L. mexicana* (Dumonteil et al., 2003; Rosado-Vallado et al., 2005).

Vaccine Studies for VL in Mouse and Hamster Models

In nature, VL in humans and animals is initiated via a parasite infection in the skin, and yet there is limited success in establishing VL following s.c./i.d. injection of BALB/c mice with *L. donovani* or *L. infantum/L. chagasi*, either alone or mixed with sand fly salivary gland extracts (Ahmed et al., 2003). Therefore, most murine VL studies are initiated by intravenous (i.v.) injection of several millions of parasites; however, such BALB/c mice develop foci of splenic and hepatic lesions, which self-heal several months later. In comparison, the Syrian golden hamster (*Mesocricetus auratus*) is considered a better small animal model that resembles some clinical features of VL (Melby et al., 2001); however, dogs are superior to rodents for vaccine studies.

In comparison to CL, much less is known regarding experimental vaccines for VL. It has been shown that s.c. inoculation of high doses (10^7) of live virulent *L. chagasi* causes a subclinical infection that protects against a subsequent i.v. challenge with *L. chagasi*; however, a similar immunization with attenuated *L. chagasi*, *L. donovani*, or *L. major* parasites that are deficient in the *DHFR-TS* gene fails to provide protection (Streit et al., 2001), suggesting the requirement for a subclinical infection for eliciting protective immunity. It has been found that i.v. immunization with 5×10^7 *L. donovani* deficient in the gene for biopterin transport (*BT1*) provides partial protection against i.v. challenge with virulent parasites (Papadopoulou et al., 2002), and it appears that, besides the dose and route of immunization, the in vivo replication of parasites is an essential factor to be considered for a VL vaccine. Given that alum-precipitated, autoclaved *L. donovani* mixed with *Macrobacterium bovis* Bacille Calmette–Guerin (BCG), but not *L. donovani*-derived LPG mixed with BCG, provides protective immunity in mice and hamsters against VL (Srivastava et al., 2003; Tonui et al., 2003), it appears that complex antigenic preparations (and antigenic epitopes) are required for adequate activation of multiple defense mechanisms for the control of VL.

In the search for novel, second-generation vaccine candidates for VL, two approaches have been taken: a systematic search via immunization of mice with fractions of an *L. donovani* cDNA expression library (Melby

et al., 2000) and a targeted search via a screening of the expression library with $CD4^+$ T cell lines generated from human subjects (Arora et al., 2005). Among several identified vaccine candidates, the fucose–mannose ligand (FML) antigen complex of *L. donovani* holds high promise. When the FML protein was tested in combination with different adjuvants, the FML mixed with Quil A or QS21 saponin provided better protection in terms of reducing parasite load in the liver and stimulating delayed-type hypersensitivity (DTH) and IgG2a responses than did the FML mixed with BCG or IL-12 (Santos et al., 2002). The main component in the FML complex is a 36-kDa nucleoside hydrolase (NH36). When BALB/c mice were intramuscularly (i.m.) immunized with different regimens (purified FML or recombinant NH36 mixed with saponin as an adjuvant, or with NH36 expressed in the VR1012 DNA vaccine vector), the best protection was observed in mice immunized with the NH36 DNA (Aguilar-Be et al., 2005). This study indicates a higher efficacy of DNA-based vaccines over that of protein-based ones. In addition, a DNA-based vaccine study involving the kinetoplastid membrane protein-11 (KMP-11), a highly conserved surface membrane protein present in all members of the family Kinetoplastidae, gave complete protection against challenge with both pentavalent antimonial-sensitive and -resistant strains of *L. donovani* in the highly susceptible hamster model (Basu et al., 2005).

Dendritic cells (DC)-based Vaccine Studies in Mice

Examination of the utility of DC vaccination as cellular immunotherapy for cancers has yielded some encouraging results and prompted similar studies in animal models of leishmaniasis. Although DC-based vaccination may lack a conspicuous application in the context of such infections predominately in developing countries, it serves as a valuable tool to define DC-targeted control methods. Using *L. major* infection as a model, Moll and colleagues have provided solid evidence that a single i.v. injection of ex vivo antigen-pulsed Langerhans cells (LCs) (Berberich et al., 2003), myeloid DCs (mDCs) (Ramirez-Pineda et al., 2004), or plasmacytoid DCs (pDCs) (Remer et al., 2007) (5×10^4–5×10^5 cells per mouse) is sufficient to induce protective immunity against a single or repeated parasite challenges in susceptible BALB/c mice. Interestingly, antigen-pulsed LCs and pDCs can mediate protection independent of additional DC stimuli (CpG, TNF-α, LPS, or CD40 ligation); however, an overnight exposure to CpG motifs is required for antigen-loaded mDCs to induce specific Th1 responses (Ramirez-Pineda et al., 2004), a phenomenon also observed for mDCs pulsed with the *L. infantum* antigen (Carrion et al., 2007). In addition, while a polarized Th1 cytokine profile is linked to protection in LC- and CpG/mDC-immunized mice, no strong correlation (or specific roles for IL-12 and IFN-α) is observed for pDC-immunized mice (Remer et al., 2007). These findings reemphasize the functional diversity of DC subsets in the control of *L. major* infection and the importance of mounting adequate local immune responses for the control of the infection (Fajardo-Moser et al., 2008). However, direct lesional injection of *L. amazonensis* antigen-pulsed mDCs (10^6 cells per mouse), together with recombinant IL-12, failed to promote healing in mice chronically infected with *L. amazonensis* (Vanloubbeeck et al., 2004). Therefore, simply providing in vitro-activated DCs or primed Th1 cells is not sufficient to ensure healing in *L. amazonensis*-infected hosts, and additional treatments aimed at reducing intracellular parasite loads and/or blocking parasite's enzymatic activities are needed in order to overcome the parasites in their persistent state. Given the unique features for DC–amastigote interaction, DC-based vaccination studies should be extended to hosts with established infection. Targeted delivery of leishmanial antigens to endogenous DCs (Zubairi et al., 2004) and the use of genetically engineered parasites that express the DC activator (Field et al., 2007) are other attractive approaches.

Vaccine Studies for Canine VL

Foxes, wild canines and dogs, and domestic dogs are important reservoirs for maintaining the population of *Leishmania* parasites that can lead to VL in humans and considered major targets in vaccine control of VL (Lemesre et al., 2007; Reithinger and Davies, 2002). Serological studies have estimated that 2.5 million dogs (16.7%, from 15 million dogs tested) in European countries are infected with *Leishmania* parasites, and higher (33–36%) seroprevalences have been reported in South American countries. Dogs 8 years old and above usually show the highest seroprevalence (up to 40–50%). In 2002, it was reported that the *Leishmania* parasite has infected more than 1000 hunting dogs in 21 U.S. states and the Canadian Province of Ontario (Enserink, 2000); however, the basis for this infection is unknown. Given that only a quarter of the seropositive domestic dogs develop clinical signs, eliminating infected dogs may not be an accepted option for dog owners. Thus, developing vaccines for canine leishmaniasis is a viable alternative for reducing the number of parasites in infected dogs and, subsequently, transmission of the parasites.

To this end, a few phase I/II vaccine trials have been performed in dogs, with killed *Leishmania* promastigotes, purified leishmanial fractions, or recombinant DNA (Giunchetti et al., 2007; Kullberg et al., 2002). For example, an FML-enriched fraction of *L. donovani* was used in a phase III vaccine trial against symptomatic canine VL, with a nearly 80% clinical efficacy. The experimental vaccine conferred about 90% protection from disease progression when used for the immunotherapy of asymptomatic dogs (Borja-Cabrera et al., 2002, 2004). At present, Leishmune® vaccine, which is composed of the FML antigen isolated from the aqueous extract of stationary-phase promastigotes of *L. donovani* (the Sudan strain), is the first licensed vaccine against canine VL and scaled up for commercialization in Brazil (Patent/INPI number: PI1100173-9) (Nogueira et al., 2005). The potential of Leishmune in the interruption of the *natural transmission* of the disease was assessed in vaccinated ($n = 32$) and control ($n = 40$) dogs in a Brazilian epidemic area. The animals were injected on the flank with three s.c. doses of Leishmune with a 21-day interval between injections. Eleven months after vaccination, the vaccinated dogs showed a 100% seropositivity to the FML and a complete absence of clinical signs and parasites in skin, lymph node, and blood for leishmanial DNA, indicating the Leishmune-vaccinated dogs were noninfectious (Nogueira et al., 2005). In the Meshkin-Shahr district, Iran, a double-blind randomized efficacy field trial was conducted with aluminum hydroxide (alum)-precipitated *L. major* (alum-ALM) vaccine plus BCG against canine VL. The vaccine group ($n = 182$) and control dogs ($n = 165$) were injected intradermally with a single dose of vaccine (200 kg of protein in 0.1 ml) or saline mixed with BCG. During a 16-month follow-up period, the incidence of *Leishmania* infection was 3.7% and 12% in the vaccinated and control groups, respectively, and the efficacy of the vaccine was 69.3% (Mohebali et al., 2004).

In contrast, a phase III field trial of a tandemly linked, multi-subunit recombinant leishmanial polyprotein (also known as Leish-111f) formulated in monophosphoryl lipid A (MPL®) adjuvant was conducted in a VL endemic area of southern Italy. After three monthly injections before the transmission season, immunized dogs showed no protection against *L. infantum* infection and disease progression, suggesting a limited utility of this vaccine to prevent *Leishmania* infection in dogs under field conditions (Gradoni et al., 2005). While variations in vaccine efficacy observed in different field trials emphasize the need to optimize the vaccine formula for different endemic regions, the development of such vaccines to reduce parasite loads in domestic dogs is highly advantageous. Other control strategies, including insecticide-impregnated dog collars and immunizing dogs with a sand fly saliva-based vaccine, would also be useful in reducing the canine and human disease incidence.

Vaccine Trials in Human Volunteers

An ideal vaccine for human leishmaniasis should be safe, free of animal products, require a minimal number of immunizations, and provide long-term protective immunity. An effective vaccine against complex diseases, such as leishmaniasis, would also require a multivalent cocktail of several antigens containing a broad range of protective epitopes that would cover a wide range of MHC types in a heterogeneous population. Vaccines made of killed whole parasites can meet some of these requirements but have shown only limited protection in studies in Rhesus monkeys (Amaral et al., 2002) and humans (Velez et al., 2005). A recent phase III trial with three i.m. injections of merthiolate-killed *L. amazonensis* (Leishvacin®) in 2597 healthy volunteers (Columbian soldiers) confirmed that the vaccine was safe but offered no protection against CL caused by *Leishmania panamensis*, according to findings during a 1-year follow-up survey in the field setting (Velez et al., 2005). Due to issues related to the use of live parasites and killed whole parasites, more attention has been given to second-generation vaccines against leishmaniasis as well as suitable adjuvants for human use.

Recently, scientists in the United States have generated Leish-111f, formulated in MPL adjuvant, referred to as Leish-111f–MPL-SE (Coler et al., 2002; Coler and Reed, 2005; Skeiky et al., 2002). This single recombinant polyprotein (111 kDa) is composed of three immunodominant leishmanial antigens (TSA, LmSTI1, and LeIF), previously identified in the context of host response to infection in infected donors and BALB/c mice, as well as their ability to elicit partial protection against *L. major* infection in BALB/c mice. MPL, a detoxified form of lipid A derived from the LPS of *Salmonella minnesota* R595, was used as an immunostimulatory adjuvant because of its ongoing clinical trials for a range of vaccines, including malaria, hepatitis B, genital herpes, allergy desensitization, and human papillomavirus (Coler and Reed, 2005). The Leish-111f–MPL-SE was shown to protect BALB/c mice against *L. major* infection to a degree equal or superior to those seen with any of the individual components of the vaccine construct or SLA, a soluble *Leishmania* lysate (Coler et al., 2002; Skeiky et al., 2002). These studies demonstrate the feasibility of manufacturing a single recombinant vaccine comprising multiple,

protective antigens and the potential use of MPL-SE as a substitute for IL-12. Thus, Leish-111f is the first anti-leishmanial human vaccine to enter phase I, double-blind, dose–response trials in healthy volunteers (Coler et al., 2002; Coler and Reed, 2005).

VACCINES FOR BLOCKING THE TRANSMISSION CYCLE OF LEISHMANIASIS: TARGETING SAND FLY-SPECIFIC COMPONENTS

About 30 different species of sand flies can carry and transmit *Leishmania* parasites. Old World *Leishmania* parasites are transmitted by sand flies of the genus *Phlebotomus*, while New World ones are transmitted by flies of the genus *Lutzomyia*. These tiny, sand-colored, blood-feeding flies (Fig. 63.1A) breed in forested areas, caves, or the burrows of small rodents. Sand flies become infected by ingesting amastigotes while taking blood from infected reservoir hosts or humans. When an infected sand fly takes blood meals, it injects a few hundred metacyclic promastigotes together with some of its saliva. The natural infection rates of sand flies with *Leishmania* parasites vary in different field studies but are generally low (0.05–2%). Thus, animals and humans in endemic areas are more often bitten by uninfected sand flies and, therefore, mount anti-saliva antibodies, as well as a cell-mediated, delayed-type hypersensitivity reaction at the bite site (Belkaid et al., 2000).

Sand fly saliva and its vasodilator peptide, maxadilan, have multiple immunomodulatory properties, in favor of establishing *Leishmania* infection at the initial stage of infection and exacerbating the infection in several murine models of CL (Andrade et al., 2007). Interestingly, mice can also be protected against *L. major* infection when pre-exposed to noninfected sand flies or pre-immunized with sand fly salivary gland extracts (SGE) or one of its components, such as *Lutzomyia longipalpis* maxadilan or a *Phlebotomus papatasi* SP-15 protein (Valenzuela et al., 2004). These results indicate that, at least in mice, a vaccine targeting sand fly-specific components would be efficient in changing local responses in the skin whenever a sand fly bites, making the microenvironment more difficult for the parasite to colonize. This type of vaccine has an advantage over vaccines targeting parasite-specific components because of repeated boosts during sand fly bites in nature. If proven effective in human trials, it would be a useful component of the strategy for the control of leishmaniasis and other vector-transmitted diseases as well. A major challenge for this type of vaccine is to define protective antigens that are shared by several sand fly species and the optimal immunization regimen for infection with *Leishmania* species other than *L. major* (Thiakaki et al., 2005).

MAJOR CHALLENGES IN VACCINE DEVELOPMENT FOR LEISHMANIASIS

In many respects, *Leishmania* parasites and *Mycobacterium tuberculosis* share some common features in their biology and relationship with mammalian hosts: slow growth in vitro, multiplying in an acidic environment within the phagolysosome, actively suppressing the macrophage's effector functions, causing chronic and persistent infection, and requiring IFN-γ- and NO-induced Th1 responses for the control of the disease. In comparison to other pathogens, *Leishmania* parasites have several unique features that can be utilized for vaccine development: (1) Unlike influenza viruses or *T. brucei*, which are notorious for antigenic switches or variations, leishmanial proteins have limited antigenic variation; (2) unlike pathogenic bacteria, *Leishmania* parasites do not secrete toxin for direct cytolysis; (3) there is limited cross-reactivity between leishmanial and host proteins (i.e., repeated injections of dead parasites or parasite antigens do not result in leishmaniasis); (4) a battery of mouse models has been developed for the study of CL (and to a lesser extent VL), and a hamster model is increasingly being used in vaccine studies for VL; (5) in most cases, parasites freshly isolated from leishmaniasis patients can be used to directly infect animals (mouse, hamster, dog) for the study of protective immunity or pathogenesis. Therefore, with the advent of effective culture conditions for the various stages of the life cycles, together with a wealth of information on the genome of *L. major* and protective immunity to this pathogen, it is tempting to speculate that *L. major* would be the first efficient vaccine for control of parasitic diseases. Why do we still not have a vaccine for CL?

KEY ISSUES

Developing an efficient vaccine for the control of leishmaniasis is not as easy as it is in the case of bacterial or viral infections (Modabber et al., 2007). The major challenges and critical issues include:

- *Leishmania* parasites have a very large diploid genome and complex, poorly understood regulation of stage-specific proteins, and molecular tools for genetic manipulation to delete or add a gene are not as widely used as they are for other microorganisms.

- The transmission cycle involves insects and small animal reservoirs, and there are complex interactions between the parasite and its sand fly vector and between the parasite and its mammalian hosts.
- Diverse parasite species are responsible for a broad spectrum of clinical manifestations—one parasite species can result in different clinical forms, and one clinical form can be caused by different parasite species.
- Disease pathogenesis is due to inadequate immune responses to parasite infection.
- Impairment in protective Th1 responses would be IL-4- and IL-10-dependent or -independent.
- Most reported vaccine studies reveal short-lived (or partial) protection in experimental models. Thus, the induction of protective immunity for leishmaniasis is complex, relying on the generation of cellular immune responses that are of considerable strength, longevity, and anatomical distribution to effectively fight the pathogen.

ACKNOWLEDGMENTS

[2]Deputy of Director General, National Institute of Infectious Diseases, Toyama, Shinjuku-ku, Tokyo, Japan

OUTLINE

ABSTRACT

Leptospirosis, caused by pathogenic *Leptospira*, is a globally important zoonotic disease that affects humans in both rural and urban settings. This disease may occur in both industrialized and developing countries; in particular, leptospirosis has become an important public health concern in Asia and Latin America. However, even in endemic areas, it remains under diagnosed due to nonspecific, broad spectrum of clinical manifestation, lacking clinical suspicion, and shortage of established early diagnostic methods. Leptospirosis in humans is transmitted by direct contact with infected animals or by exposure to water or soil contaminated by the urine of infected animals.

The spectrum of the disease is wide, ranging from asymptomatic infection to severe disease affecting multiple organs with high mortality. Much attention has recently been paid in the severe pulmonary form of leptospirosis, which is globally emerging as an important clinical form of the disease.

The efficacy of a vaccine for preventing leptospirosis has been recognized, but serovar-specific protection limits the effectiveness of currently available vaccines and a globally accepted vaccine has not been developed. Progress has been made in the areas of pathogenesis of *Leptospira* and immunity against leptospirosis; in particular, pathogenic mechanisms in kidney and lung, identification of adhesion proteins and role of cell-mediated immunity against leptospirosis. However, the molecular mechanism still remains inadequately understood due to lack of genetic tools to study pathogenic *Leptospira*. The whole-genome sequences of pathogenic *Leptospira* have been completed. More recently, random mutagenesis in pathogenic *Leptospira* has been successful using the *Himar1 mariner* transposon. Genome information and this technique will facilitate the identification of virulence factors as well as the understanding of the pathogenesis of leptospires, which is promising to develop a new effective vaccine for leptospirosis.

INTRODUCTION

Leptospirosis is a worldwide zoonotic disease affecting humans in both rural and urban settings, and in both industrialized and developing countries (Levett, 2001; Bharti et al., 2003; Cachay and Vinetz, 2005; McBride et al., 2005; Ricaldi and Vinetz, 2006). It is well known that leptospirosis vaccine prevents the disease (Koizumi and Watanabe, 2005). However, the development of a new vaccine is urgently needed because currently available vaccines have disadvantages, including short duration of immunity, adverse reactions, and serovar-specific effectiveness. In this chapter, we have summarized recent progress on basic research of leptospirosis, which may contribute to the development of new effective vaccines for leptospirosis.

HISTORY OF THE DISEASE

Leptospirosis is a zoonosis distributed worldwide, caused by infection with pathogenic *Leptospira*. The syndrome, an infectious disease (leptospirosis) with jaundice and nephritis, was first reported by Weil in 1886, whose name was given to severe leptospirosis (Weil's disease) (Weil, 1886). Although this is regarded as the first description of severe leptospirosis, an apparently identical syndrome and its endemicity was described before Weil's report (Levett, 2001; Faine et al., 1999).

The causative agent of Weil's disease was discovered by Inada and colleagues in Japan in 1914–1915. They could consistently succeed in transmitting infection to guinea pigs from patient's blood. They detected a spirochete in the liver tissue of a guinea pig injected with the blood of a patient suffering from Weil's disease. Besides the discovery of the causative organism of the disease, they clarified the source and route of infection, its pathology and morbid anatomy, distribution of the organisms in the tissues, excretion of the spirochetes, its division, filterability, and morphological characterization (Kobayashi, 2001). In October 1915, German groups reported independently the detection of spirochetes in the blood of guinea pigs inoculated with the blood of patients (Hübener and Reiter, 1915; Uhlenhuth and Fromme, 1915). After Inada's work was published in English, the occurrence of leptospirosis was confirmed rapidly in Europe (Faine et al., 1999).

Although the etiologic agent of Weil's disease was demonstrated in 1915, it is now recognized that *Leptospira* was first described by Stimson (1907). He observed spirochetes with hooked ends in the tubules of the kidney of a patient who was believed to have died of yellow fever, and called them *Spirochaeta interrogans* due to their resemblance to a question mark.

As mentioned above, Inada's group described the role of rats as a source of human infection soon after the discovery of *Leptospira*. Leptospirosis in domestic animals, such as dogs and livestock, was recognized during the 1920s and 1930s and the late in 1930s, respectively (Faine et al., 1999).

ETIOLOGIC AGENT

Classification

Leptospires are spirochetes that belong to the genus *Leptospira*, the family Leptospiraceae, in the order Spirochaetales (Fig. 64.1) (Faine et al., 1999). The family also contains other genera *Leptonema* and *Turneriella* (Faine et al., 1999; Levett et al., 2005). *Leptospira* consists of both pathogenic and saprophytic (nonpathogenic) species. *Leptospira* species are defined according to DNA relatedness and there are now 13 named species and 4 unnamed genomospecies (Table 64.1) (Brenner et al., 1999; Levett et al., 2006). Leptospires

are divided into numerous serovars defined by a cross-agglutination–adsorption test. There are more than 230 serovars recognized among pathogenic *Leptospira* and over 60 serovars of nonpathogenic leptospires. Antigenically related serovars are grouped into serogroups (Faine et al., 1999).

Leptospires are helicoidal bacteria, usually 6–20 μm long and 0.1 μm diameter. One or both ends of the cells distinctively hooked (Faine et al., 1999). The leptospiral cells are composed of cytoplasmic membrane and peptidoglycan cell wall, which are surrounded by an outer membrane. Two flagella (axial filaments) are located at each end of the cell and in the periplasmic space. Leptospires are obligate aerobic spirochetes with optimal growth at pH 7.2–7.6 and temperature 28–30°C. The long chain fatty acids are sources of both carbon and energy. Leptospires are cultivated in artificial media containing either 8–10% rabbit serum or Tween 80/bovine serum albumin, and in low-protein or protein-free media (World Health Organization, 2003).

Antigens Encoded by Agent

Lipopolysaccharide (LPS)

Leptospires possess LPS, which is absent in the outer membrane other pathogenic spirochetes, *Borrelia* and *Treponema*. Variations in the carbohydrate composition of LPS reflect the antigenic diversity (serovars) among pathogenic leptospires (Faine et al., 1999). Leptospiral LPS has lower endotoxic activity than enterobacterial LPS (Nahori et al., 2005). It was recently found that the LPS O-antigen content of leptospires in liver and kidney of acutely infected guinea pigs was markedly reduced compared with those in the kidney of chronically infected rats (Nally et al., 2005a). This result suggests that regulation of O-antigen synthesis may be different between disseminated acute infection and chronic infection in animals.

PROTEIN ANTIGENS

The immunogenic proteins, especially the outer membrane surface proteins of pathogenic *Leptospira*, may be effective as immunogens and potential virulence determinants. Protein antigens, which are recognized by human patient sera and experimentally infected or immunized animals sera, have been described and some of them have been cloned and characterized (Haake et al., 1991, 1993, 1998, 1999, 2000; Shang et al., 1996; Park et al., 1999; Guerreiro et al., 2001; Branger et al., 2001; Nally et al., 2001, 2005b, 2007; Matsunaga et al., 2002, 2003, 2006; Cullen et al., 2002, 2003, 2004, 2005; Haake and Matsunaga, 2002; Palaniappan et al., 2002; Koizumi and Watanabe, 2003a, 2003b, 2004; Artiushin et al., 2004; Hsieh et al., 2005; Verma et al., 2005). Proteomic analysis combined with available genome sequence identified several novel outer membrane proteins (Nally et al., 2005b). Furthermore, a surfaceome strategy has been developed and potential surface-exposed proteins have been identified (Cullen et al., 2005). These analyses have been performed using in vitro cultivated leptospires. Recently, Nally et al. (2007) have developed a method of characterization of the proteome of hydrophobic membrane proteins in *Leptospira* expressed during acute infection relative to that of in vitro cultivated *Leptospira*.

PROTECTIVE IMMUNE RESPONSE

Antibody

The primary mechanism of immunity to *Leptospira* is believed to be solely humoral (Adler and Faine, 1977). Protective immunity was conferred by passive transfer of monoclonal antibody alone (Jost et al., 1986, 1989). These antibodies were directed against leptospiral LPS. Active immunization with LPS and epitopes derived from LPS protected experimental animals from lethal challenge (Schoone et al., 1989; Sonrier et al., 2000); very low levels of antibody were protective (Schoone et al., 1989). The protective immunity conferred by leptospiral LPS as an immunogen is generally serovar-specific (Sonrier et al., 2000). Interestingly, sera from patients with leptospirosis cross-reacted with antigens from nonpathogenic (saprophytic) *Leptospira biflexa* serovar Patoc (strain Patoc I) (Addamiano and Babudieri, 1968; Turner, 1968). Matsuo and colleagues extracted the antigenic components from *L. biflexa* Patoc I by a hot phenol–water method, which strongly reacted with not only anti-*L. biflexa* serum, but also with various antisera against pathogenic leptospires, regardless of their serovars or serogroups. Nuclear magnetic resonance studies demonstrated that the main structural part of the antigenic components of LPS had a repeating disaccharide of →3)-β-D-Man*p*-(1→4)-β-D-Man*p*-(1→ (Matsuo et al., 2000a). Furthermore, not only antisera against various pathogenic leptospires, but also sera from patients with leptospirosis, reacted with exocellular mannans from *Rhodotorula glutinis* that have the same structural backbone of →3)-β-D-Man*p*-(1→4)-β-D-Man*p*-(1→ (Matsuo et al., 2000b; Gorin et al., 1965). Administration of *L. biflexa* LPS preparation to hamsters was protective against a challenge with virulent *L. interrogans* serovar Manilae without any side effects (Matsuo et al., 2000c).

Since protein-conjugated polysaccharide vaccines against *Haemophilus influenzae* type b, pneumococci and meningococci have been successful; it is assumed similar conjugated polysaccharide vaccines for leptospirosis could be developed.

In addition to antibody against LPS, sera from patients with leptospirosis contain antibodies against several protein antigens (Guerreiro et al., 2001). Protein extracts prepared from a pathogenic *Leptospira* can induce protective immunity against challenge with a heterologous serovar strain in an experimental animal model (Sonrier et al., 2000). Some leptospiral protein antigens have been shown to elicit protective immunity in animal models. Immunization with recombinant proteins, such as OmpL1 and LipL41, and Lig proteins conferred protective immunity (Haake et al., 1999; Koizumi and Watanabe, 2004; Palaniappan et al., 2006). Vaccination using an adenovirus vector and plasmid vector encoding the *lipL32/hap-1* gene induced cross-protection in the gerbil model of leptospirosis (Branger et al., 2001, 2005) (see "2Vaccines" section).

Cell-Mediated Immunity

Although immunity against leptospiral infection was thought to be primarily humoral (Faine et al., 1999), recent studies point to a role for cell-mediated immunity in protection from leptospirosis. Peripheral blood mononuclear cells (PBMCs) from cattle immunized with a killed *Leptospira borgpetersenii* serovar Hardjo vaccine proliferated and produced IFN-γ after in vitro stimulation with leptospiral antigens (Naiman et al., 2001). $CD4^+$ $\alpha\beta$ T cells and $WC1.1^+$ $\gamma\delta$ T cells were the main source of IFN (Naiman et al., 2001, 2002; Rogers et al., 2005). $CD4^+$ T cells were shown to be required for $\gamma\delta$ T cells (Blumerman et al., 2007). The PBMCs from Hardjo-vaccine immunized cattle also responded to stimulation with serovar Grippotyphosa antigen preparation (Brown et al., 2003). PBMCs from nonvaccinated cattle also responded to leptospiral antigens, but the responses were lower than those of vaccinated cattle. The low cell-mediated immune response in unvaccinated cattle may be associated with lack of protection from chronic infection (Naiman et al., 2002). Thus, protective immunity against serovar Hardjo infection in cattle correlates with establishment of Th1 immunity. Pronounced expression of Th1 cytokines mRNAs was also detected in hamsters after inoculation with *Leptospira* (Vernel-Pauillac and Merien, 2006). An uncharacterized leptospiral glycolipoprotein elicited in vitro production of TNF-α and IL-10, and upregulated the expression of CD69 and HLA-DR on human PBMCs (Diament et al., 2002). This glycoprotein also induced IL-6 production and monocyte expansion in human PBMCs (Dorigatti et al., 2005). The heat-killed leptospires also induced the production of IFN-γ, IL-12 and TNF-α in human whole blood in vitro (de Fost et al., 2003). Naïve human PBMCs from healthy individuals proliferated and produced IFN-γ, IL-12, and TNF-α in vitro after stimulation with *L. interrogans* (Klimpel et al., 2003). High numbers of leptospires caused the expansion of $\gamma\delta$ T cells, while low numbers of leptospires induced $\alpha\beta$ T cells. In patients with acute leptospirosis the number of peripheral blood $\gamma\delta$ T cells increased significantly (Klimpel et al., 2003; Barry et al., 2006). The in vivo role of $\gamma\delta$ T cells in protection from leptospiral disease remains to be elucidated.

EPIDEMIOLOGY

Significance as Public Health Problem

Leptospirosis has worldwide distribution. Based on global data collected by International Leptospirosis Society surveys, 300,000–500,000 cases of leptospirosis are estimated to occur annually (World Health Organization, 1999; Hartskeerl, 2006). However, this number is probably an underestimate and the true extent of leptospirosis remains unknown due to lack of worldwide surveillance. The incidence of human infection is higher in tropical areas than in temperate regions and in developing countries than in industrialized countries. Leptospirosis is currently recognized as a globally important public health problem, especially in Asia and Latin America (Bharti et al., 2003; McBride et al., 2005; Ricaldi and Vinetz, 2006). In these tropic areas, large outbreaks of leptospirosis are most likely to occur after floods, hurricanes, or other disasters, which affect both rural and urban areas (Ko et al., 1999; Trevejo et al., 1998; Sanders et al., 1999; Easton, 1999; Mudur, 2005; Maskey et al., 2006). Occupational exposure, such as rice farming and other agricultural activities is still significant in rural areas of the tropics (Tangkanakul et al., 2000; Sharma et al., 2006). Leptospirosis has also become an urban problem in the tropics. Outbreaks occur in poor urban slum communities during the same seasonal period of heavy rainfall annually (Ko et al., 1999; Bharadwaj et al., 2002; Johnson et al., 2004; LaRocque et al., 2005). In urban slums, infrastructural deficiencies, such as open sewers, produce the ecological conditions for rodent-borne transmission and contribute the transmission of leptospirosis during epidemics (McBride et al., 2005). Risk for infection in urban dwellings is not limited to tropical areas as the importance of urban leptospirosis

was recognized in a U.S. inner-city population (Vinetz et al., 1996). In metropolitan Tokyo, more than 20% of rats harbor leptospires and patients with Weil's disease are thought to be due to contact with environments contaminated with rat urine (our unpublished data).

Leptospires infect the proximal renal tubules of various mammals and are excreted in the urine of carrier animals. Probably every known species of mammals is a potential carrier and excretor of leptospires (Faine et al., 1999). Important animal reservoirs of leptospirosis for human transmission are rats and mice near human habitats, domestic animals such as cattle and swine, companion animals, especially dogs, and wild animals, especially rodents. Leptospirosis in humans is transmitted by direct contact with infected animals or by exposure to water or soil contaminated by the urine of infected animals (Faine et al., 1999).

Leptospirosis has been considered to be primarily an occupational disease associated with activities such as rice and other agricultural practices, mining, sewer maintenance, livestock farming, and fish farming (Levett, 2001). There is a significant risk associated with recreational exposures occurring during water sports such as swimming, canoeing, and rafting (Reisberg et al., 1997; Narita et al., 2005; Nakamura et al., 2006; Nardone et al., 2004), and in travel and adventure tourism (Reisberg et al., 1997; van Creel et al., 1994; Sejvar et al., 2003; Jansen et al., 2005). The large outbreaks of leptospirosis in recreational activities are associated with competitive events (Morgan et al., 2002), even in international adventure race (Sejvar et al., 2003). In endemic areas, humans contract leptospirosis from activities of daily life (Johnson et al., 2004).

Potential as Biothreat Agent

Leptospira is not considered as a potential biothreat agent. However, there is merit to the attention of leptospirosis in bioterrorism since its clinical manifestation can mimic those of viral hemorrhagic fevers (Bharti et al., 2003; Monsuez et al., 1997).

CLINICAL DISEASE

Leptospirosis is an acute febrile illness. The spectrum of symptoms in leptospirosis is extremely broad; from asymptomatic infection or mild manifestation to severe disease including jaundice, renal failure, hemorrhage, and death. Asymptomatic seroconversion is common in human infection occurring in up to 70% of all serologically identified cases (Ashford et al., 2000; Phraisuwan et al., 2002). Acute leptospirosis starts with the initial symptoms such as fever, chills, headache, myalgia, and conjunctival suffusion after an incubation period of 2–30 days (usual range is 5–14 days) (Levett, 2001; Faine et al., 1999). About 90% of recognized infections are mild and self-limited. Five to ten percent of the patients develop severe forms of disease, such as Weil's disease characterized by jaundice, renal failure, hemorrhage, and severe pulmonary hemorrhage syndrome with or without jaundice and renal failure. Mortality rate can be as high as 5–15% and 30–60% (Dolhnikoff et al., 2007), respectively.

The jaundice in leptospirosis does not seem to be associated with hepatocyte damage, but seems to be more related to the cholestasis of sepsis (Bharti et al., 2003). Serum bilirubin levels may be very high and transamilase levels are typically increased only for 2–3 times above normal level, suggesting leptospirosis rather than viral hepatitis (Faine et al., 1999).

Renal involvement is common in leptospirosis; the majority of the patients have abnormalities on urinalysis. Blood urea and creatinine elevate rapidly (Faine et al., 1999). Acute renal failure (ARF), which occurs in 10 to over 60% of cases (Visith and Kearkiat, 2005), frequently accompanies hypokalemia and nonoliguria, even polyuria. In the patients with ARF, oliguria is a significant predictor of death (Daher et al., 1999). Thrombocytopenia occurs in up to 50% of the patients with leptospirosis, which does not seem to result from disseminated intravascular coagulation (Edwards et al., 1982, 1986; Nicodemo et al., 1997).

Pulmonary involvement in leptospirosis has recently gained much more attention as several epidemics of severe pulmonary form of leptospirosis have been reported (Ko et al., 1999; Zaki and Shieh, 1996; Yersin et al., 2000; Seijo et al., 2002; Vijayachari et al., 2003; Segura et al., 2005). Occurrence of respiratory manifestation in leptospirosis varies from 20% to 70%. Symptoms can be mild and nonspecific, including chest pain, cough, and dyspnea but the presence of severe pulmonary hemorrhage with or without acute respiratory distress syndrome is associated with higher mortality. Respiratory symptoms usually appear between fourth and sixth day of disease and may lead to death in less than 72 h (Dolhnikoff et al., 2007).

Aseptic meningitis may be found in up to 25% of cases. Cardiac involvement is probably more common than is recognized, including myocarditis, nonspecific electrocardiogram abnormalities, and atrial fibrillation (Plank and Dean, 2000). Leptospirosis involves ocular manifestation. Conjunctival suffusion is a common clinical finding in the acute stage of illness (Martins et al., 1998). Uveitis is a rare but an important sequel of leptospirosis (Rathinam, 2002),

which is presumed to occur by an immune-mediated process; although isolation and/or DNA detection of *Leptospira* has been demonstrated in aqueous humor of patients (Mancel et al., 1999).

Leptospirosis has diverse clinical manifestations easily confused with many other diseases in tropics, such as dengue fever or dengue hemorrhagic fever, malaria, and scrub typhus (Sanders et al., 1999; LaRocque et al., 2005; Zaki and Shieh, 1996; Wongsrichanalai et al., 2003; Suputtamongkol et al., 2004; Karande et al., 2005). The differential diagnosis also include influenza, HIV seroconversion, and hantavirus infections (Bharti et al., 2003).

TREATMENT

Controversy remains about efficacy of antibiotics in treating leptospirosis (Pappas and Cascio, 2006). However, many experts recommend the use of antibiotic therapy for severe leptospirosis and clinically and epidemiologically suspected cases (McBride et al., 2005; Vinetz, 2003; Yang et al., 2005). Although optimal treatment of leptospirosis is not clearly defined (Pappas and Cascio, 2006; Griffith et al., 2006), doxycycline is recommended for mild disease and severe cases of leptospirosis should be treated with intravenous penicillin (World Health Organization, 2003; McClain et al., 1984; Watt et al., 1988). Recent clinical trials support the use of cephalosporins (Suputtamongkol et al., 2004; Panaphut et al., 2003). Intravenous ceftriaxone was shown to be as effective against severe leptospirosis as intravenous penicillin. The median duration of fever was same in both groups and there was no significant difference in the duration of organ dysfunction and the overall mortality rate between two groups (Panaphut et al., 2003). Another study revealed that cefotaxime and doxycycline were each as effective as penicillin for treatment of severe leptospirosis. The mortality rate, time to defervescence, and progression of dysfunction of vital organs was similar among the three groups (Suputtamongkol et al., 2004).

A wide range of antimicrobial agents has an activity against *Leptospira* in vitro and/or animal models, but their relevance in clinical outcomes remains unknown (Pappas and Cascio, 2006; Griffith et al., 2006).

The utility of doxycycline (200 mg/week) in preventing susceptible population from the disease has shown in a study using U.S. soldiers in Panama (Takafuji et al., 1984). Doxycycline prophylaxis in endemic areas or recreational activity was also shown to be protective; although these results were not statistically significant (Sejvar et al., 2003; Gonsalez et al., 1998; Sehgal et al., 2000).

In severe cases, supportive treatment for dehydration, hypotension, renal failure, and pulmonary involvement is also required. Nitric oxide inhalation has been anecdotally resulted in marked clinical improvement of pulmonary hemorrhage (Borer et al., 1999). Corticosteroids have been shown to reduce mortality and change the outcome significantly when they were used early in the management of pulmonary leptospirosis (Shenoy et al., 2006).

PATHOGENESIS

Pathogenic leptospires enter into bloodstream via small abrasions and breaches of skin, conjunctiva, and mucosa (Faine et al., 1999). Pathogenic *Leptospira* is able to translocate through polarized Madin-Darby canine kidney cell monolayers rapidly, suggesting that evasion from killing by host cells permits pathogenic leptospires to quickly reach the bloodstream and disseminate to multiple organs (Barocchi et al., 2002). Leptospires circulate and survive in the bloodstream in the initial phase of disease, indicating that they are able to escape from killing by the complement system, especially the alternative pathway. Pathogenic leptospires showed serum resistance whereas nonpathogenic *Leptospira* was sensitive (Meri et al., 2005; Verma et al., 2006). Serum resistance was found to correlate with the binding of the soluble complement regulator factor H on the pathogenic leptospiral cell surface. As a consequence, pathogenic leptospires deposited much less C5, C6, C8, and C5b-9 on their surfaces than the nonpathogenic *Leptospira*, resulting in serum resistance of pathogenic leptospires (Meri et al., 2005). Verma et al. (2006) have recently identified the human factor H-binding protein of *Leptospira*, LfhA. LfhA is a putative lipoprotein and located in the outer membrane of the cells. LfhA is expressed during natural infection, suggesting its relevance in the protection of leptospires from complement-mediated killing and immune evasion.

The primary lesions to small endothelial blood vessels caused by *Leptospira* lead to hemorrhage and localized ischemia in multiple organs. Several hemolysins have been identified in leptospires (Artiushin et al., 2004; Segers et al., 1990; Lee et al., 2000, 2002; Zhang et al., 2005; Hauk et al., 2005). These hemolysins are divided into two groups, sphingomyelinase or nonsphingomyelinase hemolysins. SphH is a pore-forming hemolysin which shows cytotoxic activity on mammalian cells (Lee et al., 2002). Lk73.5 showed cytotoxicity on equine pulmonary endothelial cells and is suggested to be expressed only in vivo (Artiushin et al., 2004), although its orthologous

protein gene in the other serovar strain was transcribed in vitro (Zhang et al., 2005).

Pathogenic *Leptospira* disseminates hematogenously to various tissues, where leptospires colonize. Leptospires interact with various cultured cells, including fibroblasts, macrophages, microglial, endothelial, and epithelial cells (Barocchi et al., 2002; Vihn et al., 1984; Thomas and Higbie, 1990; Merien et al., 1997, 2000; Cinco et al., 2006). A 36 kDa fibronectin-binding protein identified only in virulent *Leptospira* functions as an adhesion protein (Merien et al., 2000). Lsa24 was recently shown to be a laminin-binding protein (Barbosa et al., 2006). This protein has been identified as LfhA (Verma et al., 2006) described above. Lig proteins are surface-exposed outer membrane proteins punctuated by tandem repeats of about 90 amino acids of bacterial immunoglobulin (Ig) like domains (Palaniappan et al., 2002, 2004; Matsunaga et al., 2003; Koizumi and Watanabe, 2004). LigA consists only of Ig-like domains, whereas LigB has an additional unique domain at the C terminus. Expression of Lig protein and *lig* mRNA was lost after attenuation of *Leptospira kirshneri* and *L. interrogans*, suggesting that Lig proteins are associated with virulence (Matsunaga et al., 2003). Expression of Lig proteins, surface exposure of LigB, and extracellular release of LigA are all enhanced by physiological osmolarity (Matsunaga et al., 2005). It has been recently demonstrated that Lig proteins bound to extracellular matrix (ECM) proteins such as fibronectin, collagen and laminin, and fibrinogen (Choy et al., 2007). Unique Ig-like domains of both LigA and LigB are responsible for the interaction with fibronectin.

In kidney, *Leptospira* colonizes and multiplies in proximal tubule epithelial cells resulting in ARF and tubulointerstitial nephritis (Yang et al., 2001). Yang et al. (2002) have shown that leptospiral outer membrane proteins (LOMPs) extracted from pathogenic *Leptospira*, but not from nonpathogenic *Leptospira* stimulated the production of a set of pro-inflammatory chemokine such as CCL2/MCP-1, CCL5/RANTES, TNF-α in cultured mouse proximal tubule cells. Toll-like receptor (TLR) 2 pathway mediated the induction of these chemokines, at least CCL2/MCP1, caused by LOMPs (Yang et al., 2006a). Recombinant LipL32, one of the most abundant outer membrane lipoproteins in *Leptospira* (Haake et al., 2000), also stimulates the TLR2-mediated induction of expression and secretion of CCL2/MCP1 (Yang et al., 2006a). They also showed that LOMPs also induced upregulation of chemokines CXCL2/MIP-2 and CXCL1/KC through the TLR2 pathway (Hung et al., 2006b, 2006a). CXC chemokines, including CXCL8/IL8, CXCL1/KC/GRO-α, and CXCL2/MIP-2, are molecules that are potentially responsible for the infiltration of leukocytes and the initiation of tubulointerstitial nephritis (Tang et al., 1997). Thus, the production of these chemokines and subsequent influx of leukocytes in kidneys results in the development of tubulointerstitial nephritis in *Leptospira* infection.

If untreated, tubulointerstitial nephritis caused by leptospiral infection leads consequently to interstitial fibrosis (Sterling and Thiermann, 1981; Penna et al., 1963). Sustained expression of TGF-β1 leads to the accumulation of ECM proteins through an increase of ECM synthesis and a decrease of ECM degradation, which result in tubulointerstitial fibrosis (Yamamoto et al., 1994; Baricos et al., 1999). It has been shown that LOMPs induced the increase of the production of type I and IV collagen, but not the enhancement of their degradation, through TGF-β1/Smad-dependent pathway in cultured human renal proximal tubular cells (Tian et al., 2006).

Leptospirosis causes a unique ARF with hypokalemia and nonoliguria. Hypokalemia is secondary to renal potassium wasting. Patients infected with *Leptospira santarosai* serovar Shermani were suspected to have a defect in the thick ascending limb (TAL) sodium reabsorption (Wu et al., 2004). LOMPs from *L. santarosai*, but not *L. interrogans*, inhibited the function of Na^+–K^+–Cl^- cotransporter NKCC2, a major transporter for apical sodium reabsorption by TAL, and the expression of *mNKCC2* mRNA in mouse TAL cells (Wu et al., 2004). On the other hand, Andrade et al. (2007) showed that expression of sodium/hydrogen exchanger isoform 3, which plays an important role in reabsorption of sodium and fluid by the proximal tubule, was significantly decreased in kidneys of hamsters infected with *L. interrogans*. These results suggest that *Leptospira* species specifically target different transporters. Alternatively, it has been shown that leptospiral glycolipoprotein endotoxin and its nonesterified unsaturated fatty acid components are a potent inhibitor of renal Na^+–K^+ ATPase (Burth et al., 1997, 2005). Leptospirosis patients showed an increased in serum concentrations of oleic and linoleic acid but a decrease in serum albumin concentrations. Correlation between disease severity and serum oleic acid:albumin or oleic plus linoleic acid:albumin ratio was revealed (Burth et al., 2005).

Severe pulmonary hemorrhage leptospirosis is now recognized as an important public health problem. Two mechanisms, a toxin-mediated and/or an immune-mediated mechanism, are suggested (Dolhnikoff et al., 2007). The amount of leptospiral antigens was not correlated with the severity of the lesion in lung autopsy (Nicodemo et al., 1997). Fewer leptospires were detected in infected hemorrhagic lung

tissues than in liver and kidney, which are without evidence of hemorrhage, in guinea pigs (Nally et al., 2004). These observations would support a host immune-mediated mechanism. Disseminated intravascular coagulation has shown to have no relation to pulmonary hemorrhage (Nicodemo et al., 1997). Nally et al. (2004) have demonstrated that IgM, IgG, IgA, and C3 were deposited along the alveolar basement membrane in infected guinea pigs, suggesting that an autoimmune process may be the cause of severe pulmonary hemorrhage leptospirosis. Deposition of Ig in alveolar septum and alveolar space was observed in human autopsy, which showed diffused pulmonary hemorrhage although diagnosis of leptospirosis was made only by Warthin-Starry stain in the lung autopsy (Yang and Hsu, 2005). The etiology of pulmonary edema is also unclear. It has been documented that resolution of pulmonary edema occurs as a consequence of active sodium transport across the alveolar epithelium (Matthay et al., 2002). Andrade et al. (2007) also observed that leptospiral infection decreased the expression of the alpha subunit of the epithelium sodium channel (α-ENaC) and induced the expression of the Na^+–K^+–Cl^- cotransporter NKCC1 in lungs of hamster model of leptospirosis. This result suggests that leptospirosis profoundly influences the sodium transport capacity of alveolar epithelial cells, resulting in impaired pulmonary fluid clearance and subsequent disturbance of lung function and increased susceptibility of the lung to injury.

Ocular leptospirosis is widely considered to be an immune-mediated disease in both humans and horses (Rathinam, 2002), although isolation and/or DNA detection of *Leptospira* has been demonstrated in aqueous humor of both uveitic people and horses (Mancel et al., 1999; Faber et al., 2000). A leptospiral DNA fragment that encodes cross-reactive protein with equine cornea has been cloned (Lucchesi and Parma, 1999). Verma et al. (2005) have recently identified novel leptospiral lipoproteins, LruA and LruB. Eye fluids of uveitic horses contained significantly high titers of Ig specific to both lipoproteins. Further, antisera raised against these proteins reacted with equine ocular components, suggesting an immune-mediated process in leptospiral uveitis. The relevance of this finding in human ocular leptospirosis remains to be confirmed.

In addition to leptospiral virulence determinants and mechanisms, host factors are presumably related to pathogenesis of leptospirosis. Elevated plasma levels of tumor necrosis factor-α are associated with disease severity and mortality among patients with leptospirosis (Tajiki and Salomão, 1996). Recently, Lingappa et al. (2004) found the association between human leukocyte antigen (HLA)-DQ6 and the risk of infection due to swallowing of waters contaminated with leptospires in an outbreak of leptospirosis.

Immune Response to Infection

Innate immunity relies on signaling by TLRs to alert the immune system against bacterial infections (Gerold et al., 2007). TLR activation leads to the release of cytokines that allow for effective innate and adaptive immune responses. Werts et al. (2001) have shown that leptospiral LPS activates human macrophages through TLR2 instead of TLR4, which is a central component for Gram-negative bacteria. Lipid A is the active component of LPS responsible for its toxic activity and functions. The structure of leptospiral lipid A moiety has been recently deciphered (Que-Gewirth et al., 2004). It has been revealed that leptospiral lipid A possesses some peculiar characteristics compared with lipid A from Gram-negative bacteria. Species specificity of recognition of leptospiral lipid A/LPS has been reported (Nahori et al., 2005). Lipid A stimulated cells through murine TLR4/MD2 but not through human TLR4/MD2, nor murine and human TLR2. On the other hand, LPS activates human cells through TLR2/TLR1 whereas both TLR2 and TLR4 are involved in signaling against LPS in murine cells. Mice are resistant to *Leptospira* infection while humans are not. The species specificity of TLRs for recognition of LPS may be a part of an effective innate immune protection against leptospirosis in mice but not in humans.

In the mouse model of leptospirosis, it has been demonstrated that TLR4 plays a crucial role in protection from acute lethal infection and control of leptospiral burden in tissues during sublethal chronic infection (Viriyakosol et al., 2006). Heat-killed *Leptospira* did not stimulate cytokine induction in $TLR4^{-/-}$ macrophages whereas cytokines were induced in both $TLR2^{-/-}$ and $CD14^{-/-}$ macrophages, indicating that cytokine responses in macrophages correlated with leptospiral clearance in vivo. Induction of cytokines by leptospiral cells was abolished by polymixin B, suggesting that these TLR4-dependent but CD14 and TLR2-independent responses are likely mediated by a leptospiral ligand(s) other than LPS.

VACCINES

History

The efficacy of a vaccine for preventing leptospirosis was shown soon after *Leptospira* was proven to be

the causative agent of Weil's disease in Japan. The heat-killed whole cell vaccine made from *Leptospira* cultures dramatically protected coal miners from Weil's disease in Kyushu where the disease was endemic (Wani, 1933). The development of killed whole cell vaccine against leptospirosis in the middle of the last century has been reviewed (Babudieri, 1959), and subsequent results of vaccine field trials were published (Torten et al., 1973; Fukumura, 1984; Chen, 1985; Ikoev et al., 1999; Sánchez et al., 2000; Yan et al.,2003; Martínez et al., 2004).

Current Licensed Vaccines

- Weil's disease and Akiyami combined vaccine (Denka Seiken, Japan) (Koizumi and Watanabe, 2005)
  Formalin-killed whole cell vaccine
  The concentrations and serovars are 2.5×10^8 cells/ml each of Australis, Autumnalis, and Hebdomadis and 5×10^8 cells/ml of Copenhageni.
  Initial vaccination: two subcutaneous injections of 1.0 ml of vaccine given at a 7-day interval.
  Booster injection: subcutaneous injection of 1.0 ml of vaccine given within 5 years after the second initial dose.
  For children (7–13 years): half dose of adult (mentioned above)

- SPIROLEPT (Thea Laboratories, France) (http://sante-az.aufeminin.com/w/sante/m3514716/medicaments/spirolept.html, 2007; Laurichesse et al., 2007)
  Formaldehyde-killed whole cell vaccine
  Supplied as a syringe with a 1-ml dose of vaccine 2×10^8 cells *Leptospira interrogans* serogroup Icterohaemorrhagiae
  Target population: people who, because of their profession or their activities of leisures, are in contact with contaminated waters or animals.
  Initial vaccination: two subcutaneous injections at a 15-day interval.
  Booster injection: 4–6 months after the second initial dose
  Ulterior booster: every 2 years
  No data is available for the children.

- Leptospirosis vaccine (Shanghai Institute of Biological Products, China) (Yan et al., 2003; http://www.siobp.com/CPJS/YFZP_13.htm, 2007)
  Polyvalent vaccine (strains/serovars not specified) composed of outer envelope fraction of leptospiral cells
  Target population: 7–60 years in epidemic area of leptospirosis. People who go to epidemic area and have not been vaccinated before.
  Initial vaccination: two subcutaneous injections (1st: 0.5 ml; 2nd: 1 ml) at a 7 to 10-day interval.
  Booster injection: subcutaneous injection of 1 ml of vaccine at 1 year after the second initial dose.
  Children (7–13 years): 1/2 dose of adult (mentioned above)
  Child (under 7) not exceed 1/4 dose of adult, if needed

- Finlay Institut, Cuba (Martínez et al., 2004; http://www.leptonet.net/html/vaccination.asp, 2007)
  Vax-SPIRAL
  Trivalent vaccine: *Leptospira interrogans* serovars Canicola, Copenhageni, and Mozak.
  Inactivated vaccine

The antibody titers (MAT titers) after vaccination were significantly lower than those developed after natural infection and seroconversion occurred with low frequency (about 20–60%), although a high seroconversion rate has been reported (90–100%) (Koizumi and Watanabe, 2005; Torten et al., 1973; Ikoev et al., 1999; Laurichesse et al., 2007; Martínez Sánchez et al., 1998; Sánchez et al., 2002). However, protection was reported to be high in such populations and efficacy rates of whole cell vaccines were about 60–100% (Fukumura, 1984; Sánchez et al., 2000; Martínez et al., 2004). Concerning the duration of immunity induced by killed vaccines, one study reported that the duration of immunity ranged between 6 months and 1 year at best while other studies reported a duration of at least 3 years (Babudieri, 1959; Fukumura, 1984; Chen, 1985). To maintain immunity, the French vaccine recommends a booster every 2 years and the Japanese vaccine at least every 5 years.

These vaccines (at least Japanese and French vaccine according to the product summary) must not be used during pregnancy.

Side effects of the whole cell vaccines have been reported, which included both systemic (such as fever, headaches, chill, malaise) and local reactions (such as redness, swelling, pain) at various frequencies.

Vaccines in Development

Although killed whole cell vaccines are used for prevention of human leptospirosis, there still remain several problems. In addition to issues on persistence of immunity and adverse events, the effectiveness of the killed vaccine is generally serovar-specific (Fukumura, 1984; Chen, 1985; Philip and Tennent, 1966). There are more than 230 serovars among the pathogenic leptospires. The local variability in serovars of endemic leptospiral strains complicates the development of a vaccine that can be used worldwide (Levett, 2001; Faine

et al., 1999). Thus, new vaccine strategies are directed to the exploration for antigens that can generate cross-protection against various serovars. The immunogenic proteins, especially the outer membrane surface proteins, of pathogenic *Leptospira*, may be effective as immunogens. The identification of proteins, which are conserved among pathogenic leptospires and can elicit cross-protection against various serovars, has become a major focus of leptospirosis research (see "Protein Antigens" section). Subunit vaccines would also have fewer side effects than killed whole cell vaccine. Sera from patients with leptospirosis have antibodies against several protein antigens (Naiman et al., 2002). Protein extracts prepared from a pathogenic *Leptospira* can induce protective immunity against challenge with a heterologous serovar strain in an experimental animal model (Narita et al., 2005). These data point to the potential use of leptospiral protein(s) as candidates for a new vaccine that could induce good protection against diverse serovars.

OmpL1 is a transmembrane porin (Haake et al., 1993; Shang et al., 1995), and LipL41 is a surface-exposed outer membrane lipoprotein (Shang et al., 1996). OmpL1 and LipL41 act synergistically to induce immunoprotection in a hamster model of leptospirosis, although neither of the individual proteins induces protective immunity (Haake et al., 1999). Southern and western blot analyses revealed that *ompL1* gene product and LipL41 protein were present in various pathogenic leptospiral serovars, but not in nonpathogenic leptospires (Haake et al., 1993; Shang et al., 1996). Patients with leptospirosis have antibodies against these proteins in their sera (Haake et al., 2000; Flannery et al., 2001). Whether or not these proteins will confer cross-protection against a heterologous challenge remains to be determined.

LipL32 is one of the most abundant proteins in *Leptospira* (Haake et al., 2000). LipL32 is a surface-expressed outer membrane lipoprotein that is conserved, both genetically and immunologically, in the various pathogenic leptospires (Haake et al., 2000; Cullen et al., 2005). LipL32 antigen induces the production of antibody in patients with leptospirosis (Flannery et al., 2001). LipL32 is also called hemolysis-associated protein-1 (Hap-1) showing hemolytic activity alone or synergistically with another hemolysin (Lee et al., 2000; Hauk et al., 2005). Vaccination using an adenovirus vector and plasmid vector encoding the *lipL32/hap-1* gene induced cross-protection in a gerbil model of leptospirosis (Branger et al., 2001, 2005).

Lig proteins are surface-exposed outer membrane proteins and their expression is upregulated during infection of mammalian hosts (Palaniappan et al., 2002, 2004; Matsunaga et al., 2003; Koizumi and Watanabe, 2004). The *lig* genes are present among various pathogenic, but not nonpathogenic, leptospires (Matsunaga et al., 2003; Koizumi and Watanabe, 2004; Palaniappan et al., 2004). Sera from human patients infected with different leptospiral serogroup strains reacted with Lig proteins (Koizumi and Watanabe, 2004; Croda et al., 2007). Furthermore, in a mouse model of leptospirosis, the Lig proteins elicited protective immunity against challenge, not only with the homologous serovar Manilae infection (Koizumi and Watanabe, 2004), but also the heterologous serovar Icterohaemorrhagiae (our unpublished data). Lig proteins also conferred protection against leptospiral infection in hamster model (Palaniappan et al., 2006).

The ability to rapidly determine full-length genome sequences has opened a new approach to vaccine design that may be relevant for the treatment of bacterial infections (Plotkin, 2005). The strategy of "reverse vaccinology," in which the full-length genome is "mined" by various computer algorithms, for genes that encode proteins with desired characteristics, has been applied to some bacteria and novel vaccine candidate sequences have been identified (Rappuoli, 2001; Serruto et al., 2004). The full-length genome sequences of two strains of *L. interrogans*, serovar Lai and serovar Copenhageni, and two strains of *L. borgpetersenii* serovar Hardjo have been published (Ren et al., 2003; Nascimento et al., 2004a; Bulach et al., 2006). A full-length genome analysis of serovar Copenhageni strain has been used to identify candidate antigens for a leptospiral vaccine (Gamberini et al., 2005). A total of 206 genes had been selected and 150 of them were expressed in *Escherichia coli*, purified, and used for immunoblotting with leptospirosis patient sera. A total of 16 proteins reacted with convalescent patient sera in immunoblotting. Four of the 10 proteins tested were highly conserved among different pathogenic leptospires.

The other group identified 226 genes as potential vaccine candidates against *L. interrogans* using in silico analysis (identification of genes that encode surface-exposed proteins), comparative genome hybridization (genes conserved in the 10 pathogenic leptospiral serovar strains) and transcriptional analysis (genes have high transcriptional level in vitro) (Yang et al., 2006b). Further research that evaluates the protective activity of these candidates is needed.

The availability of genome sequences of *Leptospira* also enabled investigation of the transcriptome using microarray technology. Following excretion in the urine from reservoir animals, *L. interrogans* is able to survive in the environment for weeks (Koizumi and Watanabe, 2005), and then be transmitted to humans, which involves a shift from ambient temperatures to 37°C and more and an upshift in osmolarity during the early

stage of infection. Recent microarray analyses identified the genes that are induced or repressed when *Leptospira* cultivated at 20 or 30°C is shifted to temperatures at 37 or 39°C or *Leptospira* is shifted to culture media supplemented with sodium chloride to physiologic osmolarity (Qin et al., 2006; Lo et al., 2006; Matsunaga et al., 2007). Several genes that were induced by physiological osmolarity were also upregulated by temperature shifts (Matsunaga et al., 2007). In contrast to *L. interrogans*, *L. borgpetersenii* cannot survive in nutrient poor environments and is transmitted by direct contact with *Leptospira* containing body fluids. Recent comparative genomic analysis revealed that *L. borgpetersenii* has undergone genome reduction relative to *L. interrogans* (Bulach et al., 2006). Many genes encoding environmental sensing, metabolite transport, and utilization functions are especially absent or pseudogenes in *L. borgpetersenii* but not in *L. interrogans.* Transcriptome analysis on osmolarity shift also demonstrated that genes that were repressed at physiological osmolarity were much more likely than other genes to be impaired in *L. borgpetersenii*, suggesting that physiological osmolarity is a key signal for the environment-to-host transmission (Matsunaga et al., 2007).

PROSPECTS FOR THE FUTURE

Both the mechanisms of *Leptospira* pathogenesis and nature of protective immunity against leptospiral infection are still poorly understood, in particular, due to the lack of efficient genetic tools. It has been reported that genetic transformation using a shuttle vector has been successfully undertaken, followed by gene knockouts by allelic exchange in the saprophytic *Leptospira* (Girons et al., 2000; Picardeau et al., 2001; Bauby et al., 2003). However, these techniques have not been successful for pathogenic leptospires. Although the availability of full-length genome sequences of *Leptospira* strains will be helpful for elucidating the pathogenesis of *Leptospira*, it has revealed that about 41% (serovar Lai), 31% (serovar Copenhageni), and 23% (serovar Hardjo) of the total genes in *Leptospira* encode unique hypothetical proteins that do not show homology with any other bacterial proteins (Ren et al., 2003; Nascimento et al., 2004a, 2004b; Bulach et al., 2006). To analyze the function of these *Leptospira* specific gene products, it is essential to develop genetic analysis tools for pathogenic leptospires. More recently, Bourhy et al. (2005) showed that the *Himar1 mariner* transposon permits random mutagenesis in pathogenic *Leptospira*. This technique will accelerate the identification of virulence factors as well as our understanding of the pathogenesis of leptospires. As new information evolves, insights will be gained into ways to improve existing, and develop effective new, vaccines for leptospirosis.

KEY ISSUES

- Leptospirosis is a globally important zoonotic disease that affects humans in both rural and urban settings, and in both industrialized and developing countries. Large outbreaks of leptospirosis occur especially in Asia and Latin America.
- The effectiveness of currently available vaccines is generally serovar-specific. Thus, new vaccine strategies are directed to the exploration for antigens that can generate cross-protection against various serovars.
- The availability of full-length genome sequences and genetic tools of pathogenic *Leptospira* will open new ways to elucidate the pathogenesis of *Leptospira* and immune mechanism(s) against leptospiral infection, as well as to develop a new effective vaccine for leptospirosis.

Malaria

Thomas L. Richie and Falgunee K. Parekh
U.S. Military Malaria Vaccine Program, Naval Medical Research Center/Walter Reed Army Institute of Research, Silver Spring, MD, USA

OUTLINE

ABSTRACT

Malaria is the most important parasitic disease with its vast distribution across the tropics and subtropics, immense public health burden, and tremendous economic impact on affected populations. Efforts to control malaria are being conducted on multiple fronts including vector control through residual house spraying, distribution of insecticide-treated bednets and improved diagnosis and treatment, including the development of new drugs and drug combinations effective against resistant strains. Despite these efforts, malaria remains prevalent in at least 87 countries with approximately 40% of the world's population living at risk; the greatest burden of malaria falls on young children with one child dying from malaria every 30 s. Civil disturbance, inadequate health infrastructure,

and poverty contribute to the lack of effective control. Experience with other infections such as smallpox, measles, and polio demonstrates that vaccines can be a highly effective and cost-efficient method of controlling an infectious agent with global impact.

The complexity of the malarial parasite has made the task of developing an efficacious vaccine difficult. Malaria is a vector-borne disease caused by a protozoan parasite of the genus *Plasmodium*, and transmitted by the bite of an *Anopheles* mosquito. The *Plasmodium* parasite has a complex life cycle with multiple stages, differential expression of antigens with each stage, and a high degree of antigenic variability. Additionally, unlike smallpox, measles, and many other infectious agents, protective immunity develops slowly, requires repeated infections, is never strong enough to prevent reinfection, and is quickly lost in the absence of exposure. Despite these challenges, there are two models of immunity that support the feasibility of developing a malaria vaccine: (1) immunization with radiation-attenuated sporozoites, which induces sterile protection against the sporozoite and liver stages of the parasite and (2) naturally acquired immunity, which is characterized by partial protection against the asexual blood stages. These models provide the basis for many of the malaria vaccine candidates currently under development, including vaccines designed to prevent infection (targeting sporozoite and liver stages) or to prevent disease (targeting blood stages). In addition, the sexual stages of the parasite can be targeted by vaccines designed to prevent transmission, an intriguing approach aimed at communitywide as opposed to individual benefit.

Currently, over 50 malaria vaccine candidates have reached various stages of clinical development. Most are subunit vaccines based on one or few antigens, and target one particular stage of the parasite life cycle. The subunit vaccines are constructed using a variety of platforms, including synthetic peptides or recombinant protein in adjuvant, viral vectors, DNA plasmids, and prime-boost combinations of these platforms. As it has become more apparent that a single antigen may not be sufficient to induce strong protective immunity against such a complex organism, a multiantigen, multistage approach is also being explored. More recently, there is focus on the attenuated whole parasite approach, which precludes the need to identify the antigens or immune mechanisms associated with protection.

This chapter will provide a summary of the history, biology, epidemiology, and clinical pathology of this important disease, and will then review progress in developing an effective malaria vaccine for widespread use.

INTRODUCTION

Malaria is the most important parasitic disease in the world, taking into account its global distribution, the number and severity of infections, and the appalling public burden. With an annual worldwide incidence exceeding 600 million clinical cases caused by the two most common malaria species, *Plasmodium falciparum* and *P. vivax* (Mendis et al., 2001; Snow et al., 2005), leading to 1.1–2.7 million deaths (attributable primarily to *P. falciparum*) (World Health Organization, 2005), malaria causes great suffering among people living in tropical and subtropical regions, with a disproportionate impact on infants, children, and pregnant women (Abdullah et al., 2007). Malaria is endemic in at least 87 countries, notably much of sub-Saharan Africa and large areas of Latin America, South Asia, Southeast Asia, and the Western Pacific, currently inhabited by at least 40% of the world's population, placing 2.5 billion people at risk (Guerra et al., 2006, 2007, 2008; Hay et al., 2004) (Fig. 65.1). Sub-Saharan Africa experiences the greatest impact, with adverse effects on health, economic development, and educational achievement (Fernando et al., 2003; Gallup and Sachs, 2001; Kihara et al., 2006; Sachs and Malaney, 2002; Worrall et al., 2007). In this region, malaria has been estimated to directly or indirectly decrease the gross domestic product by 1–5% (Gallup and Sachs, 2001; Sachs and Malaney, 2002). Malaria also poses a threat to travelers, often constituting the most significant health risk for those visiting malarious areas, whether via international or within-country travel (Richie, 2004). Development projects relying on the influx of personnel from nonmalarious areas can be compromised, contributing to the economic burden. As an added concern, coinfection with malaria can adversely influence the severity of other pathogens, such as HIV, and vice versa (Abu-Raddad et al., 2006).

Although the application of control measures such as insecticide-treated bednets and residual insecticide spraying, and the introduction of efficacious new drug regimens such as artemisinin combination therapies (ACTs) can significantly reduce the burden of malaria in a given community (Bhattarai et al., 2007; Bosman and Mendis, 2007; Rieckmann, 2006), historically such interventions have proven difficult to sustain. This is due to a variety of causes, including costs, poor public health infrastructure, civil disturbances, the development of insecticide resistance by the vector, and drug resistance by the parasite. As exacerbating forces, climate change or environmental disruptions can create more favorable habitats for mosquito breeding, leading to the expansion of vector populations into regions

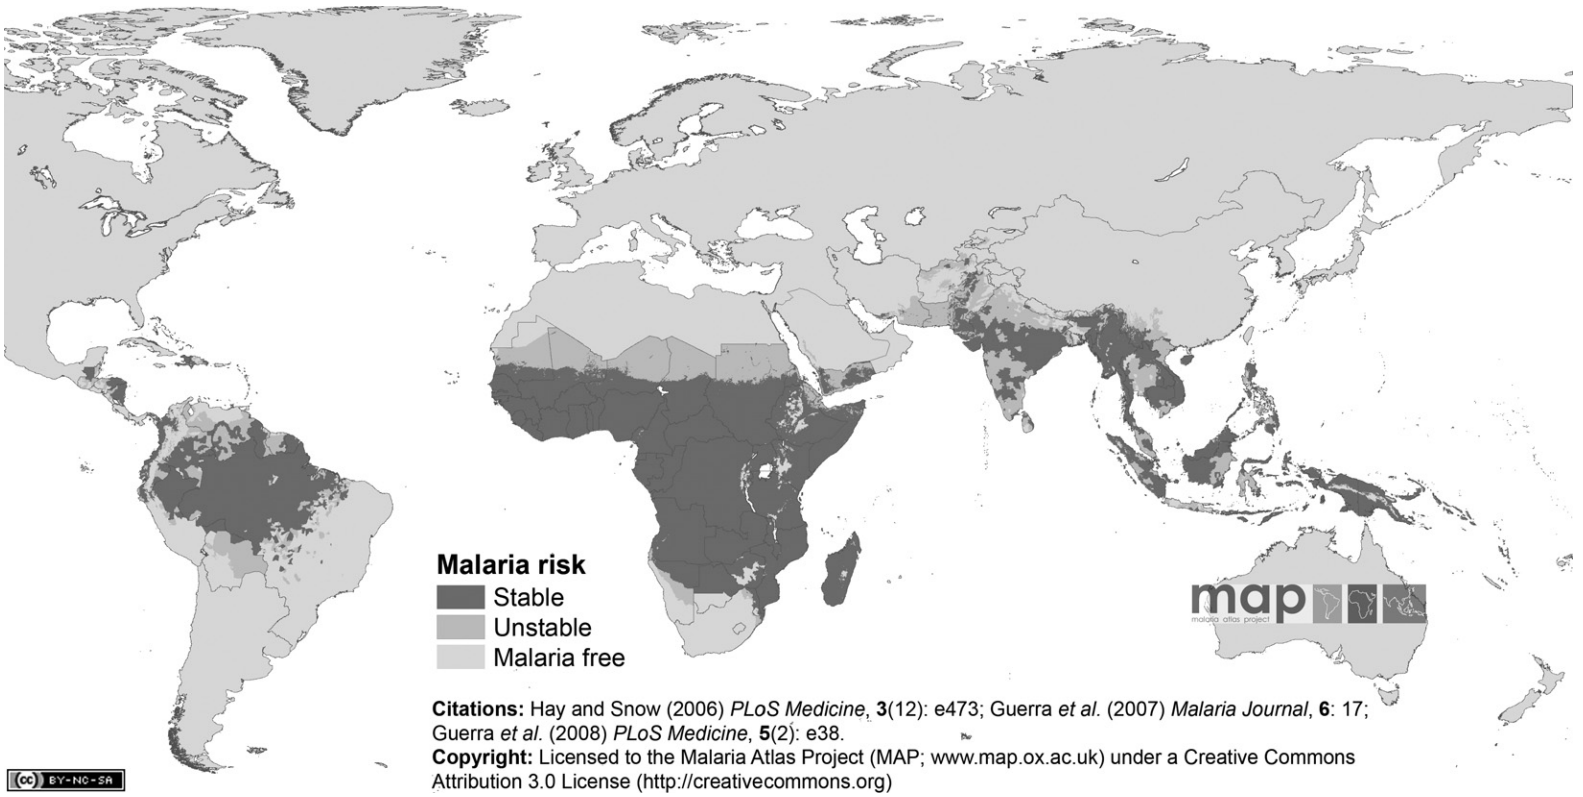

FIGURE 65.1 Global risk of *P. falciparum* malaria. The map is derived from nationally reported case-incidence data, medical intelligence, and temperature and aridity boundaries for the dominant *Anopheles* vectors, with risk expressed as the number of people infected per 1000 per annum (the annual parasite incidence, or API) (Guerra et al., 2008). Dark shading indicates stable malaria (API $>$ 0.1 per 1000 per annum), intermediate shading indicates unstable malaria (API $<$ 0.1 per 1000 per annum), and light shading indicates no risk. The distribution of *P. vivax* adds additional countries, particularly in subtropical regions, including areas well outside the tropics such as Korea (data not shown). Reprinted with permission from PLoS Medicine. (Guerra et al., 2007, 2008; Hay and Snow, 2006). of irrigation or higher altitudes (Afrane et al., 2006; Githeko et al., 2006). For these reasons, a strongly protective, long-lasting malaria vaccine would provide an extremely cost-effective intervention, and is therefore considered an urgent international health priority. The ongoing efforts to create a vaccine constitute one of the great public health enterprises of our time.

Preventing malaria through immunization is a fascinating biomedical challenge, and has drawn scientists from many disciplines and spawned major achievements, including the sequencing of the *P. falciparum* genome (Gardner et al., 2002) as well as the genomes of several other *Plasmodium* species (Hall et al., 2005), the establishment of online databases containing extensive genomic, transcriptomic, and proteomic information (Di Girolamo et al., 2005; Le Roch et al., 2003; Winzeler, 2006; Zhou et al., 2008) and the development of large reagent repositories (Adams et al., 2000). Great progress has been made elucidating, at the molecular level, the biology and antigenic structure of this complex parasite (Conway, 2007; Cowman and Crabb, 2002). After decades of effort, however, a licensed vaccine is still not available and the leading candidate in development is only modestly effective. This chapter will provide a synopsis of the history, biology, epidemiology, and clinical expression of this important disease and then will review the progress being made toward developing an effective malaria vaccine for widespread use.

HISTORY

Malaria has most certainly been afflicting humans for centuries. Early medical writings from India, China, and Assyria described illnesses characterized by intermittent fevers (Cox, 2002). The early writings of the Sumerians, the first civilization that settled between the Tigris and Euphrates rivers, frequently described fevers typical of malaria (Desowitz, 1991). Around the same time, the Chinese medical volume dated from 2700 B.C., the Nei Ching, provided an account of tertian and quartan fevers, and accurately described the spleen enlargement that often follows. The Nei Ching purported that these fevers were caused by an imbalance of the Yin and Yang, and prescribed medicinal plants as cures (Cox, 2002; Desowitz, 1991). Around 1600 B.C., the Hindu epic religious texts, the Vedas, provided records of fevers that caused severe illness and death, suggesting that malaria was prevalent in India at that time (Desowitz, 1991). Hippocrates, in the fifth century B.C., accurately described clinical manifestations of malaria including the tertian and quartan fevers and the enlarged, stiff spleens (Cox, 2002; Desowitz, 1991). Hippocrates speculated that this illness was caused by an external agent, particularly the vapors and mists coming from the marshes. Indeed, the name of this disease, malaria (mal means bad; aria is air), which was adopted in the mid-eighteenth century, reflects this belief that malaria was caused by a miasma rising from the swamps in the environs of Rome. This observation was made when travelers from the city developed the telltale signs of the infection within a week or two of visiting the countryside. The theory that malaria was caused by evil air rising from marshy waters was further supported by repeated observations of a decline in malaria cases after draining of swamps (Desowitz, 1991).

Despite the assortment of historical texts describing this distinct illness over the centuries, it was not until 1880, when Alphonse Laveran first observed the crescent-shaped gametocyte of *P. falciparum*, the causative agent of falciparum, or malignant tertian malaria, that the true etiologic agent was discovered (Bruce-Chwatt, 1987; Desowitz, 1991). From the blood of a feverish soldier stationed in Algeria, Laveran discerned several different morphologies of the malarial parasite, including "crescent-shaped bodies" (the gametocytes of *P. falciparum*), "rounded bodies with dancing/lashing surface filaments" (the exflagellating male gametocyte), and "ring-like hyaline bodies" within red blood cells (ring stages) (Desowitz, 1991). Finally, in the 1890s, Ronald Ross and Battista Grassi proved that the gametocytes are taken up by the female *Anopheles* mosquito during a blood meal, thereby demonstrating the route of transmission of this deadly infection (Desowitz, 1991).

ETIOLOGIC AGENTS

Classification

Malaria is a vector-borne disease caused by a protozoan parasite of the genus *Plasmodium*, transmitted by the bite of a female *Anopheles* mosquito. Of the numerous species of *Anopheles* occurring worldwide, approximately 60 are involved in malaria transmission (Oaks et al., 1991). Because of the nocturnal habits of the *Anopheles* mosquito, malaria is transmitted between the hours of dusk and dawn. The *Plasmodium* parasites belong to the protozoan Order Apicomplexa, which includes other pathogens such as Babesia, Toxoplasma, and Cryptosporidium. Apicomplexa are morphologically distinguished by the presence of a specialized complex of apical organelles (micronemes, rhoptries, and dense granules) involved in host-cell

invasion (Binder and Kim, 2004; Cowman and Crabb, 2006). There are scores of species of *Plasmodium* that infect a wide variety of hosts (e.g., reptiles, amphibians, birds, and a variety of mammals including nonhuman primates (NHPs)), but only four that primarily or exclusively infect humans: *P. falciparum*, *P. vivax*, *P. malariae*, and *P. ovale* (Fig. 65.2). A fifth species, *P. knowlesi*, resides in NHPs but can be transmitted to humans and has been recognized as an important zoonotic infection in parts of Malaysia (Cox-Singh et al., 2008; Vythilingam et al., 2006). The human malarias are thought to have originated in Southeast Asia from simian species, from where they spread to Africa and Europe (Cox, 2002). Malaria was probably introduced into the Americas in the sixteenth century, and was a significant public health problem in the USA through the first half of the twentieth century until its eradication in 1951.

Plasmodium Life Cycle

The life cycle of *Plasmodium* is shown in Figs 65.2 and 65.3. The infection begins when sporozoites (Fig. 65.2A) are injected into cutaneous or subcutaneous tissue or directly into microvessels of the blood or lymphatics with the saliva of the feeding mosquito (Jin et al., 2007). Sporozoites deposited into interstitial spaces disperse rapidly using a gliding motility and are able to identify and enter blood vessels. Movies of this process, made using intravital cinematography, can be seen online (Vanderberg and Frevert, 2004). The circulatory system carries the sporozoites to the liver, where they invade hepatocytes. Recent evidence suggests that sporozoites initially penetrate the cell membranes of several cells, first Kupffer cells then multiple hepatocytes, passing through the cytosol and exiting again, leaving behind components of their surface coat and sometimes destroying the hepatocyte on traversal (Ishino et al., 2004; Mota et al., 2001). Movies of this process are likewise available on the Internet (Frevert et al., 2005).

After the unexplained migration, which results in a local inflammatory response and the presentation of surface coat antigens to the immune system (Bongfen et al., 2007), sporozoites invade their host hepatocyte nondestructively, by inducing an invagination of the cell membrane, resulting in the formation of a parasitophorous vacuole within which the sheltered parasite can obtain nutrients from the host cell as well as from the interstitial fluids beyond. After increasing many-fold in size, the parasite undergoes asexual (clonal) replication, known as exoerythrocytic schizogony, whereby it divides into thousands to tens of thousands of merozoites, depending on the species (approximate range 2000–40,000) (Fig. 65.2B). When the nuclear and cytoplasmic division processes are complete, merozoites are released into the circulation. It has recently been shown in the murine malaria species, *P. berghei* and *P. yoelii*, that merozoites may be released in membrane-bound packets called merosomes or extrusomes, which potentially circumvent phagocytic cells in the liver as well as neutralizing antibodies (Baer et al., 2007; Sturm et al., 2006).

Liver stage development is generally completed in 5–14 days, with some variation by species. For *P. falciparum* and *P. malariae*, all parasites complete development, and merozoite progeny are directly released into the bloodstream. The liver stage parasites from *P. vivax* and *P. ovale*, however, can enter a state of dormancy (hypnozoite forms), reactivating weeks, months, or years later to complete development, leading to *relapse* of the blood stage infection. Remarkably, a relapse of *P. ovale* has been recorded 4 years after primary infection (Trager and Most, 1963). In some areas, such as Korea, the hypnozoite life form has enabled *P. vivax* to adapt to seasonal climates where cold winter eliminates the activity of the vector; the parasite remains dormant for several months, emerging the following spring when renewed vector activity permits transmission. These relapses are to be contrasted with *recrudescences*, which occur regularly with all species of human malaria and constitutes new waves of blood-stage parasites originating from subpatent populations of blood-stage parasites. Relapse and recrudescence both cause recurrent parasitemia in *P. vivax* and *P. ovale*, and can be difficult to distinguish, whereas only recrudescences cause recurrent parasitemia in *P. falciparum* and *P. malariae*.

Merozoites released into the bloodstream invade erythrocytes. Protein products of the apical organelles of the parasite (rhoptries, micronemes) engage receptors on the erythrocyte membrane propelling invagination and, as in the liver, formation of a parasitophorous vacuole (Charpian, 2008) (Fig. 65.4). Once inside the erythrocyte, parasites enter a second trophic period in which the parasite enlarges, similar in nature but not as long lasting as the trophic period in the liver. The early trophozoite is known as the ring form because of its unique ring-shaped morphology (Fig. 65.2C, D). The enlargement of the trophozoite is accompanied by the ingestion of erythrocyte cytoplasm and the proteolysis of hemoglobin. A by-product of this metabolism, hemozoin, accumulates as refractile, pigmented granules visible within the infected erythrocyte and within macrophages that have ingested erythrocyte debris (Egan, 2007; Goldberg, 1993; Hanscheid et al., 2007). The enlarging trophozoite undergoes clonal nuclear divisions,

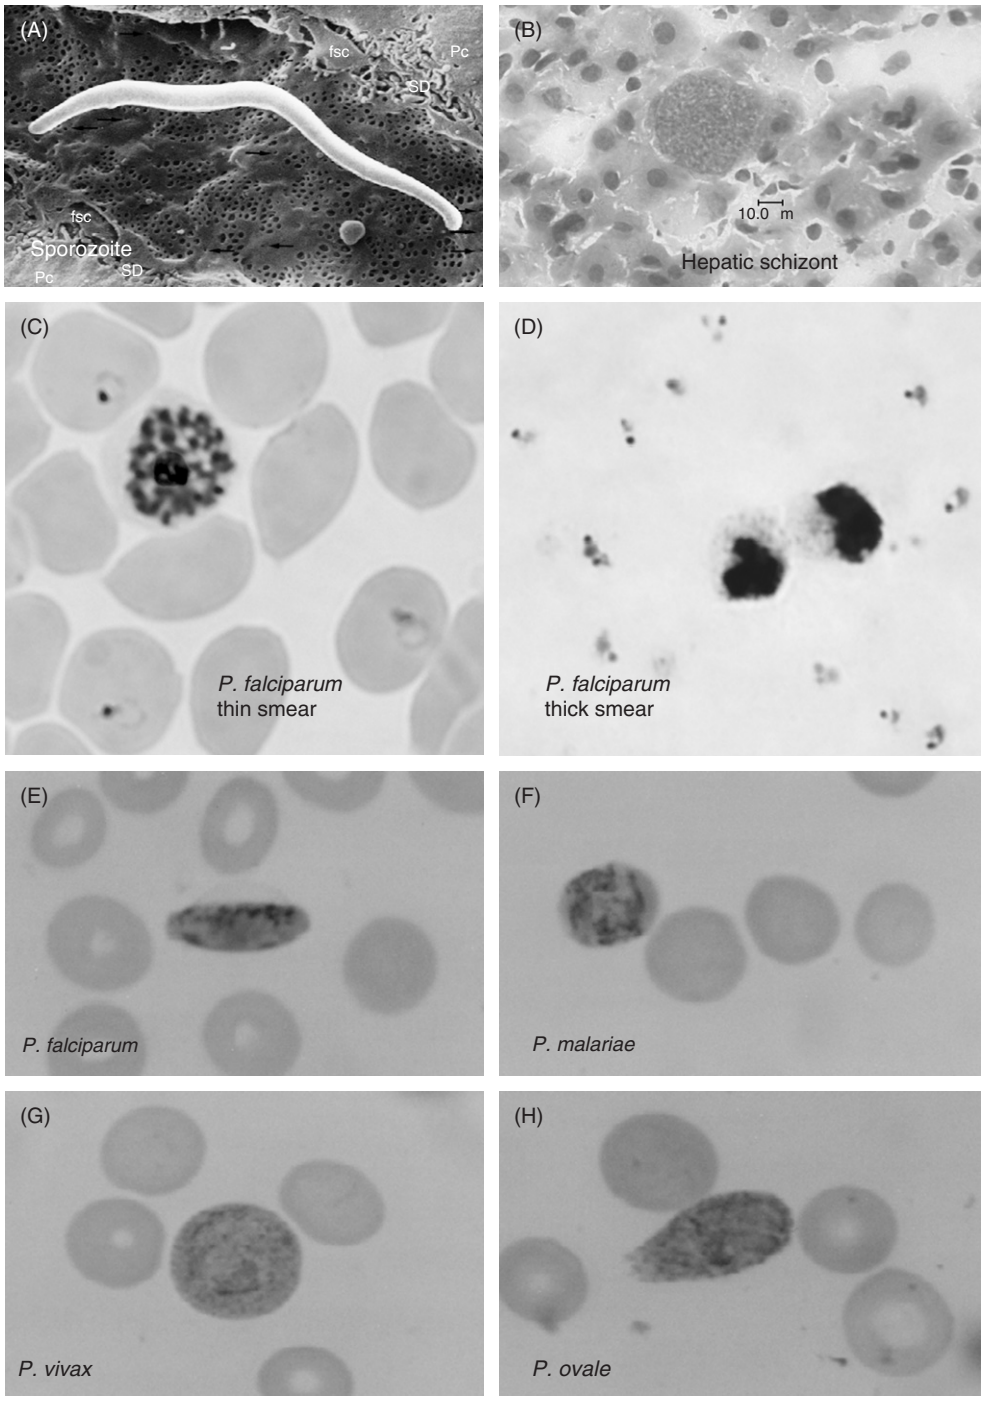

FIGURE 65.2 The malaria parasite. (A) Scanning electron micrograph of a *P. cynomolgi* sporozoite superimposed on SEM of liver sinusoidal sieve plates; parasite is approximately 10μm in length (photograph composite by Ute Frevert; http://www.med.nyu.edu/parasitology/faculty/ufrevert.html) (Cochrane et al., 1976; Wisse et al., 1985). (B) Hematoxylin and eosin stain of 6-day old *P. falciparum* schizont in chimpanzee liver surrounded by normal-appearing parenchyma; 40μm diameter (can range to 80μm) (10μm bar) (photograph by John Sacci). (C), (D) Giemsa stain of thin smear and thick smear of *P. falciparum* blood culture, showing ring-infected erythrocytes; erythrocytic stage schizont is seen on the left with individual merozoites ready for release; this form normally not seen in peripheral blood due to cytoadherence and sequestration (photographs by Ted Hall). (E)–(H) Giemsa stain of characteristic erythrocytic stages of *P. falciparum* (banana-shaped gametocyte), *P. malariae* (band-shaped trophozoite in a normocyte), *P. vivax* (large amoeboid trophozoite in a reticulocyte with Schuffner's dots in the erythrocyte cytoplasm), and *P. ovale* (fibrionated edge to the parasitized oval erythrocyte, also with Schuffner's dots), from a child with quadruple infection (photographs by Purnomo) (Purnomo et al., 1999).

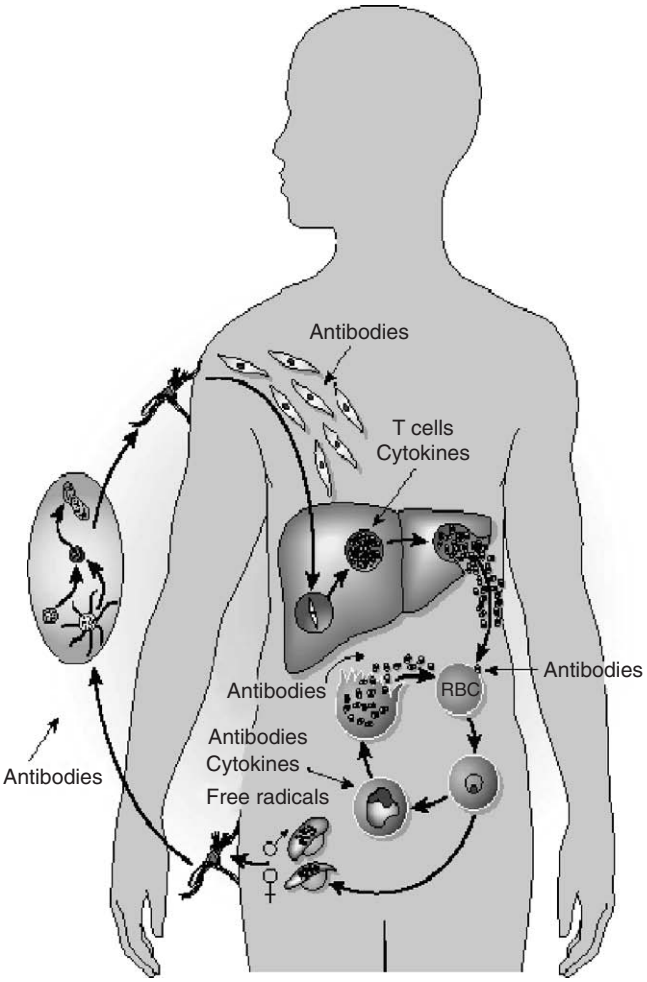

FIGURE 65.3 *Plasmodium* life cycle. Parasite morphology, mobility, host-cell specificities, patterns of protein expression, and resulting immunologic vulnerabilities vary from stage to stage. The induction of antibodies is particularly important for vaccines targeting sporozoites, the induction of cell-mediated immune responses for targeting liver stages, and the induction of both antibodies and antibody-dependent cytotoxic responses for targeting blood stages. The ideal vaccine will induce all these responses against multiple stages. The depiction of the life cycle in the insect vector is simplified; see text for details. Reprinted by permission from Macmillan Publishers Ltd (Richie and Saul, 2002).

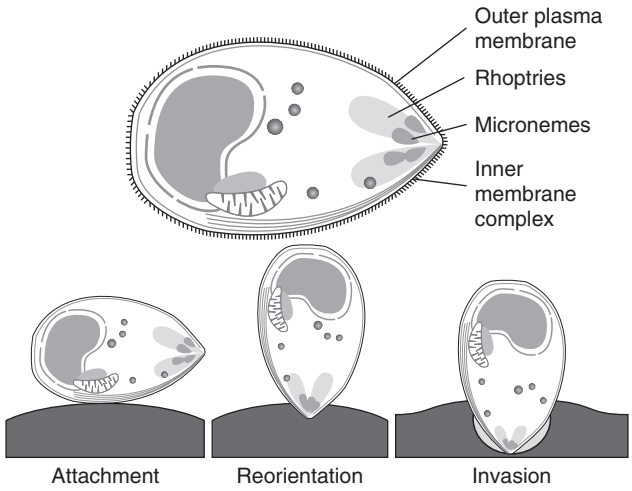

FIGURE 65.4 Merozoite invasion of erythrocyte. This figure illustrates a functionally critical element of host-parasite biology—the invasion of the erythrocyte. The interaction begins with low-affinity binding between the surfaces of the two cells, followed by apical reorientation powered by an actin–myosin motor. Once the apical end contacts the erythrocyte surface, a tight junction is formed utilizing a different set of parasite proteins secreted from the apical organelles. This junction migrates circumferentially along the merozoite, leading to invagination and shedding of the merozoite surface coat. Finally, the erythrocyte membrane reseals, leaving the parasite encased in the parasitophorous vacuole. The entire process takes about 30 s. The secretion of key parasite proteins *after* the apical end is juxtaposed may obstruct access by antibodies, making it difficult to block the process. At least 48 proteins are associated with the merozoite surface and apical organelles (Cowman and Crabb, 2006), including MSP1, AMA1, and EBA175. Reprinted with permission from Alan Cowman, Brendan Crabb, and Jake Baum (http://www.wehi.edu.au/facweb/indexresearch.php?id = 16).

generating a blood-stage schizont (Fig. 65.2C), which releases merozoites when the erythrocyte ruptures. *P. falciparum* or *P. vivax*, each produce approximately 5–40 merozoites per schizont (depending on the species), leading to logarithmic expansion of the parasite population.

Most of these parasite progeny will again undergo asexual growth and schizogony, the cycle lasting 48 h for *P. falciparum*, *P. vivax*, and *P. ovale*, 72 h for *P. malariae*, and 24 h for *P. knowlesi*. However, a proportion develops into the sexual forms of the parasite—micro- and macrogametocytes—which are targeted for ingestion by a female *Anopheles* mosquito. Conversion to gametocytes differs by species, *P. vivax* developing gametocytes soon after release from the liver stage, *P. falciparum* developing gametocytes after several days (Mota et al., 2001; Weatherall et al., 2002).

The ingestion of the gametocytes by the mosquito induces gametogenesis, which consists of exflagellation of the microgametocyte, further development of the macrogametocyte into the macrogamete, and fertilization of the macrogamete by the motile microgamete, all taking place in the mosquito midgut. The now diploid zygote develops into a motile ookinete that traverses the intestinal wall and transforms into an oocyst on the external gut surface. Within the oocyst, the parasite undergoes multiple rounds of asexual replication, including reductive divisions restoring the haploid state (Sinden, 1991). The oocyst releases

thousands of sporozoites, which travel through the insect hemocoel to the salivary glands. After penetrating the salivary glands and entering the lumen, they are ready to be injected into another human host. The duration of the sporogonic cycle varies by species and is temperature-sensitive, but may typically take 14–18 days.

Antigens Encoded by Plasmodium

Proteins on the sporozoite surface, including the circumsporozoite protein (CSP) and the thrombospondin-related adhesion protein (TRAP) (Roussilhon et al., 2007) (also called the sporozoite surface protein 2, or SSP2) enable gliding motility, invasion of hepatocytes (binding to heparin sulfate proteoglycans), and additional functions (Garcia et al., 2006; Sibley, 2004; Sinnis and Coppi, 2007; Sinnis and Nardin, 2002). Many additional proteins are likely expressed on the sporozoite surface. Following hepatocyte invasion, additional proteins, such as liver stage antigen 1 (LSA1), UIS3 (UIS, upregulation in sporozoites) and UIS4 are newly expressed or expressed in greater quantity. These liver stage proteins play hundreds of roles in the complex interaction between parasite and host, permitting the breakdown of host-cell structure, the establishment of a new architecture, and the uptake of nutrients from outside the cell. These events occur through the interface of the parasitophorous vacuole membranes as well as through various channels and pores.

Rapid progress is now being made functionally characterizing preerythrocytic stage (sporozoite plus liver stage) proteins by using the technique of targeted genetic disruption (gene knockout) (D'Ombrain et al., 2007; Labaied et al., 2007; Mueller et al., 2005a). Absence of a particular protein may halt development at a certain stage, and the morphological and molecular characteristics of these arrested parasites provide information regarding the role of the missing molecule.

As hepatic stage schizonts mature, erythrocyte proteins are expressed. Merozoite surface molecules are involved in the attachment, apical reorientation and invasion of erythrocytes (Fig. 65.4), including several merozoite surface proteins (MSPs), the apical membrane antigen 1 (AMA1) and the erythrocyte-binding antigen 175 (EBA175), all leading vaccine candidates. Key invasion proteins may be secreted after completion of reorientation of the parasite and approximation of the apical organelles with the erythrocyte membrane. This last-minute release lessens the accessibility of plasma and thus the susceptibility to antibody attack. Invasion itself is an active process characterized by a ring of attachment that migrates up the oval cylinder of the merozoite, pulling/pushing it into the expanding parasitophorous vacuole. Once within the erythrocyte, additional proteins are expressed to mediate nutrition and growth, and a system of channels and pores develops, as within the hepatocyte (Merckx et al., 2008). Of particular interest are the antigens expressed on the surface of the infected erythrocyte, some of which are highly immunogenic and elicit antibody responses that limit parasite replication. The best studied erythrocyte surface protein is *P. falciparum* erythrocyte membrane protein 1 (PfEMP1), encoded by approximately 50–60 different genetic loci within the parasite genome (*var* gene family). By expressing alleles in sequence on knobby protruberances appearing on the surface of infected erythrocytes during the late trophozoite/schizont stages, PfEMP1 undergoes antigenic variation, and this is likely an important factor responsible for the successive, recrudescent waves of parasitemia that characterize malarial infection. PfEMP1 is also one of the molecules responsible for sequestration of mature blood stages in the microvasculature (see "Pathogenesis" section below).

The final stage of the parasite, the gametocyte, expresses its own set of proteins in preparation for ingestion by the mosquito and the subsequent sudden change of environment resulting from transition from human blood to the mosquito midgut (Kooij and Matuschewski, 2007; Matuschewski and Mueller, 2007). Mature gametocytes appear relatively silent metabolically and immunologically, circulating in the blood and possibly arresting in skin microvessels (Gautret et al., 1996) until ingested by the vector.

PROTECTIVE IMMUNE RESPONSES

SSPs are considered to be potential targets for antibody responses, and indeed, sporozoites coated with antibodies recognizing CSP are immobilized, leading to a process called the circumsporozoite reaction whereby the surface coat is shed (McCarthy and Clyde, 1977; Vanderberg et al., 1969). Videos of this process can be viewed on the Internet (Vanderberg and Frevert, 2004). Antibody-mediated attack is thus a potential mechanism for vaccine-induced immunity during the first minutes following inoculation by the mosquito, offering an opportunity to disrupt gliding motility and thus immobilize the sporozoites in the skin or block the ligand-receptor binding required for hepatocyte invasion. Once the sporozoite has successfully entered a host hepatocyte, the ability of

antibodies to affect development is restricted, although there is evidence that antibodies to antigens such as LSA1 and EXP1 expressed by liver stage parasites may nevertheless be associated with protection in endemic settings (John et al., 2008; Meraldi et al., 2004).

In the liver, cell-mediated immunity emerges as the primary protective response, as demonstrated by the transfer of protection in conjunction with the adoptive transfer of splenocytes recognizing sporozoite and liver stage antigens (Khusmith et al., 1991, 1994, Rodrigues et al., 1991). Protection results from the recognition by lymphocytes of parasite molecules expressed on the surface of infected hepatocytes in the context of Class I MHC molecules. The parasite is killed by CD8+ cytotoxic T lymphocytes (CTL) or through the induction of nitric oxide triggered by interferon-gamma, with both CD8+ and CD4+ T cells playing a role (Doolan and Martinez-Alier, 2006). In addition, natural killer cells may contribute to protection (Hansen et al., 2007).

During liver stage development, parasites are relatively few in number (likely less than 100) and restricted to a single organ, whereas blood stage parasites occur in billions and circulate throughout the body. Thus, the liver stage provides a window of opportunity for completely aborting the infection. For this reason, many vaccine developers are focused on targeting liver stage antigens and inducing potent cell-mediated immunity (Hill, 2006b). Ideally, vaccines will induce both antibody- and cell-mediated responses thereby targeting both sporozoites and liver stages, to provide high-grade resistance to infection (Schofield et al., 1987).

After release from hepatocytes, the parasite enters the blood and is again susceptible to antibody attack. Merozoite surface proteins are considered prime candidates for inclusion in vaccines and in fact comprise the majority of vaccines in development. Antibodies to these proteins can prevent merozoite adherence, apical reorientation, and invasion of the erythrocyte, an effect measured in vitro through growth inhibition assays (Bergmann-Leitner et al., 2006; Miura et al., 2007b). Following erythrocyte invasion, parasite proteins expressed on the surface of the erythrocyte represent another target, and antibodies could potentially interrupt nutrient uptake or cytoadherence (see "Pathogenesis" section below). Parasitized erythrocytes have decreased deformability, and if prevented from sequestering in postcapillary venules through antibody-mediated reversal of cytoadherence are subject to removal from circulation by splenic macrophages and other immune cells of the reticuloendothelial system. Antibodies recognizing surface-expressed parasite proteins can also facilitate parasite killing through antibody-dependent cellular cytotoxicity (ADCC) (e.g., IgG1 or IgG3) (Bouharoun-Tayoun et al., 1990, 1995).

The effect of antibodies targeting blood-stage proteins has been demonstrated in vivo, through the transfusion of immunoglobulin purified from semi-immune human adults to children with acute malarial infection. The children experience clinical improvement and a reduction in the number of circulating parasites (Bouharoun-Tayoun et al., 1990; Sabchareon et al., 1991). It has been more difficult to demonstrate a dominant role for cell-mediated immunity in blood stage infection in vivo (Kumar and Miller, 1990; Weidanz et al., 1990). One supportive finding is the protection observed in humans following immunization with a whole parasite blood stage vaccine, which appeared to be associated with cell-mediated immune responses in the absence of detectable antibody (Pombo et al., 2002).

Another protective mechanism targeting blood stage infection is the potential neutralization of malarial toxins released from infected erythrocytes at the time of rupture. Parasite-derived molecules, such as the glycosylphosphatidylinositol (GPI) sequences that anchor many membrane-bound parasite proteins, have pyrogenic and other toxic properties. It is hypothesized that a significant component of naturally acquired immunity (NAI) is derived from the ability of antibodies to neutralize malarial toxins (Schofield et al., 1987, 2002). Although targeting malarial toxins released on schizont rupture might not limit parasite multiplication, it could lessen the clinical expression of the infection by curtailing cytokine release and other inflammatory events.

Finally, antibodies may potentially play a role in preventing sporogony in the mosquito gut. Antibodies induced by a vaccine containing gamete or gametocyte proteins normally not expressed or not exposed in the human host can be passively imbibed by a feeding mosquito, and then attack the parasite proteins newly expressed or newly exposed in the mosquito gut. This can be demonstrated in an in vitro/in vivo model in which human blood harboring gametocytes is used for membrane feeding by mosquito vectors. When the mosquito guts are examined several days later, oocyct numbers can be reduced if an antibody targeting various sexual stage proteins is added to the blood prior to its ingestion (Arevalo-Herrera et al., 2005; Miura et al., 2007a). This has given rise to the search for a transmission-blocking vaccine, which would benefit a given vaccine recipient not through protection against infection but by reducing transmission throughout the community (see "Transmission-Blocking Vaccines" section below).

EPIDEMIOLOGY

Significance as a Public Health Problem

Worldwide, *P. vivax* and *P. falciparum* are the most common of the four human malarias. Both are prevalent throughout much of the tropical regions of South and Southeast Asia, the Western Pacific and Latin America, with *P. vivax* often the predominant species. In sub-Saharan Africa, however, *P. falciparum* nearly always predominates. This is particularly true in West Africa where *P. vivax* may be virtually absent due to the high prevalence of the Duffy negative phenotype, which precludes erythrocyte invasion by *P. vivax* (see "*P. vivax* Vaccines" section below). *P. malariae* is also widespread across the tropics, often occurring in sympatry with other species and occasionally found to be the predominant species. *P. ovale* has the most limited distribution; occurring in sub-Saharan Africa, in the region of New Guinea and in parts of the Philippines and Southeast Asia (Carter and Mendis, 2002; Collins and Jeffery, 2005; Lysenko and Beljaev, 1969).

Malaria epidemiology can be characterized by several indices, two of the most important being the prevalence of malarial infection, determined as the number of positive blood smears relative to the number examined (often separately determined by age group), and the incidence of malarial infection, measured as the rate of acquiring new infections. The latter is formally measured by tallying new-onset parasitemia in cohorts of drug-cleared volunteers followed prospectively for a defined period, but as this is labor intensive, costly, and entails risks for the volunteers, incidence is usually approximated by the easier-to-measure, closely related entomologic inoculation rate (EIR), which is the number of infective bites received per person per year (Beier et al., 1994). This is calculated by capturing human-landing mosquitoes during nocturnal surveys and determining the proportion that harbor sporozoites.

The need to provide a general classification of malaria burden in a given geographic area has led to distinguishing different levels of endemicity, focusing on prevalence: hypoendemic areas have a prevalence less than 10% and lower EIRs/transmission rates; mesoendemic areas have a prevalence ranging from 11% to 50% and moderate EIRs/transmission rates, while hyperendemic areas show a prevalence of 50% or more and have higher EIRs/transmission rates. In some classification systems, spleen rates in young children have been incorporated into the determination of endemicity but this system is not used commonly at the present time.

The conduct of point prevalence surveys to measure prevalence, of prospective cleared-cohort studies to measure incidence or of nocturnal mosquito landing collections to measure EIR can be impractical for characterizing the malaria burden across a nation. As a result, countrywide data are usually assembled by determining the annual parasite incidence (Branch et al., 2005) defined as the annual number of parasite-specific local malarial infections by geographic unit (Guerra et al., 2006, 2007, 2008). API figures are based on available medical intelligence, usually febrile malaria cases reported from health clinics supplemented with the results of surveys where blood smears are taken from residents with fever. API emphasizes clinical malaria and provides less information on the potentially large number of asymptomatic infections that may be present. It is useful as a surveillance technique for monitoring increasing or decreasing trends in the burden of malaria.

Another approach to characterizing malaria epidemiology focuses on the continuity of transmission and resulting patterns of clinical immunity, defining three categories: (1) stable malaria (2) unstable malaria, and (3) epidemic malaria (Carter and Mendis, 2002). Superimposed on this is the seasonality of transmission, which usually reflects patterns of rainfall. In stable malaria, a population is exposed to a fairly constant rate of malarial infection throughout the year, with at least one clinical infection experienced by most individuals on an annual basis. In these regions, regular exposure to infection allows for the development of naturally acquired protective immunity (Hviid, 2005; Schofield and Mueller, 2006). The risk of clinical malaria in these regions is therefore age-dependent, with the greatest morbidity occurring in infants and young children (<5 years) who have had few exposures to infection and whose ability to mount an effective immune response may be limited, relative to adults, by age-dependent differences in the immune system (Reyburn et al., 2005; Schofield and Mueller, 2006). In contrast, teenagers and adults, although frequently infected, experience clinical malaria less frequently, and when they do, the symptoms are usually mild. This protected state in older children and adults, called naturally acquired immunity (NAI), is characteristic of the high transmission areas of sub-Saharan Africa. However, the development of an effective protective immunity has also been noted in other areas of the world with lower, but stable levels of transmission (Baird, 1995; Baird, et al., 1998; Branch et al., 2005). To add to the complexity, there may be significant differences in age-dependent clinical expression of disease within high transmission areas, with the highest transmission areas characterized by the development of

severe malarial anemia in infants and young children and the somewhat lower transmission areas characterized by cerebral malaria in older children (Snow and Marsh, 2002).

In unstable malaria, there may be permanent malaria transmission; however, there are large fluctuations in the rate of exposure to infection among individuals. The irregularity of transmission may result in greater intervals between infection precluding the development or maintenance of effective protective immunity. In areas of unstable malaria (Fig. 65.1), the risk of clinical malaria is less age-dependent, and individuals tend to be susceptible to the severe complications of malaria throughout life. This phenomenon may partially explain the frustrating fact that as malaria control is successfully instituted in a given region, and the level of endemicity is reduced, the public health impact of the infection may remain unchanged or even worsen (Dicko et al., 2007; Mbogo et al., 1995; Snow and Marsh, 2002) (Fig. 65.5). This is important when planning for the fielding of a partially protective malaria vaccine, because the semieradication of the parasite may serve to increase the susceptibility of the general population to clinical malaria, and thus sustain or increase morbidity and mortality rates despite progress against the parasite.

In the third broad category, epidemic malaria, there is a sudden increase in vector populations, or alternatively malaria may be reintroduced to an area from which the parasite (but not the vector) has been eradicated. Devastating malaria epidemics occurred in the early 1930s in South Africa (Sharp and le Sueur, 1996), in 1958 in Ethiopia (Fontaine et al., 1961), and in 1986 in Madagascar (Mouchet et al., 1998), and have been a recurrent feature in many areas with periodic excessive or failing rainfall, illustrated by the history of epidemics in India (Bouma and van der Kaay, 1996). Epidemics often occur in situations where there has been limited previous exposure and thus limited opportunity to acquire protective immunity, and partly for this reason, epidemic malaria can cause extreme morbidity and mortality throughout a population, especially with *P. falciparum* infection, with mortality rates exceeding 10%. Factors precipitating epidemic malaria in a population can relate to importation of the disease by travelers, failure of public health surveillance, deforestation, and climate change. There is concern that global warming could abruptly expand the range of malaria transmission by increasing vector populations at higher altitudes and by shortening the duration of the sporogonic cycle in the mosquito, which is temperature-dependent (Munga et al., 2006; Patz and Olson, 2006). Epidemic malaria could also become a significant concern following the fielding of a successful malaria vaccine. If the vaccine eradicates malaria from areas with high vector capacity and then the parasite is reintroduced later, either due to waning vaccine coverage or to the evolution of resistance to the vaccine by the parasite, epidemic malaria could result.

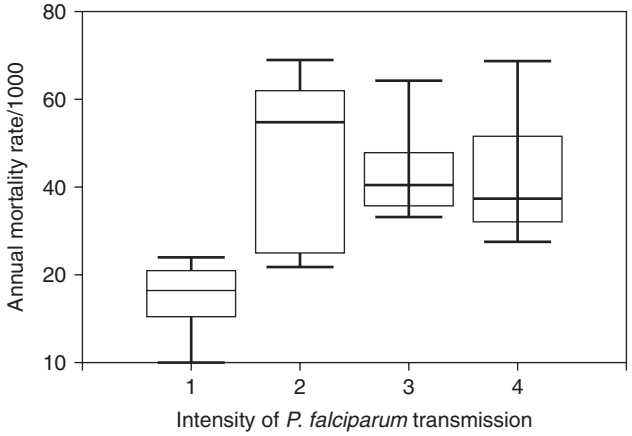

FIGURE 65.5 Relationship between all-cause mortality rate in early childhood and *P. falciparum* malaria transmission intensity in Africa. Box plot showing median , 25%, 75% quartile ranges around the median (box depth), and upper and lower limits of all-cause childhood mortality per 1000 children aged 0–4 years per annum at four transmission intensities. Malaria transmission above a certain threshold is associated with significant increases in mortality rates, as shown in this figure by the striking increase (approximately two-fold) in all-cause annual mortality rates comparing low-endemicity areas (category 1, childhood infection prevalence ranging from 0% to 24%) to low-to-moderate endemicity areas (category 2, prevalence 25–50%). As transmission intensity rises further, there appears to be a plateau effect, with mortality rates associated with moderate-to-high endemicity areas (category 3, prevalence 51–74%) and with high-endemicity areas (category 4, prevalence 75–100%) similar to those associated with low-to-moderate endemicity areas. These data suggest that a malaria control strategy such as vaccination may not significantly improve childhood mortality rates unless substantial reductions in prevalence of malaria are achieved. Note that in this analysis, a covariate such as differences in socioeconomic status among the 26 sites included in the data set could influence both rates of malarial infection and all-cause mortality. Reprinted from Advances in Parasitology, Vol 52, Snow and Marsh, 2002, with permission from Elsevier.

Across these categories, EIR may range widely, from less than 1 to greater than 1000 infective bites per year. In general, higher EIRs characterize stable malaria, but transmission can also be stable at lower EIRs, and both very low (Lindblade et al., 1999) as well as very high EIRs may characterize epidemic malaria.

Pregnancy-Associated Malaria (PAM)

At all levels of endemicity, including highly endemic areas characterized by the acquisition and

maintenance of NAI, pregnant women are at greater risk for clinical malaria than nonpregnant women. The risk is especially great when experiencing a first pregnancy, a phenomenon originally described by Clark in 1915 during studies conducted during malaria epidemics (Clark, 1915). It is now well established that pregnancy is associated with an increased frequency (up to 12-fold in some studies) and density of parasitemia with *P. falciparum*, as well as increased severity of infection (Brabin, 1983, 1991; Brabin et al., 1988; Bruce-Chwatt, 1983; Menendez, 1995, 2006; Okoko et al., 2003). When it occurs during pregnancy, malaria increases the risk of maternal mortality twofold, and is the most common cause of maternal death in hyperendemic areas (Brabin, 1991). This is a major health challenge, given that each year approximately 24 million women living in malaria-endemic regions become pregnant.

Malarial infection during pregnancy is associated with adverse fetal and infant outcomes, including abortions, stillbirths, premature delivery, congenital malaria, intrauterine growth retardation, low birthweight (LBW), and infant death (Okoko et al., 2003; Uneke, 2007). Placental malaria is often a key mediator of these adverse fetal outcomes because the accumulation of parasites in the placenta and the associated maternal immune response can interfere with the efficient transfer of oxygen and nutrients to the fetus (Ismail et al., 2000; Menendez et al., 2000; Okoko et al., 2002). The most severe fetal consequences, such as abortions, stillbirths, and congenital malaria, are frequently encountered in regions of unstable or epidemic transmission (Menendez et al., 2000), while in regions of high, stable transmission, the primary adverse infant outcome is LBW (Guyatt and Snow, 2004). LBW in turn is associated with diminished survival in the first year of life (McMormick, 1985), mediated in part by an increased risk of acquiring other infections. In fact, it is estimated that 5.7% of infant deaths in sub-Saharan African are indirectly associated with maternal malarial infection (Guyatt and Snow, 2001), and approximately 200,000 infants die each year as a result of malaria during pregnancy (Steketee et al., 2001).

One reason proposed for the increased risk of malaria during pregnancy may be the pregnancy-associated alteration in the immune system to prevent immunological rejection of the fetus. Specifically, the proinflammatory Th1, cell-mediated response is downregulated, while the Th2 response is enhanced. This immunologic shift has been hypothesized to increase the susceptibility of pregnant women to many infections, particularly intracellular organisms requiring strong cell-mediated immunity, such as *Plasmodium*. In addition, the placenta provides a novel sequestration site for *P. falciparum*. It is believed that placental malaria results from a specific population of parasites that preferentially sequester and cytoadhere to chondroitin sulfate A in the placenta through the binding of PfEMP1 variants binding preferentially to this molecule (Fried and Duffy, 1996; Fried et al., 2004; Hviid, 2007; Rogerson et al., 1995, 2007). Natural protective immunity against PAM is acquired during the course of multiple pregnancies, with the development of anti-PfEMP1 antibodies recognizing placental infected erythrocytes. This proposed mechanism for explaining the severity of malaria in first pregnancies and for the reduction in risk in multiparous women has instigated research into developing a pregnancy-specific malaria vaccine with CSA-binding PfEMP1 as the primary antigenic target (see "Pregnancy-Specific Vaccines" section below).

It is worth noting that *P. vivax* also contributes to PAM and its complications, and in fact *P. vivax* is an important cause of congenital malaria (Lesko et al., 2007).

Potential as a Biothreat Agent

Malaria is generally considered to have low potential as a biothreat agent, as it can be transmitted only by the insect vector, by parenteral administration (e.g., blood transfusion) or transplacentally. It also has an incubation period of a week or more if transmitted via mosquito bite, so there is time to administer presumptive treatment in case of exposure to infectious mosquitoes. Therefore, it cannot be effectively weaponized. On the other hand, malaria is amenable to abuse by terrorists, e.g., if infected mosquitoes are released surreptitiously in crowded areas in a nonmalarious area.

CLINICAL DISEASE

In contrast to liver-stage infection, which is entirely without clinical signs, symptoms, or changes in routine hematological or chemical parameters, the multiplication of parasites within the blood results in an accelerating clinical syndrome, particularly in nonimmune individuals. The classic fevers of blood stage malaria coincide with the synchronous lysis of millions of infected erythrocytes and are probably mediated by pyrogenic parasite-derived products such as GPI, as mentioned previously. These malaria toxins precipitate the release of inflammatory cytokines such as tumor necrosis factor, contributing to headache, body

aches, fever, chills, nausea, vomiting, diarrhea, general weakness, and prostration. These symptoms are similar to those of other infectious organisms, however; so the diagnosis of malaria requires the demonstration of parasites on a Giemsa-stained blood film. On the other hand, the characteristic malaria paroxysm, when observed in the right setting, is a strong indicator of the diagnosis.

A paroxysm typically begins with dramatic shaking chills (rigors) lasting 10–15 min or longer, which may rattle the bed and often completely incapacitate the sufferer. This period, during which the infected individual may experience a feeling of extreme cold, is followed by a hot stage, in which the patient appears agitated, restless, and disoriented. The body temperature may exceed 40°C, and the patient may complain of severe headache, backache, and pain in the limbs. This is followed by a defervescent phase, during which the patient sweats profusely and generally feels better, although left with weakness and fatigue, and often falling asleep. Body temperature may be normal upon awakening, and the patient may remain free of symptoms and able to go about daily activities until the onset of the next paroxysm 2–3 days later.

Paroxysms can occur in tertian cycles (48 h for each cycle, called tertian because fever occurs on the first and third days) or quartan cycles (72 h) depending on the species. *P. falciparum*, *P. vivax*, and *P. ovale* have a tertian cycle and *P. malariae* a quartan cycle, reflecting the underlying periodicity of blood stage schizogony. Quite often, however, the classic periodicity is not present because there are multiple asynchronous cohorts of parasites infecting the blood at the same time, so fevers come and go without a recognizable pattern.

The first wave of parasitemia, if controlled by the immune system or by subcurative drug therapy, will in nearly all cases be followed by recurrent waves of parasites (termed recrudescences, as previously described). In addition, patients with infections caused by *P. vivax* or *P. ovale* may experience malaria relapse weeks, months, or more than a year following the primary infection.

Complications

Uncomplicated malaria, as caused by all five species infecting humans, can be extremely debilitating, particularly in nonimmune individuals. As the infection progresses, white blood cell and platelet counts fall, and the red blood cells are gradually depleted as a result of direct lysis and diminished production from germinal centers. After several days, enlargement and tenderness of the liver and spleen may occur. The severity of infections with *P. vivax*, *P. ovale*, and *P. malariae* generally does not progress beyond this point, with serious complications generally limited to individuals with preexisting conditions. In contrast, *P. falciparum* frequently leads to progressive clinical deterioration, engendering a variety of severe complications. In sub-Saharan Africa, where the majority of falciparum-related deaths occur, approximately 1 in 100 pediatric cases of *P. falciparum* malaria will progress to severe disease (Greenwood et al., 1991).

Cerebral malaria is one of the most dreaded complications of *P. falciparum* infection. It is characterized by decreased level of consciousness, progressing from delirium to obtundation, stupor, coma, and death. Patients may present with a severe headache followed by drowsiness, increasing confusion and prostration. Seizures are a key feature of cerebral malaria and may often herald the onset of coma. Other serious complications of falciparum malaria which may occur with or without altered consciousness include hypoglycemia, hyperpyrexia, hyperparasitemia, pulmonary failure, renal failure, jaundice, bleeding disorders, sepsis, severe metabolic acidosis, and a variety of other conditions. The clinical manifestations of severe disease are thus varied, giving rise to malignant tertian malaria's reputation as a great imitator, mimicking meningitis, encephalitis, stroke, hepatitis, pulmonary edema, acute abdomen, acute renal failure, and many other conditions. All manifestations of severe malaria have, in common, the need for immediate diagnosis and institution of parenteral antimalarial therapy with maximum supportive care. The World Health Organization has published a list of criteria for severe malaria, aiming to promote appreciation for the importance of the diagnosis and the institution of appropriate treatment (World Health Organization, 2005).

Most patients surviving severe malaria will recover completely. However, some patients, particularly pediatric patients, may experience increased intracranial pressure, brain ischemia, and in some cases transtentorial herniation during the infection. Those that recover may be left with significant neurological sequellae, including cortical blindness, hemiparesis, generalized spasticity, cerebellar ataxia, hypotonia, or more subtle neurological deficits (Weatherall et al., 2002).

Another prominent syndrome of severe and complicated malaria is severe malarial anemia (SMA), which is particularly common in areas of sub-Saharan Africa with high transmission intensities (Snow and Marsh, 2002). In these settings, SMA is often the leading cause of malaria-related mortality in infants and young children (Obonyo et al., 2007).

The other species of human malaria may, on occasion, lead to complicated disease, although it is unusual. *P. vivax* can cause fatal splenic rupture (Mokashi et al., 1992; Ozsoy et al., 2004; Yagmur et al., 2000; Zingman and Viner, 1993), and there are now several reports that this species may cause other severe complications reminiscent of *P. falciparum* (Barcus et al., 2007; Kochar et al., 2005; Kumar et al., 2007; Lomar et al., 2005). Chronic *P. malariae* has classically been associated with nephrotic syndrome (Collins and Jeffery, 2007). The zoonotic parasite, *P. knowlesi*, has been reported to lead to fatal complications (Cox-Singh et al., 2008), possibly associated with its very rapid growth in the blood—the only species infecting humans with a 24 h cycle.

TREATMENT AND PROPHYLAXIS

A large arsenal of drugs exists for the treatment of uncomplicated malaria, although there is often a problem with their availability in a given location (Lufesi et al., 2007). Unfortunately, there has been a recent series of distributions of fraudulent drugs that lack antimalarial activity in several countries (Newton et al., 2008). For standard treatment and prevention of malaria, the reader is referred to Griffith et al. (2007), Magill (2006), and Whitty et al. (2006). Malarone or mefloquine are highly effective, but additional regimens, such as ACTs, sulfadoxine/pyrimethamine, chloroquine (for sensitive strains of *P. falciparum* and for the nonfalciparum species), or quinine/doxycyline can be highly effective, with special considerations required for pregnant women and infants (Coll et al., 2008). In countries where artemisinin derivatives are available (compounds derived from the Chinese herbal plan *Artemesia diminuta*), there are often a variety of ACTs in the market, such as artemether-lumefantrine (Hatz et al., 2008). Artemisinin compounds cause a rapid knockdown of parasite populations in the blood, and when combined with a second agent to synergize in the killing of parasites and to prevent the recrudescence of resistant organisms, they are extremely effective antimalarials, and indeed are transforming the treatment of malaria in countries where they have been adopted as first-line therapy (Bosman and Mendis, 2007). These same compounds are now the treatment of choice for severe *P. falciparum* malaria (Day and Dondorp, 2007), and if available should be selected in favor of parenteral quinine or quinidine. The lack of artemisinin compounds in the USA is being addressed by a partnership between the Walter Reed Army Institute of Research and Sigma-Tau Pharmaceutical, the latter planning to seek licensure of artesunate for parenteral use during the latter half of 2008 (A. Magill, personal communication).

In addition to the immediate institution of parenteral antimalarials, patients with severe malaria require emergent and intensive supportive care to control seizures, hypoglycemia, brain edema, respiratory failure, acidosis, dehydration, sepsis, renal failure, and other complications. Many experimental compounds and procedures, such as administration of steroids and antitumor necrosis factor have been tested and found not to improve the success of treatment (Hoffman, 1988; Warrell, 1982; van Hensbroek, 1996; Enwere, 2005). Even with optimal support, treatment of severe malaria may be unsuccessful, and mortality rates can rise to 50% in remote areas where intensive care, dialysis, and mechanical respiratory support are not available, although they are generally much lower (Ranque et al., 2008; Winkler et al., 2008). A major improvement in the treatment of severe malaria has accompanied the development of rectal administration of artesunate, which can now be given in an outpatient setting while the patient is being transported to the hospital and can be lifesaving (Karunajeewa et al., 2007).

Ironically, the treatment of severe malaria can be poor in highly developed countries. This is due primarily to lack of experience by physicians working in parts of the world where malaria in not endemic. The travel history may not come to light, diagnostic procedures may be inadequate, and in some cases the required drugs may not be available (Magill, 2006). Travelers or their family members must insist that caregivers consider malaria as a cause of illness, and in some cases proactively help to identify clinicians qualified to care for this potentially devastating infection.

Many drugs that kill blood stage parasites do not kill hypnozoites, with the exception of 8-aminoquinolines such as primaquine (Crockett and Kain, 2007). If a patient has been diagnosed with *P. vivax* or *P. ovale*, a course of primaquine should be initiated as part of follow-up care in order to prevent relapse.

Many of the same drugs used for treating malaria are used for malaria prophylaxis and therefore prescribed for the traveler. Weekly chloroquine is the drug of choice only in those few areas of the world where chloroquine-resistance has never been reported, including parts of the Caribbean and parts of the Middle East. In most other areas, weekly mefloquine, daily Malarone, or daily doxycycline are recommended, with daily primaquine another possibility in those with normal glucose-6-phosphate dehydrogenase activity. Tafenoquine is under study as another potential prophylactic agent (Crockett and

Kain, 2007). Malarone, primaquine, and tafenoquine have the advantage of killing parasites during liver stage development, and thus their administration can be stopped a week after departure from a malaria-endemic area, whereas the blood schizonticides such as chloroquine or mefloquine need to be continued for a month to wait for all parasites to exit the liver and enter the blood, where they can be killed by these drugs, and are thus less convenient for short trips.

As a general rule, the prescription of a drug for malaria prophylaxis for a given individual should be performed by a travel medicine specialist, taking into account drug-resistance patterns in the area to be visited, the traveler's age and pregnancy/lactation status, and various key aspects of the traveler's medical history (seizures, heart disease, drug allergies) and preferences (weekly vs. daily administration, tolerance of side effects (Senn, 2007)). The complexity of prescribing the best antimalarial and the difficulties of side effects and compliance are major reasons why a "fire and forget" vaccine would be particularly helpful for travelers.

In addition to treatment and prophylaxis, antimalarial drugs are gaining increasing importance as tools of public health. It has now been shown that intermittent "presumptive treatment" (IPT) of malaria during key stages of life where the risk of clinical and severe malaria is greatest, namely infancy, early childhood, and pregnancy, can markedly reduce morbidity and mortality. Thus, IPT for infants (IPTi) (Sokhna et al., 2008) and pregnant women (IPTp) (Asa et al., 2008) has been instituted as national health policy in some countries although implementation has proven to be challenging (Hill and Kazembe, 2006).

The evolution of resistance to antimalarial drugs has historically been and currently remains an exceedingly important problem, especially for *P. falciparum* (Ekland and Fidock, 2007) but also for *P. vivax* (Baird, 2004) and occasionally *P. malariae* (Maguire et al., 2002). There must be continuous monitoring for this phenomenon in endemic areas (Laufer et al., 2007; Price et al., 2007; Vestergaard and Ringwald, 2007), and the institution of national treatment policy changes regarding first- and second-line drugs when significant resistance is detected. A component of retaining the upper hand against the parasite is the ongoing development and licensure of novel antimalarial drugs.

POSTEXPOSURE IMMUNOPROPHYLAXIS

It has long been known that treatment with immunoglobulin derived from semi-immune adults can lead to reductions in parasite density and clinical improvement (Bouharoun-Tayoun et al., 1990; Sabchareon et al., 1991) and that the presence of partial immunity enhances the curative effect of drug treatment, even permitting clearance of parasites that are resistant to the drug employed (Enevold et al., 2007). In addition, immune sera can assist in the identification of antigenic targets, aiding the development of effective vaccines (Lundquist et al., 2006; McIntosh et al., 2007; Nixon et al., 2005). However, due to the availability of excellent antimalarial drugs, there is no application for postexposure immunoprophylaxis.

PATHOGENESIS

Description of the Disease Process

The pathogenesis of malarial infection relates directly to the biological events associated with each stage of the life cycle, which differ markedly in the degree to which they disrupt normal host processes. Although sporozoites migrate destructively through the liver parenchyma, their numbers are few (500 are deposited in the skin during a 15 min mosquito bite, with typical numbers reaching the liver in nature likely far fewer) (Jin et al., 2007), damage is localized, and there is no detectable compromise in liver function. Tissue sections taken from infected mouse livers reveal an inflammatory reaction at the site of sporozoite migration (Mota and Rodriguez, 2004), but this is clinically silent. In marked contrast, blood stage infection by all five malarial parasites infecting humans precipitates a dramatic clinical syndrome, including extensive erythrocyte destruction, toxin release, febrile response, and a host of metabolic derangements. *P. falciparum* infection, however, has an additional feature arising out of its distinct pattern of sequestration in the deep venous microvasculature of organs throughout the body including the brain, lung, liver, kidney, dermis, bone marrow, and placenta (Schofield and Grau, 2005; Trampuz et al., 2003). This sequestration characterizes the late trophozoite and schizont stages of the parasite, explaining why *P. falciparum* schizonts are rarely seen in the peripheral blood. It follows the direct binding to endothelial cells of parasite antigens expressed on the surface of infected erythrocytes (with modified host erythrocyte surface proteins contributing). As mentioned previously, an important parasite protein responsible for binding is PfEMP1, the immunodominant antigen undergoing sequential expression of antigenically variant alleles enabling repeated immune escape and recrudescent parasitemia. Other molecules are involved as well,

and a variety of receptors expressed on endothelial cells bind PfEMP1 and other ligands, including ICAM1 and VCAM1 (Sherman et al., 2003).

Although cytoadherence is a primary factor in sequestration and the associated disruption of normal flow, additional processes contribute, including rosetting (the binding of nonparasitized erythrocytes to parasitized erythrocytes), reduced red cell deformability, and the accumulation of unbound, uninfected erythrocytes as a result of locally poor vascular flow. This vascular "log jam" leads to the local release of inflammatory cytokines and an associated cascade of events that precipitate serious metabolic derangement including local tissue hypoxia and acidosis. As a general rule, it appears that the site of sequestration determines the degree of organ compromise. For example, sequestration in the cerebral vasculature results in cerebral malaria, sequestration in the kidney results in acute renal failure, etc. Sequestration in the placenta is a special case that explains the prevalence of severe disease in pregnant women, particularly primagravida. The awareness that sequestration is an important contributor to severe disease has led to the concept of developing vaccines or immunotherapies that prevent or reverse cytoadherence, thereby protecting the patient against the adverse manifestations of malaria.

Although sequestration is a major factor associated with pathogenesis, there are a host of additional pathogenic features of malarial infection, including the release of malaria toxins, the destruction of erythrocytes, and the enlargement of the spleen. In the latter case, chronic malaria contributes to the debilitating and potentially fatal tropical splenomegaly syndrome, also called hyperreactive malarial splenomegaly due to the associated increases in IgM and hyperplasia of the lymphoreticular system (Singh, 2007).

The consequences of malarial infection are so severe and the parasite so common that selection pressures have been exerted on the human population, making malaria, as expressed by one expert, "the strongest known force for evolutionary selection in the recent history of the human genome" (Kwiatkowski, 2005). These selection pressures have led to the genetically based adaptive mechanisms that in the presence of endemic malaria provide a selective advantage. Many of these have been described, including the changes in proteins and their structure underlying sickle cell anemia, the thalassemia, G6PD deficiency, ovalocytosis and many similar conditions including a role in shaping the ABO blood grouping. More recently, additional polymorphisms have been described affecting human immune system and inflammatory genes that likewise confer a selective advantage by offering protection against severe malaria. The reader is referred to excellent reviews for a detailed description of the field (Hill, 2006a; Kwiatkowski, 2005; Timmann et al., 2007).

IMMUNE RESPONSE TO INFECTION

While many protective immune mechanisms have been demonstrated, as described in "Protective Immune Responses" section above, the immune response to natural infection is complex and also fundamentally different from the persistent sterile immunity that follows many acute infectious diseases. The parasite is adept at living chronically in the host, either by evading the immune response, or by actively limiting its potency. NAI is never sufficient to prevent infection or to prevent the circulation of parasites at low levels or the generation of gametocytes that can infect a mosquito, even after a lifetime of exposure. The mechanisms whereby malaria evades or suppresses the immune response are diverse, including:

1. escape in time (the entry of merozoites into an erythrocyte is completed in less than 30 s),
2. escape within host cells (avoids exposure to plasma and thus to antibodies and complement),
3. sequestration of maturing blood stages in the microvasculature (escaping splenic filtration),
4. presentation of immunodominant repeat sequences to divert the immune responses (e.g., CSP repeat sequences),
5. inhibition of expression of host costimulatory molecules (e.g., CD80) needed for activation of lymphocytes (Sponaas et al., 2006; Steers et al., 2005),
6. inhibition of antigen processing and/or expression of MHC Class I or II molecules on the surface of antigen presenting cells (Steers et al., 2005),
7. stimulation of regulatory T cells (Tregs—CD4+, CD25+, FOXP3+) to downregulate T-cell responses against the liver and blood stage parasites (Hisaeda et al., 2008),
8. allelic/antigenic variation of key antigens (e.g., PfEMP1),
9. induction of blocking antibodies that limit the effectiveness of antibodies otherwise able to disrupt vital molecular pathways such as MSP1 processing and erythrocyte invasion (Uthaipibull et al., 2001),
10. mimicry of host sequences of commensal microorganisms in order to fall under the umbrella of tolerance (Good et al., 1993; Wide et al., 2006),

11. presentation of variant sequences to induce altered peptide ligand antagonism (Plebanski et al., 1997),
12. use of alternative pathways for key processes such as the invasion of erythrocytes (Baum et al., 2005; Stubbs et al., 2005), and
13. inhibition of the respiratory burst in Kupffer cells (Usynin et al., 2007) and many others.

The more closely parasite biology is studied, the more it appears that the parasite is capable of orchestrating the immune response to its advantage, enabling chronic infection and ongoing production and transmission of gametocytes. In sum, the natural immune response to acute infection can be considered ineffective if judged by the host's ability to eliminate the parasite, although, as described previously, a degree of clinical immunity gradually develops with repeated exposure. Countervailing this perversion of immune function in order to induce a highly effective immune response is a significant challenge for vaccine developers.

VACCINES

The development of a malaria vaccine represents one of the most important scientific and public health enterprises of our time (Epstein et al., 2007a). Attempts began early in the twentieth century (Desowitz, 1991), but despite tremendous advances in our understanding of the parasite and of the host immune response, the goal remains elusive. Providing high-level protection against the malarial parasite will entail overcoming multiple hurdles and likely require a complex vaccine design (Mahanty et al., 2003). Some of the principal impediments to progress are as follows.

1. Stage-specific antigen expression: *Plasmodium* expresses a different, complex array of antigens on its surface and on the surface of the infected host cell at each stage of its life cycle, reflecting different tissue environments and growth requirements. The predominant antigens expressed during the preerythrocytic stages are largely distinct from those expressed during the asexual or sexual blood stages. A vaccine targeting one stage of the parasite life cycle would have to be 100% effective in order to prevent progression to the next stage where growth would occur unchecked, or alternatively the vaccine would have to include antigens from multiple stages. This indicates that a simple vaccine based on one or two antigens is unlikely to be broadly protective.
2. Allelic variation: Key antigens demonstrate extensive allelic diversity (de Souza-Neiras et al., 2007; Ferreira et al., 2007; Mahajan et al., 2005), with the encoding genes harboring significantly greater variability than immediately adjacent flanking regions of DNA, indicating that the antigens have experienced strong immune selection favoring polymorphism (Amodu et al., 2007). It is not surprising that, given the history of selection, immune responses are generally allele-specific, with cross-protection developing only gradually following repeated exposure, if developing at all. Therefore, vaccines based on a single allele are unlikely to provide protection in the field where multiple alleles are circulating and where individuals may typically be infected by multiple strains (Fig. 65.6). The finding that a newly discovered antigen exhibits extensive polymorphism is usually interpreted as prima facie evidence of the importance of the antigen as an immunological target. However, this same information conveys the difficulty of employing the antigen effectively as a vaccine candidate. One way to circumvent allelic variation is to design chimeric immunogens or combine immunogens into mixtures or epitope strings that induce cross-protective responses or responses targeting multiple alleles. The evaluation of these vaccines will require careful assessment of allele-specific vs. cross-protective responses when tested in the field. To enable this detailed analysis, investigators are characterizing the genetic

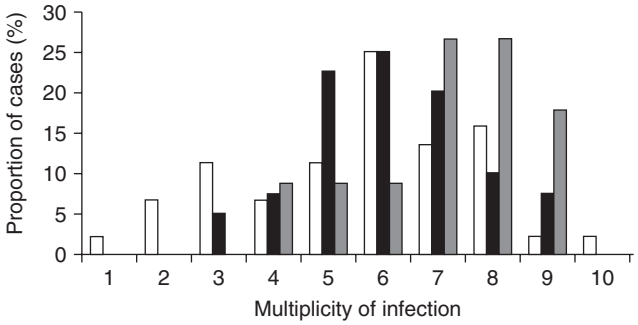

FIGURE 65.6 Multiplicity of infection in peripheral, placental, and cord blood in Senegalese women. The graph shows the number of parasite genotypes detected by PCR in peripheral (black bars), placental (white bars), and cord (hatched bars) blood at the time of delivery. These data are based on the diversity exhibited by only the MSP1 and MSP2 antigens, therefore likely underestimating the true multiplicity of infection in these samples. Journal of Clinical Microbiology, Vol 43, Jafari-Guemouri et al., 2005, with permission from American Society for Microbiology.

polymorphisms present in parasite populations at vaccine testing sites so that trials can be adequately powered to detect allele-specific protective effects (Takala et al., 2007).

3. Antigenic variation: Individual *Plasmodium* parasite clones have the ability to sequentially replace and thereby antigenically vary key protective proteins, exemplified by PfEMP1 expression on the surface of the infected erythrocyte (Kyes et al., 2007). A review of *var* and other variant gene families discovered in *P. falciparum* including *rif*, *stevor*, and *Pfmc-2TM*, is provided by Dzikowski et al. (2006). To date, is has not been possible to identify conserved and immunogenic sequences inducing strongly cross-protective responses targeting these antigens.
4. Genetic restriction of the host immune response: Key immune responses to malarial antigens, such as those targeting liver-stage parasites, are cell-mediated and thus genetically restricted. Individuals with different HLA haplotypes respond to different T-cell epitopes from a given antigen, or may not respond at all. Therefore, vaccines designed to act via the induction of cell-mediated immunity must contain a variety of CD4+ and CD8+ T-cell epitopes in order to provide broad population coverage, and this may be difficult to achieve if vaccines are based on one or two antigens (Doolan et al., 1997).

In the most general sense, barriers to developing a malaria vaccine emerge from the contradiction inherent in the parasite's ability to evade the host immune response and establish a chronic infection. One may wonder if the proposal to harness the immune response to reject the parasite is not an exercise in futility.

Evidence for the Feasibility of Developing a Malaria Vaccine

Two models of immunity help to allay the above concerns, indicating that developing an effective malaria vaccine is indeed feasible: (1) immunization with irradiated sporozoites and (2) repeated blood stage infection, through natural exposure or malarial therapy (the treatment of neurosyphilis with malarial fevers in the preantibiotic era).

Immunization with Irradiated Sporozoites: Model of Sterile Immunity

In 1967, Nussenzweig et al. (1967) first demonstrated that mice immunized with radiation-attenuated sporozoites were protected against challenge with fully infectious sporozoites. Similar studies in NHPs likewise demonstrated protection or partial protection (Collins and Contacos, 1972; Jahiel et al., 1970). These findings were rapidly extended to humans, with sterile protection (i.e., absence of blood stage infection) first reported in 1973 (Clyde et al., 1973a, 1973b; Hoffman et al., 2002).

In this model, malaria-infected mosquitoes are exposed to irradiation, which damages but does not kill the sporozoites the mosquitoes are harboring. The optimal dose of 12,000–15,000 cGy was empirically determined—higher radiation doses reduce protection, and lower doses lead to breakthrough blood stage infections. The mosquitoes are allowed to feed on hosts, or alternatively, crude preparations of irradiated sporozoites isolated from infected mosquitoes by dissection may be injected intravenously in the case of animal models. The weakened sporozoites travel to the liver and undergo partial development, expressing new antigens, such as LSA1, but then stop developing, without releasing merozoites into the bloodstream. A portion of the injected sporozoites migrate to the lymph nodes rather than to the liver, where presentation of malarial antigens in germinal centers contributes to the immune response (Chakravarty et al., 2007).

In humans, sterile protection has been induced in 13 of the 14 volunteers by this method, provided that the infectious mosquito bites total at least 900–1000. In the few volunteers studied, protection was induced following immunization with *P. vivax* as well, although protection was not cross-specific (Hoffman et al., 2002). Intriguingly, protection did appear to be cross-protective among strains, suggesting that the attenuated sporozoite approach could help to circumvent the problem of antigenic polymorphism that hinders the development of effective subunit vaccines.

This sterile protection induced in the irradiated sporozoite model is thought to be mediated by CD8+ T-cell responses recognizing preerythrocytic stage antigens expressed on the surface of infected hepatocytes, with CD4+ T-cell responses and antibody responses contributing (Jobe et al., 2007; Tarun et al., 2007; Vanderberg et al., 2007); however, the mechanisms of protection are not completely understood, nor have the antigenic targets been identified. Although responses targeting the CSP contribute to protection, they are not required and 100% protection can be achieved in the absence of these responses (Gruner et al., 2007; Kumar et al., 2006).

In summary, the irradiated sporozoite model demonstrates that it is possible to induce immune responses directed toward antigens expressed by

preerythrocytic stage parasites that completely prevent blood stage infection in humans. If these antigens could be identified and the correct immune responses generated, it should be possible to mimic the irradiated sporozoite vaccine by using a subunit approach and thereby achieve high-level protection.

Repeated Exposure to Infection: Model of Partial Immunity

NAI through repeated exposure to blood stage parasites provides a second model of protection supporting the feasibility of developing malaria vaccines, in this case vaccines targeting blood stage antigens. There appear to be two components to this immunity, developing at different rates: (1) antidisease immunity and (2) antiparasite immunity. In endemic areas, the risk of fatal malaria is highest during the first 2–3 years of life and then considerably diminishes by age 5 with sufficient exposure. Antidisease immunity develops rapidly during this period, with a reduction in the risk of life-threatening disease after one or more infections (Gupta et al., 1999). Antiparasite immunity develops more gradually, manifest as low-grade parasitemias with spontaneous clearance (Branch et al., 2005). The development of both clinical and parasitological immunity has also been observed with malarial therapy for the treatment of neurosyphilis (Collins and Jeffery, 1999a, 1999b, 2005, 2007; Collins et al., 1989, 2004; Molineaux et al., 2002).

The protection underlying NAI is thought to be mediated by antibody responses targeting blood stage antigens, since immunoglobulin preparations from semi-immune African adults reduced symptoms and parasitemia when administered to children with acute malarial infections (Bouharoun-Tayoun et al., 1990; Sabchareon et al., 1991). Additionally, it has been shown that antibody responses to specific blood stage antigens, such as MSP1, are associated with clinical resistance to malaria in residents of endemic areas. In summary, NAI demonstrates the feasibility of developing a partially protective vaccine targeting blood stage parasites that limits parasite density and reduces the risk of clinical disease and death.

These two models broadly define approaches to malaria vaccine development: (1) preerythrocytic stage vaccines (antiinfection vaccines) aimed at mimicking the irradiated sporozoite model that entirely prevent blood stage infection by killing sporozoites and developing liver-stage parasites, and (2) erythrocytic stage vaccines (antidisease vaccines) that mimicking NAI, reducing parasite density, morbidity, and mortality in infected individuals.

Although this classification is supported by a strong rationale, the distinction is often blurred. For example, it has been demonstrated that a vaccine based on the CSP, a preerythrocytic stage protein not expressed by blood stage parasites, may reduce the frequency of clinical episodes in African children for a period of at least 18 months following immunization, with an even stronger effect on reducing severe disease (see discussion of the RTS,S vaccine below), thereby mimicking NAI. It is presumed that the mechanism is related to reduced liver-stage parasite burden and reduced frequency of merozoite release into the blood, which may limit genetic diversity of the circulating parasites and thus the likelihood of a pathogenic strain entering the blood (Enosse et al., 2006).

In addition to preerythrocytic- and erythrocytic-stage vaccines, there is a third category —transmission-blocking vaccines—which target the sexual stages (gametocytes) of the parasite and aim to reduce or prevent transmission, and these are generally placed in a group by themselves (see "Transmission-Blocking Vaccines" section below).

History of Malaria Vaccine Development

Protein-Based Vaccines

As just described, the first substantial advances in malaria vaccines were achieved in the 1960s and 1970s with the demonstration that irradiated sporozoites could provide sterile protection, but no further development of this approach was attempted due to the impracticality of a vaccine delivered by a mosquito bite. Consequently, most development efforts during the past 30 years have focused on the subunit approach, which involves formulating defined partial- or full-length antigens to induce potent immune responses targeting the antigens involved in key biological processes required for parasite development. The subunit approach was launched with great enthusiasm in the early 1980s following the identification and cloning of the first preerythrocytic-stage antigen, the CSP (Dame et al., 1984; Yoshida et al., 1980). It was anticipated by many that this discovery would rapidly lead to an effective vaccine.

Early studies in animal models using CSP or CSP epitopes as the vaccine antigen were promising, but when tested in humans, several formulations including peptide–protein conjugates and recombinant proteins failed to provide consistent protection against experimental sporozoite challenge, although in a few individuals sterile protection was achieved (Ballou et al., 1985; Brown et al., 1994; Fries et al., 1992; Heppner et al., 1996; Herrington et al., 1987; Rickman et al.,

1991; Sherwood et al., 1996). Early vaccines were limited by suboptimal epitope configuration and adjuvant formulation. It was not until the antigen was engineered as the virus-like particle RTS,S and adjuvanted with a proprietary oil-in-water emulsion that it induced protection (Gordon et al., 1995; Stoute et al., 1997). This vaccine, RTS,S/AS02a, is discussed in "RTS,S" section below as it remains a leading candidate vaccine. Other efforts to develop CSP or CSP epitopes as vaccine antigens, including formulation as multiantigen peptides (MAPs) or virus-like particles similar to RTS,S, but utilizing hepatitis B core antigen rather than hepatitis B surface antigen, have induced strong immune responses but failed to protect or were sidelined due to reactogenicity (Nardin, 2000, 2001, 2004; Edelman, 2002; Oliveira, 2005; Walther, 2007; Gregson, 2008).

Several blood stage antigens were also cloned and sequenced in the 1980s, identified from cDNA expression libraries screened with growth-inhibitory serum obtained from semi-immune humans living in malaria-endemic areas or from *Aotus* monkeys exposed to repeated *P. falciparum* infections (Ardeshir et al., 1985; Kemp et al., 1983). Many of the identified antigens remain leading vaccine candidates to this day, although, disappointingly, none has proven to protect against infection when tested in humans. There have been some encouraging findings, however: the Combo B vaccine, derived from three blood stage antigens (MSP1, MSP2, and RESA) formulated in Montanide ISA 720, was tested in 5–9-year-old children in Papua New Guinea and reduced the parasite density in the study group not pretreated with sulfadoxine-pyrimethamine, relative to the comparator group (Genton et al., 2002). This finding corresponded to a paucity of the 3D7 allele of MSP2 (the allele included in the vaccine) in the infections acquired by vaccine recipients during the observation period, whereas the nonvaccine FC27 allele showed no differences among study groups, implying that vaccination did protect against infection with parasite harboring the 3D7 allele. These finding have encouraged vaccine developers, and the search for an effective blood stage vaccine remains viable.

Another development enterprise that figured prominently in the field was led by Dr. Manuel Patarroyo of the National University of Colombia. This vaccine, called SPf66, combined three synthetic peptides from blood stage antigens, joined with epitopes from the CSP. SPf66 was tested extensively in South America, Africa, and Asia in the 1990s in a variety of settings and age groups. After the completion of these studies, a meta-analysis of 10 randomized, placebo-controlled trials involving nearly 10,000 study subjects was performed to assess the value of the SPf66 vaccine. This revealed moderate (28%) efficacy against *P. falciparum* infections in South America, but, disappointingly, no significant protection in trials conducted in Africa or Asia (Graves and Gelband, 2006). The vaccine has not been developed further.

DNA Vaccines

In the early 1990s, a novel vaccine platform—immunization with "naked" DNA—was first tested against malaria. A murine model was used to demonstrate that intramuscular administration of recombinant DNA plasmids encoding the CSP of *P. yoelii* permitted the uptake of the plasmids by host cells and subsequent expression of the malaria transgene, and induced an immune response affording protection against sporozoite challenge (Sedegah et al., 1994). Because of the intracellular synthesis and processing of the antigenic targets, DNA vaccines allow for HLA presentation of Class I T-cell epitopes via the endogenous presentation pathway, thereby inducing the cytotoxic T lymphocyte (CTL) responses believed to contribute to the destruction of developing liver stage parasites. DNA has the advantage that transgenes can be switched without changing manufacturing processes, codon usage can be optimized or harmonized (Hillier et al., 2005; Narum et al., 2000, 2001), key epitopes can be strung together (Doolan et al., 1997) or genes can be shuffled to increase antigen coverage and immunogenicity (Cai et al., 2007).

Based on these considerations and the demonstration of protection in mice, the U.S. Navy engaged in a program called MuStDO (multistage DNA vaccine operation) in the late 1990s to develop DNA vaccines for preventing malaria in humans. The first two clinical trials demonstrated safety (Epstein et al., 2004; Le et al., 2000) and induced CTL and interferon gamma responses targeting CSP (Wang et al., 1998, 2001). However, there were no measurable antibodies, a departure from the murine model in which both CTL and antibodies were routinely induced by DNA immunization. Assuming that multiple antigens would be required for protection, a mixture of five plasmids encoding preerythrocytic stage antigens (CSP, SSP2/TRAP, EXP1, LSA1, and LSA3) was tested with or without a sixth plasmid encoding human granulocyte macrophage-colony stimulating factor (hGM-CSF). As in the initial trials, cell-mediated immune responses were detected, but there were negligible antibody responses and no protection against sporozoite challenge (Wang et al., 2005). Based on the results of this trial, further testing of naked DNA as

a stand-alone regimen was not pursued. Now, after a gap of several years, intensive efforts to optimize the platform have resulted in improved immunogenicity. Electroporation has dramatically increased tranfection efficiency (Cemazar and Sersa, 2007), and this, along with many additional improvements (Laddy and Weiner, 2006), may soon bring DNA back to the forefront of vaccine development.

Even as the testing of DNA as a stand-alone regimen was sidelined, the importance of DNA as a priming agent was recognized. Volunteers primed with three doses of DNA encoding CSP and boosted with RTS,S/AS02A (see "RTS,S" section below) more than a year later showed stronger cell-mediated immunity than volunteers receiving RTS,S/AS02A without priming (Wang et al., 2004). These data, supported by similar findings in animal models, established the value of naked DNA as a priming agent able to induce long-lasting memory T cells capable of improving the immunogenicity and protection of a booster vaccine given subsequent to the DNA prime (see "Prime-Boost Strategy" section below).

Virally Vectored Vaccines

In the late 1990s and early 2000s, efforts shifted to viral vectors as a possibly better way to deliver DNA encoding malarial antigens. Viral vectors retain a key attribute of DNA, namely the intracellular synthesis of the parasite protein by a eukaryotic host cell, leading to Class I as well as Class II presentation and thus the induction of both CD8+ and CD4+ T-cell responses. Eukaryotic host cell synthesis favors native protein folding, which is difficult to achieve when parasite proteins are synthesized by a prokaryote such as *E. coli*, although this problem with bacterial expression can be overcome with codon harmonization or special refolding steps during the manufacturing process (Hillier et al., 2005). However, unlike DNA, viral vectors may target particular host cells such as dendritic cells, and are intrinsically designed for efficient cell entry and transfection. Moreover, viral vectors provide a stimulatory danger signal that activates the innate immune system via Toll-like receptors (TLRs), enhancing immunogenicity. As an added attribute, viral vectors can be designed to express multiple transgenes placed into different expression cassettes. Although in some cases manufacturing and scale-up can be more difficult for viral vectors than for DNA, and there may be concerns regarding the adequacy of attenuation, these challenges can generally be addressed successfully.

Promising viral vectors include attenuated mammalian poxviruses such as Modified Vaccinia Ankara (MVA), avian poxviruses such as canary pox or fowl pox (FP), human adenoviruses attenuated via genetically-engineered gene deletions, simian adenoviruses (Sridhar et al., 2008), viral replicon particles (VRPs, derived from Venezuelan equine encephalitis virus), and the yellow fever vaccine vector (Tao et al., 2005). One of the first studies of malarial antigens delivered by a viral vector involved the recombination of seven different malaria genes into a NYVAC poxvirus platform, creating the NYVAC Pf7 vaccine (Tine et al., 1996), a joint effort by the U.S. Army and Virogenetics, Inc. When tested in the clinic, this vaccine was immunogenic and achieved a modest level of protection against experimental sporozoite challenge: one out of 35 volunteers was sterilely protected and the onset of parasitemia was delayed relative to controls in others (Ockenhouse et al., 1998). Many considered this to be a promising result meriting further study, but the vaccine was not pursued further. Other viral platforms, such as adenovectors, are now entering clinical testing and will be described below in "Vaccines Currently under Development" section (Li et al., 2007).

Prime-Boost Strategy

The most recent evolution in the history of subunit vaccines is sequential immunization with two different vaccine platforms, which has proven superior to immunization with either platform alone. Some platforms are more effective as priming agents (e.g., DNA), while others can serve both to prime and boost (adenovirus, poxvirus). The superiority of heterologous over homologous regimens may relate to the ability of heterologous regimens to reduce competition between the antigen expressed by the transgene and the multiple viral antigens expressed by the vector, since the transgene is the only protein expressed in common between the two immunizations, enabling an anamnestic response to the target antigen. The heterologous approach may also avoid neutralization by antivector responses induced by the prime, leading to higher host cell transfection rates and therefore enhanced transgene expression when the boost is administered.

In a remarkable series of clinical studies, the malaria vaccine development program at Oxford University systematically explored a variety of heterologous prime-boost regimens in humans, focusing on DNA or FP followed by MVA (Dunachie et al., 2006a, 2006b; Moore and Hill, 2004). In most of these studies, the immunogen was ME-TRAP, a multiepitope string coupled to the full-length preerythrocytic stage antigen TRAP (SSP2) (McConkey, 2003) spliced into a DNA plasmid or poxvector, although the CSP was

also studied (Walters and Sperandio, 2006). These regimens achieved markedly improved cellular immune responses, and were associated with a calculated average 92% reduction in liver stage burden combining data from several human trials (Bejon et al., 2005). In a few studies, there were volunteers sterilely protected against sporozoite challenge, with delays in onset of parasitemia exhibited in others (Webster et al., 2005). These prime-boost regimens involving DNA and poxvectors were transitioned to testing in Africa, but, disappointingly, in two different Phase 2b trials, no protection was observed (Bejon et al., 2006, 2007; Moorthy et al., 2004). These vaccines, like many others, have been sidelined while efforts are underway to improve the viral platforms.

Many clinical trials testing heterologous prime-boost regimens can be anticipated in the coming years. Tempering the excitement, however, is an awareness of the difficulties associated with developing two different vaccines for use in one regimen, including the challenges of forming the business partnerships that are often required, the complex administration schedules and increased expense. These concerns currently motivate efforts to improve homologous regimens to the point where they may equal the immunogenicity of heterologous regimens.

Other Platforms

Bacteria have been evaluated as delivery systems for several decades. The transgene is expressed from plasmids residing in the host bacterium. Efforts to develop Salmonella as a delivery platform for malarial antigens continue, e.g., at the University of Maryland (Chinchilla et al., 2007) and the University of Newcastle (McKelvie et al., 2008). Bacillus Calmette-Guérin (BCG), a live and attenuated strain of *Mycobacterium bovis*, is also under development as a platform for malaria vaccines (Beveridge et al., 2007; Rapeah and Norazmi, 2006; Zheng et al., 2002). Protozoa, including Toxoplasmosis have also been used as delivery systems for malarial antigens (Charest et al., 2000).

Whole Organism Vaccines

Spurred by the many challenges facing subunit vaccines, the last 5 years have seen the reemergence of the whole organism approach. During more than 40 years, irradiated sporozoites provided a highly meritorious model but pointedly lacked viability as a licensable product (Luke and Hoffman, 2003). Rather than targeting an identified biological process, the whole organism approach seeks to identify the best immunogen, presenting to the immune system a complex array of antigens that are tested for protection (Pinzon-Charry and Good, 2008). In this approach, neither the antigens nor the protective immune mechanism needs to be identified. This empirical approach is supported by the fact that most licensed vaccines have been developed in this fashion, and consist of whole, attenuated organisms or material isolated from whole organisms such as a toxin or crude antigen preparations.

Most pathogens are less complex than *Plasmodium*, however, which has a genome comprising more than 5300 genes. Moreover, most of these pathogens can be easily cultured, facilitating attenuation and enabling scale-up for mass production. The only stage of any human malarial parasite that can be routinely and easily cultured is the blood stage of *P. falciparum*, and this requires human blood as the substrate—thus, there has never been a way to attenuate preerythrocytic stages via repeated passage nor to collect significant quantities of immunogen from the preerythrocytic stage of any malarial parasite or from the blood stage of any species other than *P. falciparum*. In terms of the irradiated sporozoite model, the only way to produce sporozoites is from mosquitoes.

There are multiple additional barriers to a whole sporozoite vaccine, including administration (using mosquitoes as the method for administration is not practical), suitability for parenteral injection (the mosquito "factory" for producing sporozoites originates in swamp-like open trays of water hardly amenable to good manufacturing practices), and storage (the sporozoites must be maintained in a metabolically active state in order to undergo partial development in the liver and induce protective responses). Finally, there are concerns about attenuation, since a single sporozoite completing liver-stage development could turn a protective vaccine into a lethal malarial infection.

Remarkably, many of the barriers have been overcome by creative bioengineering, enabling the revitalization of the attenuated sporozoite concept. There are now at least two approaches under development, both supported by the Malaria Vaccine Initiative at PATH, with funds provided by the Bill and Melinda Gates Foundation. One approach is based on sporozoites genetically attenuated via irradiation and the other is based on genetic attenuation via targeted gene deletion (knockout). There are intriguing data suggesting that a whole, attenuated blood stage vaccine may be feasible as well (Pombo et al., 2002). The attenuated whole organism approach is now on an accelerating development track, in parallel with subunit vaccines, and the malaria vaccine field is galvanized to observe the outcome of the first clinical trials.

Within this historical framework, the next section will review a selection of active vaccine candidates

focusing on those in clinical development. There are many additional vaccines not described, most of which have not yet reached clinical testing. Exhaustive lists of candidates have recently been published, and are available for perusal on the Internet (World Health Organization Rainbow Table; Moran et al., 2007).

Vaccines Currently under Development

Preerythrocytic Stage Vaccines

Preerythrocytic stage malaria vaccines have induced complete protection against blood stage infection by targeting sporozoites and liver stage parasites. Partially effective preerythrocytic stage vaccines have reduced liver stage parasite burden and the frequency and severity of clinical episodes of malaria.

Vaccines Based on Circumsporozoite Protein

CSP forms the surface coat of the sporozoite and is involved in sporozoite invasion of hepatocytes, with a recently described role in sporozoite morphogenesis (Kappe, 2004). Humans protected with irradiated sporozoites generate antibodies and lymphocytes recognizing CSP (Egan et al., 1993; Krzych et al., 1995), and sera induced by CSP have been shown to inhibit sporozoite invasion (Hollingdale et al., 1987) and CTL to destroy infected hepatocytes (Franke et al., 2000). The antigen is protective in animal models (Bharadwaj et al., 1998; Charest et al., 2000; Doolan et al., 1996; Lanar et al., 1996; Sedegah et al., 1994; Wang et al., 1995), and CD8+ and CD4+ T-cell responses to specific epitopes within CSP have been described (Doolan and Good, 1992; Marussig et al., 1997; Zevering et al., 1998). Although there have been many vaccine compositions based on CSP, only the RTS,S recombinant protein vaccine, developed in 1987, has consistently induced protective responses in humans, and only when formulated in particular adjuvant systems (Ballou and Cahill, 2007; Heppner et al., 1996, 2001, 2005).

RTS,S (CSP) (Adjuvanted Hybrid CSP-HepB Particle) The world's leading malaria vaccine, RTS,S, is the product of a twenty year collaboration initiated in 1984 between the Walter Reed Army Institute of Research (WRAIR) and GlaxoSmithKline Biologicals (GSK) (Ballou and Cahill, 2007; Heppner et al., 1996, 2001; 2005). The CSP antigen in RTS,S is a hybrid protein containing part of the tandem **r**epeat region of CSP (R), a contiguous segment of the C-terminal flanking region harboring key **T**-cell epitopes (T) and the N-terminus of the hepatitis B **s**urface antigen (HBsAg) (S). This fusion protein (RTS) is expressed by the yeast *Saccharomyces* in 1:4 ratio with unfused HBsAg (S). The RTS and S proteins spontaneously assemble into virus like particles with CSP arrayed on the surface. RTS,S was first successfully adjuvanted with GSK's proprietary adjuvant AS02A (an oil-in-water emulsion containing the two immunostimulants QS21 and MPL) and more recently with the liposomal AS01B and with AS02D, two additional proprietary adjuvant systems developed by GSK (Mettens et al., 2008).

In a meta-analysis of Phase 2a trials, RTS,S/AS02A was shown to have induced sterile protection against experimental sporozoite challenge in 41% of malaria naïve adult volunteers (95% CI [22–56%], $p = 0.0006$) and partial protection in the majority of those not sterilely protected, as evidenced by a significant delay in onset of parasitemia (Kester et al., 2001). A subsequent Phase 2b trial conducted in semi-immune Gambian adults with lifetime exposure to malaria demonstrated a 34% reduction in the incidence of first parasitemia (95% CI [8–53%]) over a 16-week follow-up period, providing evidence for protection against naturally transmitted malaria (Bojang et al., 2001).

Following these promising results, the vaccine advanced to Phase 1 studies in children in the Gambia and Mozambique, where it was shown to be safe and immunogenic (Bojang, 2005). Subsequently, a Phase 2b, randomized, double-blind, controlled trial conducted in children 1 to 4 years of age in Mozambique demonstrated an overall reduction in time to the first clinical episode of malaria of 30% (95% CI [11–45%]) at 6 months, with a one year extension to the surveillance period showing sustained protection (35%, 95% CI [22–47%]) (Alonso et al., 2004, 2005) (Fig. 65.7). Furthermore, RTS,S/AS02A showed 58% (95% CI [16–81%]) and 49% (95% CI [12–71%]) protection against severe malaria during these same observation periods, at 6 and 18 months, respectively (Alonso et al., 2004, 2005). Most recently, RTS,S/AS02D reduced the rate of new onset parasitemia in infants over a six month observation period by 66% (95% CI [43–80]%) (Aponte et al., 2007). These results demonstrate the potential of RTS,S to reduce the burden of malaria in endemic areas, and have established it as a leading malaria vaccine candidate.

A large Phase 3 trial is scheduled to begin in late 2008 in seven countries across Africa under a partnership agreement between GSK and PATH MVI, a grantee of the Bill and Melinda Gates Foundation (Ballou and Cahill, 2007), with costs shared between GSK and MVI. This Phase 3 trial will determine if the encouraging findings in Mozambique extend to other geographic areas encompassing diverse populations and transmission conditions. If all goes well in the

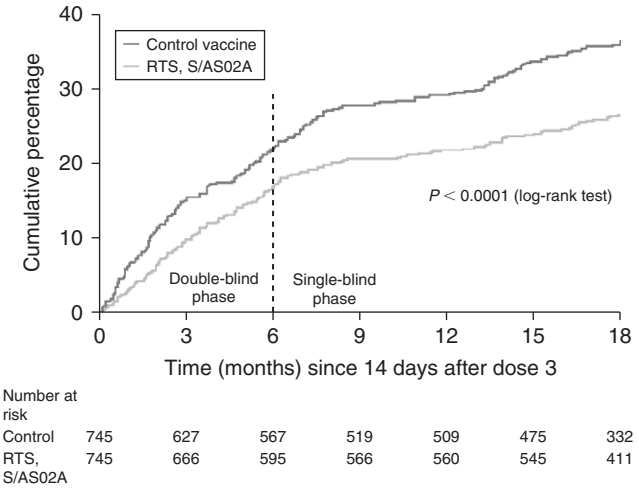

FIGURE 65.7 Kaplan-Meier curves for the cumulative proportion of children with at least one episode of clinical malaria. Protection against clinical malaria was sustained for 18 months in 1–4-year-old children living in Mozambique, following immunization with RTS,S/ASO2A. Reprinted from The Lancet, Vol. 366, Alonso et al., 2005, with permission from Elsevier.

Phase 3 trial, the sponsor, GSK, anticipates submitting its file to the European Medicines Agency for a positive opinion under the Article 58 procedure by 2011. In anticipation of a successful outcome to this Phase 3 trial, the processes required for host country approval and national public health policy decision-making are already being developed.

RTS,S Combinations There have been several efforts to improve RTS,S by (1) prime-boost combination with other vaccine platforms including DNA (Epstein et al., 2004) and poxvirus (Dunachie et al., 2006b) and (2) through combination with other preerythrocytic (TRAP/SSP2) and blood stage (MSP1) antigens. None has led to significant improvements, and in one case (combination with TRAP/SSP2) appeared to have compromised the protection afforded by RTS,S (Ballou and Cahill, 2007; Heppner et al., 2005). On the horizon are prime-boost regimens pairing RTS,S with adenovirus, a combination that strongly boosts cell-mediated immune responses without compromising the already excellent antibody responses (Hutchings et al., 2007; Rodriguez et al., 2008; Stewart et al., 2007). Although the clinical development pathway for an adenovirus-recombinant protein prime-boost regimen for CSP has not been defined, it is a high priority.

Ad35.CS (Gene Encoding CSP) (Adenovirus Serotype 35) The National Institute of Allergy and Infectious Diseases (NIAID) at the National Institutes of Health (NIH) has partnered with the biotechnology company, Crucell, to develop a CSP-based vaccine using an adenovirus serotype 35 vector. This vaccine, called Ad35.CS, is currently being tested in a Phase 1 trial by Vanderbilt and Stanford Universities, and was demonstrated to be safe and immunogenic (B.F. Hall, personal communication). Assuming that appropriate safety and immunogenicity criteria are met, NIAID currently plans further evaluation of this product in clinical trials in Africa and elsewhere.

Vaccines Based on TRAP/SSP2 TRAP/SSP2 is a highly conserved SSP associated with gliding motility and hepatocyte invasion (Muller et al., 1993). Immunization with TRAP/SSP2 has induced protection or partial protection against sporozoite challenge in mice (Khusmith et al., 1991; Schneider et al., 1998; Wang et al., 1996), monkeys (Bhardwaj et al., 2003), and humans (Dunachie et al., 2006a; Webster et al., 2005). CD8+ T-cell-dependent cytolytic activity mediated by HLA-restricted epitopes in TRAP/SSP2 has been identified in humans immunized with irradiated sporozoites (Wizel et al., 1995a, 1995b) as well as humans living in malaria-endemic areas (Aidoo et al., 1995).

TRAP/SSP2 1 Multiepitope String (Gene Encoding this Antigen) (MVA and FP) Adrian Hill at Oxford, whose pioneering clinical studies of prime-boost regimens were described earlier, is developing TRAP/SSP2 for delivery by a simian adenovirus-vector (Reyes-Sandoval et al., 2008). The antigen is expressed as a fusion protein linking the TRAP/SSP2 molecule to a multiepitope string of T- and B-cell epitopes (ME-TRAP). A clinical trial funded by the Medical Research Council and the Wellcome Trust is currently underway at the Jenner Institute to test this approach, in collaboration with the biopharmaceutical company, Okairòs. Future plans include using simian adenovectors in prime-boost approaches with MVA and building internal adjuvants into the vector to enhance immunogenicity, a project supported by the Foundation for NIH (Bill and Melinda Gates Foundation Grand Challenge in Global Health Program). Clinical trials of blood stage antigens delivered by simian adenovirus and MVA vectors are also planned.

Vaccines Based on Liver-Stage Antigen 1 LSA1 is a 230 kDa preerythrocytic stage protein containing a large central region consisting of over eighty 17 amino acid residue repeat units flanked by highly conserved C- and N-terminal regions (Fidock et al., 1994; Zhu and Hollingdale, 1991). LSA1 is expressed

only by liver stage parasites, not by sporozoites; currently, its function is not known. Humans immunized with irradiated sporozoites demonstrate proliferative responses against LSA1 (Krzych et al., 1995), and people living in endemic regions demonstrate interferon gamma responses (John et al., 2004; Migot-Nabias et al., 2000) and CTL responses (Hill et al., 1992) against specific LSA1 epitopes. A study conducted in Kenya indicated that high levels of IgG targeting LSA1 are associated with protection from infection (John et al., 2008).

FMP011 (LSA1) (Recombinant Protein) Based on these data, WRAIR and GSK developed an LSA1-based recombinant protein vaccine, called falciparum malaria protein 011 (FMP011) (Hillier et al., 2005). After demonstrating immunogenicity in mice and NHPs (Brando et al., 2007; Pichyangkul et al., 2008), FMP011 was tested in malaria-naïve healthy adult volunteers using AS02A and AS01B as adjuvants. In a Phase 1/2a clinical trial, the vaccine was shown to be safe and to induce strong antibody responses and strong CD4+ T-cell responses. However, no protection or delay in parasitemia was observed following sporozoite challenge (J. Cummings, personal communication), indicating that a different quality of immune response may be required to achieve protection with LSA1. An adenovirus construct containing the same sequence used to make FMP011 was tested in a prime-boost regimen with FMP011, and this regimen induced high CD8 responses in mice (Rodriguez et al., 2008) suggesting that adenovirus protein prime-boost may prove more effective for the induction of a protective immune response in humans than FMP-11 alone.

Vaccines Based on Liver Stage Antigen 3 LSA3 is a relatively conserved preerythrocytic stage antigen selected by differential immune responses from irradiated sporozoite immunized volunteers, either protected or not upon challenge. Using lipopeptide formulations, DNA, adjuvated peptide, or recombinant protein, the antigen is protective in mice (Sauzet et al., 2001) and induces CD4 Th1-related protection against *P. falciparum* challenges in *Aotus* monkeys (Perlaza et al., 2003) and chimpanzees (BenMohamed et al., 2004; Daubersies et al., 2000).

PfLSA-3-rec (LSA3) (Recombinant Protein) A vaccine based on LSA-3 is being developed by the Institute Pasteur, as a recombinant protein and, under consideration, as a lipopeptide. The recombinant protein construct, PfLSA-3-rec, has been formulated in adjuvant and is being tested at Radboud University Nijmegen Medical Centre in the Netherlands with funding by the European Commission, for safety, immunogenicity, and protective efficacy against experimental sporozoite challenge in humans.

Vaccines Based on Multiple Preerythrocytic Stage Antigens

FP9-PP and MVA-PP (Gene Expressing Polyprotein Linking LSA3, STARP, Pfs16, Exp1, TRAP/SSP2, LSA1) (MVA and FP) Adrian Hill at Oxford has constructed a polyprotein 3240 amino acids in length called L3SEPTL that includes six preerythrocytic stage antigens: LSA3, sporozoite threonine and asparagine rich protein (STARP), exported protein-1 (Exp1), Pfs16 (an integral membrane protein expressed by sexual stage parasites as well as sporozoites), TRAP/SSP2, and LSA1 (Prieur et al., 2004). This linked sequence of genes has been cloned into DNA, MVA, and FP vaccine delivery platforms. A Phase 1/2a trial was conducted in 2006 at Oxford University using prime-boost combination of FP and MVA; although the vaccine was safe and moderately immunogenic, there was no protection against experimental sporozoite challenge (A. Hill, personal communication).

Vaccines Based on Sporozoites

PfSPZ (Metabolically Active, Radiation-Attenuated Sporozoites) PfSPZ is a metabolically active, nonreplicating (attenuated by radiation) sporozoite vaccine being developed by Stephen Hoffman at Sanaria, Inc, a biotechnology company aiming to induce complete protection against malarial infection by using sporozoites as immunogens. The company has overcome the previously discussed biological and manufacturing obstacles by designing a process meeting regulatory and commercial standards for safety, purity, potency, and stability (Fig. 65.8). With scale-up, this process should allow for the production of enough vaccine to fulfill global requirements. PfSPZ will be assessed for safety, tolerability, immunogenicity, and protective efficacy in healthy adult volunteers in 2009. The clinical trial will be conducted by the U.S. Naval Medical Research Center and the University of Maryland Center for Vaccine Development, with support provided by PATH MVI. The trial will explore whether or not the high levels of protection demonstrated in humans 30 years ago following the delivery of fresh, radiation-attenuated sporozoites via mosquito bite can be reproduced by a commercially viable product that is cryopreserved, thawed, and delivered via

FIGURE 65.8 Manufacturing sporozoites. (A) Feeding sterile mosquitoes on sterile gametocytemic blood cultures is part of the manufacturing process required to produce sporozoites for injection. (B) Approximately 2 weeks later, the sporozoites are harvested from the salivary glands and then purified. Photographs by Robert C. Thompson, Sanaria, Inc.

needle and syringe. Sanaria had recently established two partnerships to develop and test sporozoites attenuated by a different approach, targeted gene deletion. One is with Columbia University and the second is with Top Institute Pharma, the Radboud University Nijmegen Medical Centre, and the Leiden University Medical Center.

Genetically Attenuated Sporozoites (Gene Knockout Sporozoites) The initial development of targeted gene deletions to create genetically attenuated sporozoites took place at the Seattle Biomedical Research Institute in collaboration with the University of Heidelburg (Mueller et al., 2005a, 2005b) and independently at Leiden University (van Dijk et al., 2005). The basic approach is to identify genes in a murine malaria model that, when deleted from the genome, lead to arrested development in the liver. These gene knockout parasite lines are tested for protective efficacy by immunizing mice with the knockout sporozoites and then challenging with intact sporozoites. Those attenuated parasites inducing protective responses with no occurrence of breakthrough blood stage infection are reproduced in *P. falciparum* by knocking out the orthologous genes, ideally creating a double knockout to ensure adequate attenuation (Jobe et al., 2007; Labaied et al., 2007). A major project based on this approach is led by Stefan Kappe at the Seattle Biological Research Institute in partnership with the Walter and Elisa Hall Institute in Melbourne and the Walter Reed Army Institute of Research (WRAIR), supported by the Foundation for NIH (Bill and Melinda Gates Foundation Grand Challenges in Global Health Program). Investigators have deleted preerythrocytic stage-essential genes from the *P. falciparum* genome, and will test these attenuated lines in a clinical trial conducted at WRAIR, delivering the sporozoites via mosquito bite. It is hoped that this vaccine will induce high levels of protection, and that the protection will prove long-lasting, since studies in the rodent models have indicated that 100% protection against sporozoite challenge can last up to 180 days after immunization with gene knockout sporozoites (Tarun et al., 2007). If successful in this proof-of-principle study, the vaccine will be engineered into a GMP production system such as that being developed for the PfSPZ vaccine.

Intact Sporozoites An interesting proof-of-principle trial has been conducted at Radboud University Nijmegen Medical Centre in the Netherlands to see if immunity to preerythrocytic stage malaria can be induced by intact sporozoites. In this clinical trial, led by Robert Sauerwein, volunteers are being exposed three times to the bites of infectious mosquitoes while protected against blood stage malaria with chloroquine. Following immunization, volunteers are challenged to look for protective immunity. While immunization with intact sporozoites under chloroquine protection is not likely a feasible strategy for a commercial vaccine, the trial will have significant bearing on research into whole sporozoite vaccines.

Asexual Erythrocytic Stage Vaccines

Asexual erythrocytic (blood) stage vaccines are designed to limit parasite density, or to counter the

effects of malaria toxins, thereby reducing the clinical manifestations of malaria.

Vaccines Based on Merozoite Surface Protein 1

MSP1 is one of the best characterized blood stage antigens and is a leading vaccine candidate. It is a 195 kDa protein, the most abundant of the nine GPI-anchored proteins on the surface of the merozoite. It undergoes proteolytic cleavage to yield four fragments (as seen on SDS-PAGE analysis of merozoite extracts), including the C-terminal 42 kDa fragment, MSP1-42. This fragment undergoes another cleavage to yield a 19 kDa fragment (MSP1-19) and a 33 kDa fragment, which are involved in merozoite invasion, with the 19 kDa fragment internalized during invasion. Antibodies to the C-terminal region of PfMSP1 inhibit merozoite invasion in vitro (Long et al., 1994), confer passive immunity in rodents (Burns et al., 1989, 2004), and are associated with resistance to clinical malaria caused by *P. falciparum* in humans in some (Branch et al., 1998; Egan et al., 1996; Riley et al., 1992) but not all (Osier et al., 2008) studies. The presence of anti-MSP1 antibodies, particularly IgG, has been associated with a decrease in blood stage infections and febrile illness (Huaman et al., 2008). Antibodies against MSP1 appear to be an indicator of NAI, and may reduce severe complications of malaria including severe malarial anemia (Dobano et al., 2008). For these reasons, MSP1-based vaccines have been extensively investigated as potential antidisease vaccines for use in endemic regions. There have been more than 20 different MSP1 constructs in various stages of preclinical and clinical development (Genton and Reed, 2007). Two development projects will be described.

FMP1/AS02A (MSP1-42) (Recombinant Protein) This recombinant protein vaccine was developed by WRAIR and GSK with support from USAID, and has progressed farthest in clinical trials among the MSP1-42 vaccine candidates. The vaccine uses the MSP1-42 from the 3D7 clone of *P. falciparum* and is expressed in *E. coli* and formulated with the adjuvant AS02A. A Phase 1 trial conducted in malaria-naïve adults in the USA demonstrated that the vaccine was safe and immunogenic (Ockenhouse et al., 2006a); a second Phase 1/2a trial in which FMP1/AS02A was delivered alone and also in combination with RTS,S confirmed these findings but did not show any protection induced by FMP1 alone or any significant enhancement of the protection afforded by RTS,S when given in combination (J. Cummings, personal communication). FMP1/AS02A without RTS,S was transitioned to Africa, where it was demonstrated to be safe and immunogenic, initially in two Phase 1b trials conducted in malaria-exposed adults, one in Kenya conducted by the Kenya Medical Research Institute (KEMRI) and Walter Reed Project (Stoute et al., 1997, 2007) and the second in Mali conducted by the Malaria Research and Training Center (MRTC), University of Bamako, with support from the University of Maryland (Thera et al., 2006), and then in a Phase 1b trial conducted in children in Kenya by KEMRI/WRAIR (Withers et al., 2006). These studies were followed by a Phase 2b trial also in Kenyan children, also conducted by the KEMRI/WRAIR with additional support from PATH MVI; unfortunately, this trial did not demonstrate any protective effect in reducing parasitemia or clinical malaria (B. Ogutu, personal communication), although a subanalysis aimed at identifying any allele-specific effects is ongoing (C. Ockenhouse, personal communication). While the FMP01 vaccine, which is based on the 3D7 allele, has been sidelined from further testing due to relatively poor induction of growth inhibitory activity in vitro and the lack of cross-strain protection seen in the Phase 2b trial, the FVO version of the MSP1-42 vaccine (FMP010) remains under clinical development by WRAIR/GSK and will soon be tested in a Phase 1 study adjuvanted with AS01B.

MSP1-42-C1/Alhydrogel + CPG7909 (MSP1-42) (Recombinant Protein) The Malaria Vaccine Development Branch (MVDB) at NIAID is developing a second MSP1-42-based vaccine, a recombinant protein containing a mixture of the 3D7 and FVO alleles formulated on Alhydrogel. The vaccine antigens are produced in *E. coli* and then refolded. Both the FVO and 3D7 forms of MSP1-42 when formulated independently on Alhydrogel proved modestly immunogenic in a first Phase 1 study (Huaman et al., 2008; Malkin et al., 2007). The antibodies generated in response to vaccination recognized both forms of the protein equally whereas the T cells predominantly recognized the immunizing allele. A second trial evaluated a vaccine composed of both the FVO and 3D7 alleles of MSP1-42 (MSP1-42-C1) formulated on Alhydrogel with or without the Toll-like receptor 9 immunostimulant CPG 7909; this trial was recently completed in the USA by the Johns Hopkins University. The vaccine combination was demonstrated to be safe, and the addition of CPG 7909 significantly enhanced the antibody response over Alhydrogel alone (L. Martin, personal communication). Despite the enhancement in specific antibody levels, parasite growth inhibition in vitro was only moderately enhanced by the immunostimulant. Thus, further development of the CPG 7909 formulation

of MSP1-42-C1/Alhydrogel has recently been halted by MVDB.

Vaccines Based on Apical Membrane Antigen 1 AMA1 is an 83 kDa membrane protein originating from micronemes in the apical complex, expressed on the surface of merozoites and involved in erythrocyte invasion (Mitchell et al., 2004). The AMA1 gene appears to have extensive cross-species homology; unlike many other malarial antigens it has no repeat residues. Antibodies to AMA1 have a strong inhibitory effect on parasite growth in vitro (Kocken et al., 2002), but this potential advantage as a vaccine candidate is balanced against the protein's high degree of genetic polymorphism (Bai et al., 2005; Escalante et al., 2001; Healer et al., 2004). This polymorphism probably indicates the importance of AMA1 as a target of protective immunity and therefore underlines the difficulties to be faced in designing a broadly protective formulation without including multiple alleles, although there is recent progress in developing chimeric constructs that induce cross-protective responses (Dutta et al., 2007). Antibodies against AMA1 have been associated with protective immunity in malaria-endemic areas (Polley, 2004; Gray et al., 2007; Osier et al., 2008), and immunization with AMA1 has afforded protection in animal models (Anders et al., 1998; Burns et al., 2004; Narum et al., 2000; Salazar et al., 2002). Recently, it has been discovered that AMA1 is present on the surface of sporozoites as well as merozoites and plays a role in hepatocyte invasion (Silvie et al., 2004), indicating that an AMA1 vaccine may be able to target both the preerythrocytic and erythrocytic stages of the parasite. This leading vaccine candidate (Remarque et al., 2008) is being developed in parallel as a recombinant protein by several different institutions. Three development efforts will be described.

AMA1-C1 (AMA1) (Recombinant Protein) The AMA1-C1 vaccine developed by MVDB at NIAID is the AMA1 construct farthest along the clinical testing pathway. It contains recombinant AMA1 proteins representing the ectodomains from both the FVO and 3D7 alleles of *P. falciparum*, expressed in *Pichia pastoris* and formulated with the adjuvant Alhydrogel. The inclusion of two alleles aims to address the antigenic heterogeneity of AMA1. Clinical trials conducted in malaria-naive adult volunteers in the USA demonstrated that the vaccine was safe and elicited functional antibody responses inhibiting the growth of asexual stage *P. falciparum* parasites in vitro (Malkin et al., 2005). Subsequent Phase 1 studies conducted in adults and children in Mali by the MRTC also showed the vaccine to be safe and immunogenic in endemic populations (Dicko et al., 2008). Based on these results, the vaccine was advanced to a Phase 2b trial in a 2–3-year-old pediatric population in Bancoumana, Mali, but did not show any protection against parasitemia or clinical disease during the first 5 months of follow-up (A. Dicko, personal communication). As with its MSP1-42 vaccine, MVDB is combining AMA1-C1/Alhydrogel with CPG-7909, and this new formulation is undergoing clinical testing in adults in the USA and in Doneguebougou, Mali (MRTC). This vaccine was found to be safe in both populations and to enhance the specific antibody response over the same formulation without the addition of CPG 7909, so it is advancing to Phase 1 evaluation in young children in Mali and will be considered for Phase 2b efficacy testing. A third formulation, AMA1-C1/ISA 720, is being tested in malaria-naïve adults in Brisbane, Australia. This trial is still ongoing, and no safety issues have been noted to date (L. Martin, personal communication).

FMP2.1/AS02A (AMA1) (Recombinant Protein) The FMP2.1 vaccine was developed by WRAIR and GSK with support provided by USAID. It consists of the ectodomain of the 3D7 allele, is produced in *E. coli*, and formulated with AS02A. Safety, tolerability, and immunogenicity were demonstrated in a Phase 1 study conducted in healthy adults in the USA (Polhemus et al., 2007), and the vaccine was then transitioned to Mali where safety and immunogenicity were confirmed in adults (Thera et al., 2008) and children (M. Thera, personal communication). There followed a Phase 2b efficacy trial, conducted in Bandiagara by the Malaria Research and Training Center (University of Bamako) in partnership with the University of Maryland; this trial was recently completed and protection (and other) results are pending. WRAIR has also conducted a Phase 1/2a challenge study in malaria-naïve adults in the USA comparing AMA1 formulated in the adjuvants AS01B and AS02A. Although the vaccine was immunogenic and strongly induced growth-inhibitory antibodies, there was no protection against sporozoite challenge (M. Spring, personal communication). However, it is difficult to rule out an antidisease effect using the experimental challenge model; information on antidisease effect should be forthcoming from the pediatric Phase 2b trial recently completed in Mali.

PfAMA1-FVO[25-545] (AMA1) (Recombinant Protein) In a third development effort, the AMA1 ectodomain

from the FVO allele expressed in *P. pastoris* is being developed by a European/African consortium, including the Biomedical Primate Research Centre (BPRC) in Rijswijk, the European Malaria Vaccine Initiative (EMVI), the MRTC in Mali and, as the sponsor, the African Malaria Network Trust (AMANET). After Phase 1 testing at Radboud University Nijmegen Medical Centre in the Netherlands, comparing several adjuvants, the vaccine was advanced to Mali, where a clinical trial conducted in Bandiagara demonstrated that the vaccine, formulated in Alhydrogel, was safe and immunogenic in African adults (M. Thera, personal communication). The future of this vaccine is unclear, given the lack of protection seen with the MVDB product in Mali and the pending protection results from the WRAIR/GSK product.

Vaccines Based on Merozoite Surface Protein 3

MSP3 is another merozoite surface protein associated with erythrocyte invasion. MSP3 is supported as a vaccine candidate by epidemiological evidence from endemic areas, where antibody levels to both conserved and polymorphic regions may be positively associated with protection against clinical malaria (Polley, 2007; Osier, 2007; Roussilhon et al., 2007; Osier et al., 2008) and also by studies in NHP models where immunization led to protection against blood stage challenge (Carvalho et al., 2004, 2005; Hisaeda et al., 2002). One development effort will be described.

MSP3-LSP (MSP3) (Long Synthetic Peptide) The merozoite surface protein 3 long synthetic peptide (MSP3-LSP) vaccine, developed by Pierre Druilhe at the Institute Pasteur, comprises the conserved C terminal region of the molecule (amino acids 186–276) associated with the induction of cytophilic antibodies stimulating monocyte-mediated protection against blood stage malaria (Oeuvray et al., 1994; Singh et al., 2004). The vaccine, formulated on Montanide ISA 720 or on aluminum hydroxide, was studied in a Phase 1 trial at the University of Lausanne, and was found to be immunogenic for antibodies, proliferative responses, and interferon-gamma production (Audran et al., 2005). Immunoglobulin isolated from 60% of the vaccine recipients up to a year after immunization inhibited *P. falciparum* erythrocytic growth in a monocyte-dependent manner in vitro and in *P. falciparum*-infected humanized SCID mice in vivo (Druilhe et al., 2005). Due to unacceptable local reactogenicity associated with the Montanide preparation in the initial trial, subsequent studies have used the aluminum hydroxide adjuvant. In a follow-on Phase 1 trial in malaria-exposed adults in Burkina Faso, the vaccine was well tolerated and induced lymphoproliferative responses, but did not increase antibodies which were already at high levels in these malaria-exposed adults (Sirima et al., 2007). MSP3-LSP is currently being studied in two Phase 1 trials in children, one conducted by the National Institute for Medical Research (NIMR) in Tanzania and the second by the Centre National de Recherche et de Formation sur le Paludisme in Burkina Faso, under sponsorship from AMANET, and safety profiles appear favorable to date. The vaccine is progressing to Phase 2b efficacy testing in Sotuba, Mali.

Vaccines Based on Other Blood Stage Proteins

Vaccines based on other merozoite surface proteins are being developed, including the development of MSP2 at LaTrobe University in Melbourne, Australia, in association with Q Pharm, Brisbane, Australia, and MSP4 and MSP5 at Monash University also in Melbourne. Both projects are receiving support from PATH MVI. In addition, the extramural program at NIH is developing the erythrocyte binding antigen EBA-175, which has undergone Phase 1 clinical testing. Another blood stage candidate, the serine repeat antigen (SERA), is being developed by Osaka University and BIKEN Pharmaceuticals in Japan. This vaccine, called SE36, is a recombinant protein consisting of the amino terminal domain (amino acids 17–382) of *P. falciparum* SERA 5, produced in *E. coli* and formulated on alum. A Phase 1 clinical trial has been conducted in malaria-naive adults in Japan by Toshi Horii.

Vaccines Based on Multiple Blood Stage Proteins

PfCP-2.9 (MSP1-19 + AMA1-domain III) (Recombinant Fusion Protein) This vaccine is a fusion antigen consisting of the C-terminal region of AMA1 and the 19 kDa portion of MSP1 produced in *P. pastoris* and formulated on Montanide ISA 720 (Pan et al., 2004). It is being developed by Shanghai Wanxing Bio-Pharmaceuticals and the Second Military Medical University in Shanghai with support from WHO and PATH MVI. The safety and immunogenicity of this vaccine were demonstrated in a Phase 1 clinical trial conducted in malaria-naïve adults at the Shanghai Changhai Hospital (Hu et al., 2008), and a second trial is planned for the same site prior to a decision whether or not to test the vaccine in endemic areas.

GMZ2 (GLURP 1 MSP3) (Recombinant Fusion Protein) This recombinant protein hybrid of two blood stage antigens, glutamate rich protein (GLURP) and MSP3, produced in *Lactococcus lactis* and formulated in

aluminum hydroxide, has been developed by Michael Theisen at Statens Serum Institut in Copenhagen. The vaccine was studied in a dose escalation Phase 1 trial in malaria-naive adults at Tübingen University in Germany, under sponsorship by EMVI. The vaccine is currently undergoing Phase 1 testing in adult Gabonese at the Medical Research Unit of Albert Schweitzer Hospital in Lambarene under sponsorship by AMANET. GLURP, formulated as a long synthetic peptide rather than as a recombinant protein, had previously been studied as a single antigen vaccine at Radboud University Nijmegen Medical Centre in the Netherlands in a Phase 1 trial sponsored by EMVI, where it was well tolerated and induced antibodies inhibiting the growth of *P. falciparum* in vitro (Hermsen et al., 2007). However, further development of GLURP as a single antigen, either as a long synthetic peptide (which proved difficult to manufacture) or as a recombinant protein (which has not yet been manufactured as a GMP product), has been sidelined pending results of the GMZ2 trials. GLURP is supported as a vaccine antigen by epidemiological data showing a strong association between antibody responses and protection against clinical malaria (Lusingu et al., 2005; Meraldi et al., 2004; Nebie et al., 2008; Soe et al., 2004) and by the induction of protective responses in NHPs (Carvalho et al., 2004, 2005).

Vaccines Based on Whole Blood Stage Parasites

Blood Stage Whole Organism Vaccine Whole blood stage parasites are being pursued as immunogens in a development effort similar to the development of PfSPZ and genetically attenuated sporozoites. Michael Good and colleagues at the Queensland Institute for Medical Research demonstrated that repeated low-dose infections (injecting only 30 *P. falciparum*-infected red blood cells) followed by drug-treatment-induced protection in malaria-naïve adults, as seen on challenge with a homologous strain of blood stage parasites (Pombo et al., 2002). The majority of volunteers (80%) developed immune responses, including T-cell responses (both CD4+ and CD8+ T cells) and interferon-gamma production, but no antibody responses. These results, supported by animal models also showing protection following blood stage immunization, including against heterologous strain challenge (Elliott et al., 2005), have led to plans for a dose-escalation Phase 1 trial. The candidate vaccine will consist of crude (killed) preparations of blood stage parasite delivered in adjuvant to potentiate cell-mediated immune responses, and will be tested in malaria-naïve adults (M. Good, personal communication).

Multistage Vaccines

The complexities of the malarial parasite, with antigenically distinct life cycle stages and extensive polymorphisms identified in leading candidate antigens, have led investigators to conclude that a multiantigen, multistage vaccine may be required to induce robust protective responses (Doolan and Hoffman, 2001). Multistage vaccines may, in particular, provide a safety net of protection should parasites break through the first (preerythrocytic) barrier of defense, thereby functioning as both antiinfection and antidisease vaccines (Fig. 65.9). Two such efforts are here described.

PEV302 and PEV301 (CSP + AMA1 Peptides) (Virosome) This vaccine is a two-component vaccine developed by the Swiss Tropical Institute and Pevion Biotech Ltd, consisting of peptides derived from CSP and AMA1 formulated in two influenza virosomes, called PEV302 and PEV301, respectively. The virosomes are composed of natural and synthetic phospholipids mixed with influenza surface glycoproteins, forming spherical vesicles that enhance the delivery and immunogenicity of peptide antigens. In a first clinical trial conducted by the Swiss Tropical Institute in malaria-naïve adults, the vaccine induced relatively strong, long-lived antibody responses that inhibited sporozoite migration and hepatocyte invasion in vitro (Genton et al., 2007; Okitsu et al., 2007). In a second clinical trial, three doses of the PEV301/302 mixture were tested alone and in combination with the Oxford ME-TRAP vaccine delivered as an MVA-MVA-FP prime-boost regimen. Encouragingly, there was evidence of protection in the virosome-alone group (Thompson et al., 2008a). Based on these results, the vaccine, which will contain 4–5 small synthetic peptides, is being transitioned to a Phase 1 trial in Tanzania, to be conducted by the Bagamoyo Research and Training Unit.

NMRC-M3V-Ad-PfCA (Genes Expressing CSP + AMA1) (Adenovirus Serotype 5) Developed by the Naval Medical Research Center in partnership with GenVec, Inc and with support provided by USAID and the U.S. Dept. of Defense, this vaccine is comprised of a mixture of two recombinant adenovirus vectors (serotype 5) encoding CSP and the AMA1 ectodomain, respectively. Currently, a Phase 1/2a clinical trial is underway at the U.S. National Naval Medical Center to test the safety, immunogenicity, and protective efficacy of this vaccine. A second adenovectored vaccine, also comprising two constructs, includes five antigens: CSP, LSA1, Ag2/CelTOS, MSP1-42 and AMA1. This vaccine will be tested in 2009 with support from

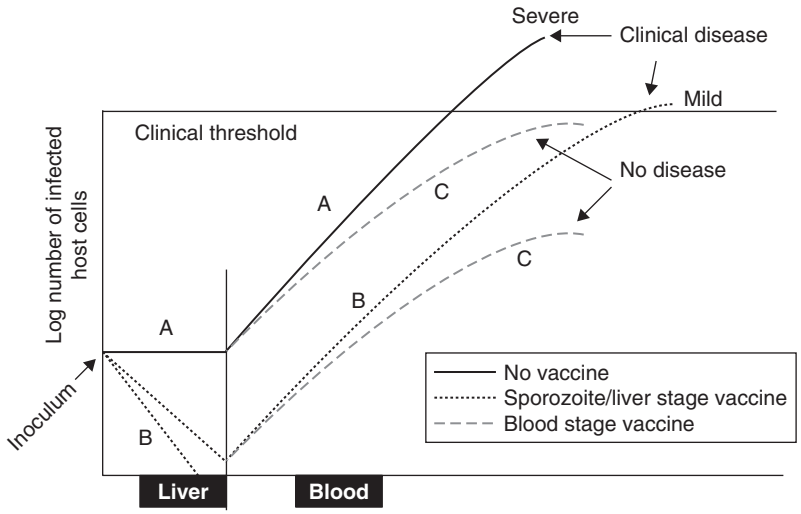

FIGURE 65.9 Two-tiered malaria vaccine. The solid line (A) portrays the normal development of *Plasmodium* in a malaria-naïve host. Following inoculation of sporozoites by mosquito bite, hepatocytes are infected (intersection of line with Y-axis), develop for five or more days and release merozoites into the blood. The parasite then multiplies many orders of magnitude, inducing clinical symptoms which in a naïve host can be severe. The incubation period in the liver provides a window of opportunity for a vaccine-induced immune response to abort the developing infection; this effect is portrayed by the dotted lines. (B) If all parasites are killed, there will be no blood stage infection (dotted line intersects X-axis). If a few parasites get through this first line of defense, the blood stage infection may be less clinically severe because the immune system has more time to respond, causing parasitemia to peak at a lower density, resulting in milder disease (dotted line B). The prediction that a preerythrocytic stage vaccine can reduce blood stage severity in this fashion is born out by the impact of RTS,S on reducing morbidity in children in Mozambique (Alonso et al., 2004) (Fig. 65.7). A blood stage vaccine, on the other hand, acts directly to limit the parasite multiplication in the blood (dashed lines, C), preventing disease even if not the infection. This prediction is born out by the impact of the Combo B vaccine on reducing parasite density (Genton et al., 2002). The two-tiered approach (preerythrocytic + erythrocytic) could be supplemented with a third component—a transmission blocking vaccine—to prevent the spread of vaccine-resistant mutants. Reprinted by permission from S. Karger, A.G. Basel (Kumar et al., 2002).

PATH MVI. Ag2 (antigen 2, or CelTOS) (Kariu et al., 2006) is a novel preerythrocytic stage antigen recognized by lymphocytes from human volunteers immunized with irradiated sporozoites and protected against sporozoite challenge (Doolan et al., 2003b).

Pregnancy-Specific Vaccines

Two genes from the 50 member *var* gene family encoding PfEMP1, var1CSA, and var2CSA are associated with the CSA-binding ability of *P. falciparum* parasites in the placenta that underlies PAM. Var2CSA, in particular, has been shown to be consistently upregulated in various CSA-binding *P. falciparum* genotypes, and is an important antigenic target under consideration for development of a pregnancy-specific vaccine (Gamain et al., 2007). Studies in mice showed that monoclonal antibodies against *P. falciparum* variant surface proteins expressed by CSA-binding parasites inhibit CSA binding (Avril et al., 2006) and that polyclonal antibodies raised in rabbits to defined VAR2CSA Duffy binding-like (DBL) domains from PfEMP1 or induced by DNA vaccines encoding VAR2CSA recognize certain polymorphic VAR2CSA epitopes held in common across geographically diverse CSA-binding parasite lines (Avril et al., 2008). These promising results support further research and investigation into the potential for a pregnancy-specific vaccine. Several such vaccine development projects are underway in various institutions, including the Seattle Biological Research Institute and the University of Copenhagen.

Transmission-Blocking Vaccines

Transmission-blocking vaccines are designed to protect the community by reducing transmission rates, even though not directly protecting individual vaccine recipients. Proponents of transmission-blocking vaccines reason that if a sufficient proportion of the population were to be immunized, malaria-related morbidity and mortality would be reduced, much as occurs through the use of bednets, which also reduce rates of transmission. Transmission-blocking vaccine would thus result in a special type of herd immunity in which none of the individuals would be immunologically protected against the infectious agent. With this type of immunity, a single infectious person entering the community could still spread the infection to others. The levels of immunity needed in a population for a given effect on malaria transmission have been

modeled and suggest that current candidate vaccines should be sufficient to provide a significant reduction in transmission intensity (Saul, 2008).

Transmission blocking is achieved by targeting proteins expressed during the sexual stages of the parasite (Pradel, 2007). Antibodies are passively imbibed by the mosquito during feeding and attack newly revealed sexual stage antigens in the gut of the mosquito, preventing the formation of oocysts and thus sporozoites.

The MVDB of the U.S. NIH is developing several transmission-blocking vaccines against *P. falciparum* and *P. vivax*. The leading candidate antigens, Pfs25, Pfs28, Pvs25, and Pvs28, are expressed on the surface of the ookinete (Pf signifying the *P. falciparum* antigen, Pv the *P. vivax* antigen). Pfs25 was originally produced in *S. cerevisiae* as a recombinant protein TBV25H. TBV25H was formulated on Alhydrogel and tested in two clinical trials, but the product was not pursued further, due in part to concerns over hypersensitivity reactions (Kaslow, 2002; Y. Wu, personal communication). More recently, Pvs25, also expressed as a recombinant protein by *S. cerevisiae*, was formulated on Alhydrogel and assessed in a Phase 1 study. The vaccine was safe and immunogenic, and antibody from the volunteers inhibited parasite development in a membrane feeding assay, with antibody titers correlating with the degree of inhibition (Malkin et al., 2005, 2007), a correlation which has been confirmed by more recent work (Miura et al., 2007a). A second trial assessed Pfs25 and Pvs25, formulated, individually, with Montanide ISA 51. The trial was halted due to systemic reactogenicity including erythema nodosum and leukemoid reaction, although Pfs25/ISA51 induced transmission-blocking antibody responses (Y. Wu, personal communication). New formulations are now under development at MVDB. Other efforts to develop transmission-blocking vaccines are being pursued at the Johns Hopkins Bloomberg School of Public Health in Maryland (LeBlanc et al., 2008), Nijmegen Medical Center, The Netherlands (Outchkourov et al., 2008), and the Ehime University in Matsuyama, Japan (Arakawa et al., 2005).

An important role for transmission-blocking vaccines may be their combination with preerythrocytic or erythrocytic stage vaccines in order to prevent the transmission of vaccine escape mutants and thus stave off the degradation of vaccine efficacy over time through the gradual spread of vaccine-resistant parasite strains. A significant challenge for testing the efficacy of transmission-blocking vaccines, whether used alone or in combination with other malaria vaccines, will be developing field-based indices for measuring transmission intensity as an outcome variable. Field trials may require randomization of villages to treatment arms and then comparison of community-specific transmission rates or clinical disease incidence.

P. vivax Vaccines

The burden of *P. vivax* across the world is huge, with 2.6 billion people at risk and 50–70 million cases annually (Guerra et al., 2006, 2007, 2008; Mendis et al., 2001). In many areas outside of Africa, *P. vivax* may often be the dominant malaria species present. Moreover, the clinical manifestations of infection (Song et al., 2003) are equivalent in terms of morbidity to those of uncomplicated *P. falciparum* malaria. Clearly, a vaccine for preventing *P. vivax* is sorely needed.

However, less attention and resources have been applied to *P. vivax* than to *P. falciparum* (Herrera et al., 2007). Although the potential severity and sheer numbers of *P. falciparum* infections are the most important reasons for this difference, there are others. One relates to the ease of maintaining blood stage parasites in culture, which is routine for *P. falciparum* (Trager and Jensen, 1976). *P. vivax* requires reticulocytes as host cells for efficient invasion and growth, and this has hindered the establishment of routine culture, although there has been significant progress (Chotivanich et al., 2001; Golenda et al., 1997; Panichakul et al., 2007; Suwanabun et al., 2001; Udomsangpetch et al., 2007). In the case of *P. falciparum*, blood stage parasite material can be obtained from in vitro cultures, and with the development of techniques to induce gametocyte production (Campbell et al., 1982), sporozoites, and liver stage material as well. These sources of parasites have not been available for *P. vivax*, creating a major impediment for those studying the biology of this species.

The lack of in vitro culture has also hindered vaccine testing, as there has been no sporozoite challenge model available since the cessation of malarial therapy. Malarial therapy was accomplished by direct human to human blood passage, or in some instances sporozoites were obtained by feeding mosquitoes on gametocyte donors. Recently, this deficit has been partially overcome by Socrates Herrera at the Malaria Vaccine and Drug Development Center in Cali Colombia. Relying on the availability of *P. vivax* cases at local health clinics for providing the donations of gametocytemic blood required to infect the mosquitoes, two successful challenges have been conducted. This should significantly accelerate progress in developing and testing *P. vivax* vaccines.

Some of the most notable progress in developing *P. vivax* vaccines reflects distinct differences between the biology of *P. vivax* and *P. falciparum. P. vivax* invades

erythrocytes by binding to the Duffy antigen/receptor for chemokines (DARC), a different entry mechanism than for *P. falciparum*. Remarkably, the invasion of erythrocytes appears to be totally dependent upon this one molecular interaction, since lack of DARC results in the erythrocyte being refractory to *P. vivax* invasion (Miller et al., 1976), with heterozygotes demonstrating reduced infection (Kasehagen et al., 2007). This dependence on the Duffy antigen is thought to explain why the parasite is uncommon or even absent from many parts of Africa, where the Duffy negative phenotype is common, particularly in West Africa.

The parasite-binding ligand, the Duffy-binding protein (DBP), is released from micronemes during the process of invasion. Studies in endemic areas have indicated a possible association between the presence of antibodies to the DBP and protection against clinical malaria (Ceravolo et al., 2008), and erythrocyte invasion can be inhibited in vitro by antibodies directed to DBP (Grimberg et al., 2007; Singh et al., 2002). Recently, the crystal structure and binding epitopes of DBP have been defined (Hans et al., 2005; McHenry and Adams, 2006; Singh et al., 2006; VanBuskirk et al., 2004). It appears that the receptor-binding site of this molecule is relatively conserved, and thus may be amenable to the development of a cross-protective vaccine.

With these supporting data, the DBP has emerged as a vaccine candidate. Vaccines based on the DBP have been tested for immunogenicity and protective efficacy in *Aotus* monkeys (Arevalo-Herrera et al., 2005), and a focused effort to develop this antigen as a vaccine for human use is underway at the International Centre for Genetic Engineering and Biotechnology in New Delhi, India, led by Chetan Chitnis and supported by the PATH MVI.

Other *P. vivax* antigens under development as vaccines include PvCSP, which has been tested in humans as a mixture of three synthetic peptides (Herrera et al., 2005), PvTRAP (Castellanos et al., 2007), PvAMA1 (Kocken, 1999), PvMSP1 (Kaushal et al., 2007), and several novel antigens (Gaur et al., 2007). An interesting PvCSP chimeric recombinant protein that incorporates important sequence variation in an effort to increase cross-strain protection has been developed and manufactured at WRAIR and is slated for clinical testing (Yadava et al., 2007).

DISCOVERY/BASIC SCIENCE

Success in making a vaccine against malaria is hardly assured, given that there are no licensed vaccines against any human parasitic infections. Fortunately, the scientific community is engaged in wide-ranging basic research that should improve the chances of success.

One of the most prominent contributions has been the sequencing of malarial genomes, including those of *P. falciparum* (Gardner et al., 2002), *P. vivax* (Carlton, 2003), and several murine and NHP malarias (Carlton et al., 2002; Hall et al., 2005). This work has led to the elucidation of malaria transcriptomes (Kaiser et al., 2004; Le Roch et al., 2003; Tarun et al., 2008; Watanabe et al., 2007; Zhou et al., 2008), proteomes (Hall et al., 2005; Tarun, 2007; Lasonder et al., 2002), interactomes (Date and Stoeckert, 2006; LaCount et al., 2005), and other derivatives. This has opened an entirely new field of endeavor, namely, malaria functional genomics or, more broadly, systems biology (Fraunholz, 2005; Winzeler, 2006).

Among many applications, these complex data sets enable the use of reverse genetics for designing vaccines. In this "genomes to vaccines" approach, screening procedures are developed for down-selecting antigen candidates, starting with the 5300+ open reading frames contained in the *P. falciparum* genome, which are available in public domain databases, such as PlasmoDB (Stoeckert et al., 2006), maintained by David Roos at the University of Pennsylvania (www.plasmodb.org), and Comparasite (http://comparasite.hgc.jp/), which includes full-length cDNA sequence data from seven subdatabases of apicomplexa protozoa (Watanabe et al., 2004). These screening algorithms have led to significant progress in the identification of new candidate antigens (Doolan et al., 2003a; Villard et al., 2007), although lack of reagents, particularly for liver stage parasites (Gruner et al., 2003), the difficulty with expression and poor immunogenicity of many malarial antigens (Aguiar et al., 2004), and the problem of developing screening tools revealing the protective potential of candidate antigens have hindered progress. With new interest in the identification of novel vaccine candidate antigens by funders such as the Bill and Melinda Gates Foundation, these efforts will surely bring payoffs for vaccine development. At least one novel antigen, currently known as antigen 2 (Ag2) (Doolan et al., 2003b), was identified using reagents from human volunteers immunized with irradiated sporozoites. Ag2 is slated for clinical testing in 2009 through a partnership between the Naval Medical Research Center, GenVec, Inc and PATH MVI. An independent group in Japan also discovered the same antigen, calling it CelTOS (Kariu et al., 2006).

Genomic data have impacted other related disciplines. For example, they have allowed the development of high-throughput processes for identifying

the crystal structure of proteins (Vedadi et al., 2007) to support our understanding of parasite molecules and to assist in identifying new antimalarial drugs; the development of protein microarrays to permit the serological screening of hundreds of malaria proteins (Sundaresh et al., 2006) in order to reveal the complex patterns of humoral responses associated with protection (Gray et al., 2007); and the elucidation of the evolutionary history of malarial parasites (Wootton et al., 2002). An important aim of the genomics revolution is the creation of a full haplotype map of *P. falciparum*, which should be particularly helpful in confronting the problem of antigenic polymorphism that challenges subunit vaccines (Carlton, 2007).

Genomics data from the host side have also had a major impact on the research on malaria. For example, high-density oligonucleotide microarrays have allowed the examination of a full panel of host immune response genes for up- or downregulation during the course of malarial infection. Generating expression profiles from the peripheral blood mononuclear cell transcriptome in this fashion may help to define the functionally complex networks of gene and protein interactions that underlie protective as well as detrimental immune mechanisms (Ockenhouse et al., 2006b; Schaecher et al., 2005). A large project, funded by the Gates Grand Challenges in Global Health Program, aims to define the natural variations in the human genome that determine an individual's susceptibility to malarial infection (Ntoumi et al., 2007).

Another area of tremendous progress has been the development of genetically altered or transgenic models, both for the parasite and the host. From the parasite's side, targeted genetic disruption has been a very productive technique for elucidating the function of the missing protein, such as UIS4 (Mueller et al., 2005a), TRSP (Labaied et al., 2007), or PfEMP1 (D'Ombrain et al., 2007), to cite just three examples. In cases where absence of the antigen may preclude growth, replacement with an ortholog may be revealing. For example, replacing the native CSP of the *P. berghei* parasite with the CSP of *P. falciparum* allowed the demonstration that protective immunity could be induced by irradiated *P. berghei* sporozoites in the absence of PbCSP, indicating that other antigens besides CSP contribute to and are sufficient for protection (Gruner et al., 2007). As another example, the expression of the ookinete antigen P25 from *P. vivax* in *P. berghei* allowed the determination of transmission-blocking activity in sera from a clinical trial of Pvs25 (Ramjanee et al., 2007). A similar model has been generated for Pfs25 (Mlambo et al., 2008). In some cases, it has been useful to express hybrid molecules including segments of both the native and transgenic molecule together, such as the integration of PfCSP repeat residues into PbCSP expressed on the surface of the *P. berghei* sporozoite to permit testing the protective efficacy of PfCSP vaccines targeting the repeat region in a murine model (Persson et al., 2002).

Of particular benefit has been the transfection of malarial parasites with green fluorescent protein (Mikolajczak et al., 2008; Ono et al., 2007) or luciferase (Franke-Fayard et al., 2006), permitting the visualization of biological processes, including the injection of parasites into the skin by the mosquito (Vanderberg and Frevert, 2004), their migration through the liver (Frevert et al., 2005), intracellular trafficking of the enzyme falcipain 2 within the infected erythrocyte (Dasaradhi et al., 2007), and the dynamics of sequestration and its role in pathology (Franke-Fayard et al., 2006). The expression of GFP by parasites has also allowed the purification of parasitized erythrocytes (Janse et al., 2006) and hepatocytes (Tarun et al., 2008), greatly facilitating the generation of parasite material for transcriptomic and proteomic analyses.

From the host side, transgenic mice have permitted the partial development of *P. falciparum* in an otherwise nonpermissive host (Morosan et al., 2006) and have been used to study the pathogenesis of malaria (Hernandez-Valladares et al., 2007) and the immunological mechanisms of protection (Romero et al., 2007; Thompson et al., 2008b). A fully "humanized" mouse model permissive for the human malarial parasites is a long-term goal. RNAi-mediated gene silencing has been another useful technique for manipulating the host in order to better understand the functions of key molecules involved in host–parasite interactions (Brown and Catteruccia, 2006). For example, this technique has helped to elucidate antiplasmodial protective mechanisms taking place in the mosquito gut (Abraham et al., 2005; Dinglasan et al., 2007).

There are many other areas where basic research may greatly impact malaria vaccine development, ranging from the axenic culture of sporozoites from gametocytes (Hurd et al., 2003) to the development of in vitro platforms for assessing immunogenicity (Byers, 2007). These studies contribute not only to the field of malaria vaccines, but to our basic understanding of the requirements for developing vaccines against other difficult pathogens.

PRECLINICAL DEVELOPMENT

Although not widely recognized by the medical community, the genus *Plasmodium* is primarily a parasite of reptiles and birds, which harbor the majority of

malaria species. *Plasmodium* is also found in a variety of mammals, including both Old and New World primates (Coatney, 1971) and a small number of African rodents (Peters et al., 1978). Several of these parasites have been adapted as laboratory models, with the murine species *P. yoelii* and *P. berghei* used most commonly. The natural host for the rodent malarias is the African thicket rat, but the laboratory mouse is susceptible to both sporozoite and blood stage challenge. Both outbred and inbred mice including immunodeficient and transgenic strains have been valuable for defining the mechanisms of protective immunity to malaria which have proven to be remarkably diverse (Doolan and Hoffman, 2000). Murine models have also been useful for testing and developing novel vaccine platforms (Gilbert et al., 2002; Hedstrom et al., 1994), and for assessing the protective potential of antigens (Khusmith et al., 1991).

The NHP malarias have played an important role by providing a model system closer to humans for evaluating protective efficacy. Some New World NHPs are directly susceptible to blood stage infection with human parasites, such as the owl monkey, *Aotus*, while others, like the rhesus macaque, require a simian parasite such as *P. knowlesi*. The original selection of antigens for the SPf66 vaccine was made in *Aotus* (Rodriguez et al., 1990), and this model has also been used effectively to demonstrate the protective potential of key antigens such as MSP1 (Siddiqui et al., 1987) and AMA1 (Stowers et al., 2002) and to explore novel technologies such as DNA vaccines and DNA adjuvants (Gramzinski et al., 1997; Jones et al., 1999) and prime-boost approaches (Jones et al., 2001). *P. knowlesi* in the rhesus monkey, a model for which a reliable sporozoite challenge is available (unlike *P. falciparum* in *Aotus*), has been very useful for demonstrating proof-of-principle for the protection afforded by prime-boost approaches (Rogers et al., 2002).

Rodents and larger animals can also be used to test immunogenicity and safety of *P. falciparum* or *P. vivax* vaccines directly if a protection read-out is not required, and thus can be used to effect improvement in technologies without having to construct vaccines using murine or simian malaria species. Examples include the assessment of antigen mixtures (Sedegah et al., 2004), novel pairing of antigens and adjuvants (Pichyangkul et al., 2008), and prime-boost immunization regimens (Stewart et al., 2007).

To effectively use these animal models, new antigens and technologies are typically assessed first in the mouse, such as the initial testing of DNA vaccines (Sedegah et al., 1994), and are then transitioned to a larger species such as NHP before proceeding to humans. The value of the NHP step, particularly the use of *Aotus* blood stage challenge, has been debated (Heppner et al., 2001; Stowers and Miller, 2001), but is clearly useful in many cases. In each model, if the goal is to demonstrate protection, vaccines need to be reformulated using the antigens of the *Plasmodium* species infecting the selected host, with the exception of blood stage challenge in *Aotus* and *Sciurius*. There is thus reliance on the assumption that orthologous antigens fulfill the same function and will demonstrate the same protective potential following transition to humans. Unfortunately, this is not always born out, and a "species gap" is often revealed. For example, in many cases, it has proven relatively straightforward to protect mice, harder to protect monkeys, and extremely difficult to protect humans. Moreover, novel technologies may work well in the mouse system, e.g., adjuvanting DNA plasmids with granulocyte macrophage-colony stimulating factor (Weiss et al., 1998) but not in the human system (Wang et al., 2005). The models are thus a mixed blessing, aiding progress but potentially misleading at the same time.

Counterbalancing this drawback is the existence of the human challenge model for *P. falciparum*, which allows an immediate assessment of vaccine efficacy, often in the initial first-in-humans trial. Disappointing results in the clinic prompt investigators to return to preclinical research, leading to an iterative vaccine development strategy, as exemplified by the development of CSP as a vaccine antigen which was formulated multiple times for human use, with intervening animal studies in most cases, before success was achieved (Ballou and Cahill, 2007). This iterative approach, illustrated in Fig. 65.10, has enabled malaria vaccine investigators to pioneer and test novel technologies, demonstrating their potential for human applications, and in some cases make improvements.

CLINICAL TRIALS

The clinical trials associated with the development malaria vaccines have a number of distinguishing attributes that collectively place them in a unique position in the field of vaccinology. There are no other vaccines against human pathogens that currently combine such an urgent need with the ability to (1) experimentally challenge volunteers in nonendemic areas and then (2) transition to the field where natural exposure provides attack rates high enough to permit the reliable assessment of efficacy using sample sizes in the hundreds and follow-up periods of 6 months or less. These favorable testing parameters allow for the efficient evaluation of the safety, tolerability,

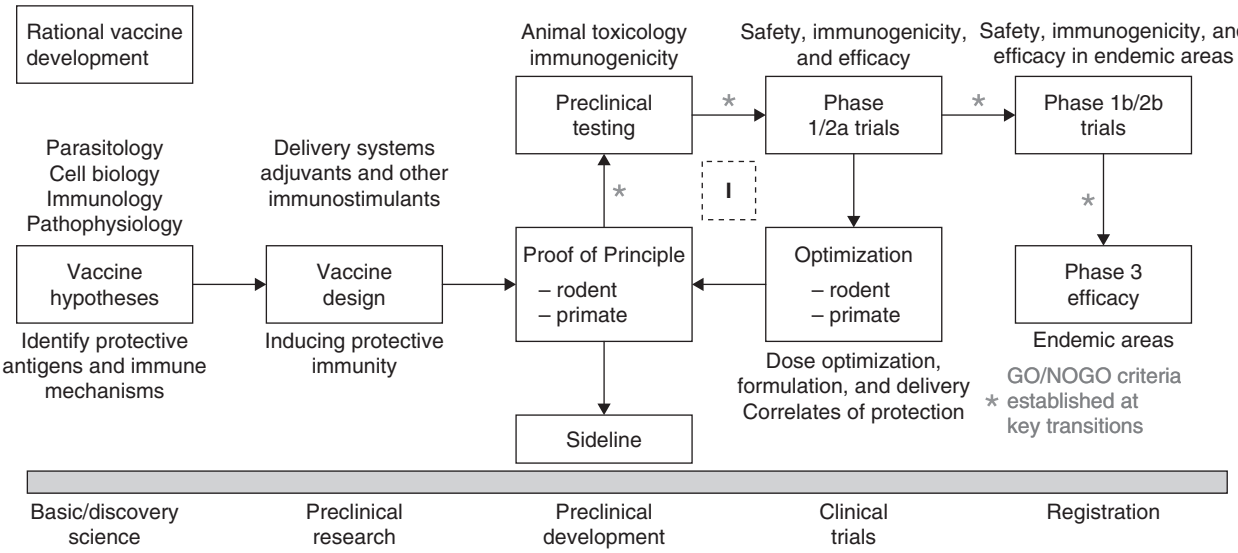

FIGURE 65.10 Iterative approach to malaria vaccine development. As there are no licensed vaccines against any parasitic infection to serve as a model, many developmental efforts have started with discovery research in an effort to understand the biological processes underlying host–parasite interactions at the molecular level. Protective antigens need to be identified, and protective immune responses revealed. This understanding is used to construct hypotheses regarding how a vaccine could be rationally designed. Prototype vaccines are then designed on the basis of these hypotheses, selecting delivery systems, including adjuvants and immunostimulants, to induce the identified protective immune responses against the identified target antigens. Reagent grade vaccines are produced (e.g., using *P. yoelii*, *P. berghei*, or *P. knowlesi* antigens) and tested to establish proof of principle in animal models. Typically, this is done with a challenge to allow testing for protection. Vaccines meeting preestablished go criteria are committed to the clinical testing pathway. At this point, a vaccine based on *P. falciparum* antigens must be made, processes worked out for manufacturing, and toxicology and immunogenicity studies performed prior to clinical testing. As described in the text, Phase 1 studies may be combined with a Phase 2a sporozoite challenge, allowing for rapid assessment of efficacy. If protection is not adequate, the vaccine is returned to the preclinical level for optimization and possible reentry into the clinical pipeline (circular pathway around the I [=iteration] in the diagram). If protection is achieved in the clinic, vaccines can move forward to testing in endemic areas. In the case of blood stage vaccines, for which experimental sporozoite challenge is less useful, vaccines can move forward to endemic areas on the basis of safety. Printed with permission from Gary Nabel, Vaccine Research Center, National Institutes of Health.

immunogenicity, and protective efficacy of vaccines, leading some investigators to conclude that malaria could be selected as a "focus disease" for testing and optimizing novel vaccine technologies that could then be applied to other infectious agents such as HIV where experimental challenge is impossible and field trials require thousands of individuals carefully selected for high risk and requiring years of follow-up (Gay et al., 2007).

Experimental malaria sporozoite challenge, described in the preceding section, is possibly the vaccine developer's most powerful tool. It is effected through the bites of five infected mosquitoes and has proven to be a safe procedure (Church et al., 1997; Epstein et al., 2007b; Hoffman, 1997; Verhage et al., 2005). It is generally well tolerated, although a proportion of volunteers will miss 1–2 days from work as a result of infection. Treatment is initiated when the blood smear becomes positive as detected by traditional microscopy, although PCR, which permits diagnosis 1–2 days earlier than microscopy, has opened the possibility of accelerating diagnosis and treatment and thereby further limiting clinical manifestations.

Sporozoite challenge is very useful for testing the efficacy of preerythrocytic stage vaccines designed to prevent infection, but is less useful for testing blood stage vaccines aiming to limit disease, due to the requirement to treat immediately upon diagnosis, which obviates the possibility of monitoring symptoms. It is theoretically possible to use PCR to measure the rate of multiplication in the blood during the roughly 2-day window between PCR diagnosis and microscopic diagnosis through repeated PCR measurements and calculation of a slope (Bejon et al., 2005; Hermsen et al., 2004), but the wide fluctuations in parasite density resulting from cyclic sequestration can be problematic for this approach. The consensus is that the efficacy of a blood stage vaccine designed to reduce disease is best tested in endemic areas with the incidence of clinical disease used as the outcome measure.

Based on these considerations, there is agreement regarding the terminology used for describing the phases of malaria vaccine testing. Phase 1 is divided into 1a and 1b according to whether the safety testing is performed in malaria-naïve or malaria-exposed individuals, the former typically enrolled at trial sites

located in nonendemic areas and the latter in endemic areas. Similarly, Phase 2a refers to experimental sporozoite challenge and Phase 2b refers to natural challenge in the field. Phase 3 has the same meaning as used generally.

Experimental blood stage challenges have been employed in the past (Cheng et al., 1997; Pombo et al., 2002) and remain an acceptable approach, but need refinement and standardization. Another potential evolution in challenge procedures is being pursued by Sanaria, Inc, which is developing the capability for generating a cryostabillate of sterile, living sporozoites that could be injected by needle and syringe. This would permit a standardized challenge in the absence of an insectary, although it is unclear if needle injection can provide data as applicable to protection against mosquito transmission as the traditional mosquito bite challenge. Finally, there are efforts underway at Radboud University Nijmegen Medical Centre in the Netherlands to generate multiple parasite strains for sporozoite challenge in order to permit assessment of heterologous strain protection (the current challenge available in the USA, Great Britain, and the Netherlands employs the 3D7 clone or parent NF54 strain).

An important question for clinical trials research is the degree to which experimental challenge predicts protection in the field. RTS,S proves that there is indeed predictive value, but because efficacy has been calculated by different methods in Phase 2a and 2b trials, it is difficult to establish a conversion factor. The time-to-event analysis used for the RTS,S field trials yields a higher figure for efficacy than if a simple proportional reduction in events analysis had been used. As a second example with data available from both Phase 2a and 2b trials of the same vaccine, the ME-TRAP antigen delivered with heterologous prime-boost regimens that sometimes sterilely protected volunteers in Phase 2a trials at Oxford (Webster et al., 2005) provided no protection when tested in the Gambia (Moorthy et al., 2004) or Kenya (Bejon et al., 2006, 2007).

There are several areas of active debate when considering trials in endemic areas. Four are discussed:

1. Case definitions: The design of field trials is complicated by the difficulty of defining incident malaria when a large proportion of the population chronically harbors the parasite in their blood, as typically occurs in sub-Saharan Africa. Case definitions vary, and often involve a threshold parasitemia combined with clinical measures such as fever. The selection of the threshold parasitemia is critical, and can strongly influence subsequent efficacy measurements (Mwangi et al., 2005; Rogers et al., 2006).
2. Radical cure: A second question is whether or not to provide radical cure (elimination of all liver and blood stage parasites through drug treatment) during vaccination. Radical cure allows a clearer assessment of incident parasitemia, but may also provide an unrealistic estimate of efficacy since a licensed vaccine is likely be delivered to both uninfected and infected individuals, and in the latter case the presence of malarial parasites could suppress the immune response to immunization (Ocana-Morgner et al., 2003). In addition, radical cure might increase the risk of subsequent clinical malaria (Owusu-Agyei et al., 2002), and at least in one trial, appeared to adversely affect the protection afforded by the vaccine (Genton et al., 2002).
3. Outcome measures: A third question relates to identifying the most useful outcome measure, e.g., incident parasitemia, clinical disease, severe disease, or mortality. One solution to this question is to establish multiple cohorts, each designed to assess a particular outcome measure, so that data on several can be collected. For each outcome, there is a trade-off in costs associated with achieving an adequate sample size to measure accurately. These questions have been addressed in several reviews (Greenwood, 2005; Guinovart and Alonso, 2007). Moreover, there is controversy regarding the most appropriate statistical analyses, such as the debate over proportional vs. time-to-event calculations for efficacy. The World Health Organization sponsored a meeting in June 2008 to discuss this question.
4. Molecular epidemiology: A fourth issue involves the need to match the testing of subunit vaccines based on particular alleles to field sites where these alleles circulate in the parasite population. Although obviously a cross-protective vaccine is desired, initial proof-of-concept field trials could attain a measure of success if the vaccines demonstrate allele-specific protective effects, indicating that a multiallele vaccine might be broadly effective. These considerations illustrate the concept of molecular monitoring during vaccine trials (Felger et al., 2003) and have led to sophisticated analyses of parasite haplotypes at field sites where testing a particular vaccine candidate is contemplated (Takala et al., 2007).

The clinical testing of malaria vaccines would be greatly facilitated if there were a surrogate marker for

efficacy. Currently, this does not exist, even for RTS,S, for which it has been a challenge to define immune correlates of protection. It can be anticipated that as more effective vaccines are developed, it should be possible to better define a surrogate marker to facilitate vaccine evaluation.

PROSPECTS FOR THE FUTURE

The development of an effective malaria vaccine for global use faces complex scientific challenges, as illustrated by the many failed vaccines and associated barriers described in this chapter. The scientific challenges are compounded by a variety of economic and socio-political obstacles. For example, the fact that the primary burden of malaria is shouldered by the world's poorest people, who often live in regions facing critical health, and social and economic issues, reduces the financial incentive for pharmaceutical companies which might otherwise prioritize malaria vaccine development. Moreover, the scientific enterprise involves testing novel platforms and delivery systems as well as addressing complex safety issues that are beyond the means of the malaria-endemic countries.

As a result of these disjunctions, malaria vaccine development has evolved into a "north-south" collaboration. Financial resources and research capacity from more affluent, malaria-free countries have joined with outstanding health institutes and initiatives present in less-prosperous malaria-endemic countries across Africa, Asia, and Latin America where the commitment to developing malaria vaccines is strongest and where there is willingness to establish the clinical trials capacity needed to field test candidates as they come through the product pipeline (Kilama et al., 2007). Donor agencies have stepped forward to assume research and development costs, and interested scientists, clinicians, and pubic health officials have joined in collegial association to provide the needed innovation and leadership. The importance of malaria prevention for international travelers (Richie, 2004) and existing market incentives (Group, 2005) encourage the involvement of developed countries and industry. In addition, military establishments, which have experienced the disastrous impact of malaria in conflicts played out across the tropics throughout history (Aronson et al., 2006; Beadle et al., 1994; Shanks and Karwacki, 1991), have a vested interest and are adding resources to the fight. Pharmaceutical firms and biotechnology companies are leading development efforts in many cases, and will shoulder increasing responsibilities as candidate vaccines pass initial safety and efficacy hurdles thereby establishing a more favorable economic equation. International organizations such as the World Health Organization and the World Bank serve to coordinate and fill existing gaps, such as assuring adequate clinical trials capacity (Moran et al., 2007). A recent product of this global partnership is the Malaria Vaccine Technology Roadmap, a document providing a framework for the coordinated development of malaria vaccines (Roadmap, 2005).

With the evolution of these public–private partnerships and the presence of promising vaccine candidates in the pipeline, the malaria vaccine enterprise appears to have a reasonable chance of success. If a potent malaria vaccine is combined with other control modalities available and in development, such as altering the genetic structure of vector populations to reduce vectorial capacity, we can contemplate, as a long-term strategy, the eradication of malaria.

KEY ISSUES

- Identification of the most protective antigens.
- Identification of protective immune mechanisms targeting these antigens.
- Developing vaccine delivery systems including adjuvants and immunostimulants that potently induce these protective responses.
- Developing formulations of antigens with sufficient valency to protect all vaccinees against all parasite strains despite (1) stage-specific expression of antigens, (2) allelic polymorphism, (3) antigenic variation, and (4) genetically restricted host responses.
- Developing immune surrogates and validated animal models.
- Developing standardized assays allowing comparison among vaccine candidates.
- Developing vaccines with adequate safety profiles.
- Developing vaccines targeting all five species of malaria infecting humans.
- Establishing cost-effective processes for manufacturing and scale-up.
- Developing workable marketing and licensure strategies enabling industry to shoulder the costs, risks, and responsibilities associated with the development, manufacture, sale, and distribution of malaria vaccines.
- Developing strategies to assure adequate distribution and administration of malaria vaccines

in malaria-endemic areas in coordination with existing vaccines and in spite of poverty and human displacement.
- Developing processes for detecting and eliminating vaccine-resistant parasite strains.

ACKNOWLEDGMENTS

The authors wish to gratefully acknowledge the comments and suggestions of the following individuals, who were contacted to assure the accuracy of particular sections of this chapter: Ripley Ballou (RTS,S), Ashley Birkett (CSP vaccine), Blaise Genton (PEV302 and PEV301), David Lanar (FMP011), Lee Hall (Ad35.CS), Adrian Hill (ME-TRAP, FP9-PP, and MVA-PP), Pierre Druilhe (PfLSA-3-rec, MSP3-LSP), Stephen Hoffman (PfSPZ), Stefan Kappe (genetically attenuated sporozoites), Evelina Angov (FMP1/AS02A, FMP010, FMP2.1/AS02A), Laura Martin (MSP142-C1/Alhydrogel + CPG7909, AMA1-C1), Robert Sauerwein (PfLSA-3-rec, PfAMA1-FVO[25-545], GMZ2), Michael Good (whole organism blood stage vaccine), Zarifah Reed (PfCP-2.9, SE36), Yimin Wu (transmission-blocking vaccines), and Alan Magill (licensure of IV artesunate in the USA).

The following are sincerely thanked for their assistance in providing photographs or figures: Ute Frevert (sporozoite), John Sacci (hepatic stage parasite), Purnomo (blood stage parasites), Ted Hall (*P. falciparum* ring stages), Stephen Hoffman and Robert Thompson (infecting mosquitoes, dissecting mosquitoes), and Gary Nabel (vaccine development algorithm).

Our appreciation is expressed to the following authors for allowing previously published material to be reproduced in this chapter: Carlos Guerra, Simon Hay, and Robert Snow (world map of *P. falciparum*), Alan Saul (life cycle), Alan Cowman, Brendan Crabb, and Jacob Baum (merozoite invasion), Robert Snow and Kevin Marsh (graph of mortality vs. transmission intensity), Sayeh Jafari-Guemouri and Phillipe Deloron (multiplicity of infection), Pedro Alonso (RTS,S Kaplan-Meier curves), and Sanjai Kumar and Judy Epstein (two-tiered malaria vaccine).

Finally, our thanks are offered to those who have allowed the referencing of unpublished data as a personal communication: Chris Ockenhouse (allele-specific protection with MSP1), Lee Hall (results of Ad35.CS Phase 1a trial), Jim Cummings (results of LSA1 Phase 1/2a trial and MSP1 + RTS,S Phase 1/2a trial), Bernhards Ogutu (results of MSP1 Phase 2b trial), Laura Martin (results of MSP142-C1/Alhydrogel + CPG7909 Phase 1a trial), Alassane Dicko (results of AMA1-C1 Phase 2b trial), Mahamadou Thera (results of FMP2.1/AS02A Phase 1b trial and PfAMA1-FVO Phase 1b trial), Michael Good (clinical testing plans for blood stage whole organism vaccine), and Yimin Wu (results of TBV25H Phase 1a trial and Pfs25/Pvs25 Phase 1a trial).

The studies reported herein that were conducted by the Naval Medical Research Center Malaria Program were conducted in accordance with U.S. Navy regulations governing the protection of human subjects in medical research. All protocols involving human subjects were reviewed and approved by the Naval Medical Research Center's Institutional Review Board in accordance with the U.S. Navy regulations (SECNAVINST 3900.39B) governing the use of human subjects in medical research. The opinions and assertions herein are the private ones of the authors and are not to be construed as official or as reflecting the views of the U.S. Navy or the Department of Defense. Work was supported by funds allocated to the Naval Medical Research Center by the U.S. Army Medical Research and Materiel Command.

Hookworm Infection

Peter J. Hotez[1,2] *and David Diemert*[1,2]

OUTLINE

ABSTRACT

Hookworm infection is a chronic intestinal nematode infection that affects approximately 576 million people worldwide, predominantly those living in poor rural areas of the tropics. The two hookworms that infect humans—*Necator americanus* and *Ancylostoma duodenale*—are transmitted via skin contact with fecally contaminated soil. Hookworm infection causes significant morbidity due to chronic anemia and protein malnutrition. Current control efforts based on periodic mass anthelmintic administration are inadequate and unsustainable. Development of vaccines against hookworm infection is therefore a global health priority. Vaccine development has so far concentrated on the more prevalent *N. americanus*. Antigens expressed during the larval stage of this worm's life cycle, such as *Na*-ASP-2 and *Na*-SAA-2, have been identified and are being developed as candidate vaccine antigens. The first candidate vaccine—*Na*-ASP-2 formulated with Alhydrogel®—is currently in phase 1 clinical testing in an endemic area of Brazil. Antigens such as *Na*-GST-1 that are expressed during the adult stage of the parasite's life cycle and are essential to the worm's use of host hemoglobin as an energy source are also being developed as vaccine components. An eventual antihookworm vaccine will combine at least two hookworm antigens, one

targeting the larval stage and another targeting the adult worm living in the gastrointestinal tract. Such a vaccine will be incorporated into existing deworming programs that target preschool and school-aged children living in areas of high transmission, to reduce the morbidity—primarily anemia and protein malnutrition—attributed to this parasite. Antihookworm vaccine development is being conducted in partnership with vaccine manufacturers in middle-income endemic countries such as Brazil, in order to ensure that the populations who need the vaccine the most will have timely access to it once efficacy is shown in phase 3 testing.

INTRODUCTION: HOOKWORM DISEASE BURDEN

Hookworm infection, together with ascariasis and trichuriasis, comprise a group of human parasitic diseases known as the soil-transmitted helminth infections (STHIs). The STHIs are among the most common infections of humans, with an estimated 807 million, 604 million, and 576 million people infected with either the roundworm, *Ascaris lumbricoides*, the whipworm, *Trichuris trichiura*, or the hookworms *Necator americanus* and *Ancylostoma duodenale*, respectively (Bethony et al., 2006). STHIs occur almost

FIGURE 66.1 Goegraphic distribution of hookworm infection in the world.

exclusively in areas of poverty where they inflict great human suffering by causing chronic infections in children that result in retardation of physical, intellectual, and cognitive development (WHO, 2005). These health effects result in the loss of up to 39 million disability-adjusted life years (DALYs) annually (Chan, 1997), a disease burden roughly equivalent to that of malaria. In addition, the STHIs exert a powerful negative influence on economic development and disrupt the education of children (Miguel and Kremer,

2004; Bleakley, 2007). The STHIs belong to a unique category of *neglected tropical diseases* that have the following features: (1) they are ancient afflictions that have plagued humankind for centuries; (2) they occur predominantly in rural areas of low-income countries; (3) they cause long-term suffering and chronic disability; (4) not only do they occur in settings of poverty but, due to their chronic negative health and educational effects, the STHIs actually perpetuate poverty; (5) despite their considerable health, educational, and economic impact, they are frequently overlooked by the global medical and public health communities; and (6) because the STHIs afflict primarily the most impoverished, pharmaceutical companies have no significant commercial incentives to develop new drugs, vaccines, or diagnostics that target these infections (Hotez et al., 2006d; Hotez et al., 2007).

Among the STHIs, human hookworm infection is the most important in terms of disease burden and cause of death. The epidemiology and impact of hookworm disease has been reviewed (Brooker et al., 2004). Briefly, it has been estimated that up to 65,000 deaths and 22 million DALYs are lost annually worldwide due to hookworm (Chan, 1997; WHO, 2002), although other investigators have derived lower values (WHO, 2004), depending on the value of the disability weights assigned to the severity of anemia, malnutrition, and cognitive impairment that result from hookworm infection (Bethony et al., 2006; Hotez et al., 2006b). Currently, the greatest numbers of cases occur in sub-Saharan Africa (Bethony et al., 2006), where hookworm is frequently co-endemic with malaria (Brooker et al., 2006; Hotez et al., 2006c), and in Asia (Bethony et al., 2006). However, significant pockets of endemic hookworm transmission also occur in Central America, Brazil, and other tropical regions of the Americas (de Silva et al., 2003; Hotez, 2004; Fleming et al., 2006). As recently as the late 1980s and early 1990s, some of the highest prevalence and intensity of hookworm infection occurred in the People's Republic of China (Hotez et al., 1997; Brooker et al., 2004). However, as a result of aggressive economic reforms and the resultant reduction in poverty and improved water and sanitation, significant progress has been made in the control of this disease in China (Hotez, 2002, 2007). Of the two major hookworms, *N. americanus* and *A. duodenale*, the former accounts for more than 70% of infections worldwide (Hotez et al., 2003a) and is especially prevalent in Africa, Southeast Asia, and the Americas (Chan et al., 1997), making it the major target of interventions; all current hookworm vaccine development is focused on *N. americanus*. Other members of the genus *Ancylostoma,* including *Ancylostoma caninum*, *Ancylostoma ceylanicum*, and *Ancylostoma braziliense*, primarily infect animals but may also cause human disease, although none have a significant public health impact (Brooker et al., 2004).

Hookworms cause injury through intestinal blood loss that results from attachment of adult parasites to the mucosa and submucosa of the small intestine with resultant rupture of capillaries in the mucosa and arterioles in the submucosa (reviewed by Hotez et al., 2004a, 2004b). Adult hookworms inject anticoagulants, antiplatelet aggregating agents, and connective tissue hydrolases into the attachment site (Cappello et al., 1995; Ledizet et al., 2005), which results in a free flow of host blood into the intestinal lumen, some of which is ingested by the adult hookworms, which then lyse the red blood cells (Don et al., 2004) and degrade the ingested hemoglobin by an orchestrated cascade of hemoglobinases, to be used by the worms as an energy source (Williamson et al., 2004).

Hookworm-related anemia results when blood loss is sufficient to deplete the iron reserves of the host. This depends on a number of factors including the number of adult hookworms present (Lwambo et al., 1992), the species of infecting hookworm—each adult *A. duodenale* hookworm causes greater blood loss than *N. americanus* (Albonico et al., 1998)—and the preexisting iron reserves of the host. Children and women of reproductive age, especially pregnant women, typically have lower iron reserves and are therefore particularly susceptible to developing this condition (Bundy et al., 1995; Stoltzfus et al., 1997b; Brooker et al., 2004). The hallmarks of hookworm disease, therefore, are iron deficiency and iron deficiency anemia (Hotez et al., 2004a). In some regions of sub-Saharan Africa, hookworm disease in children and pregnant women is almost as important as malaria as a cause of anemia (Brooker et al., 1999), and is a major cause of anemia in Brazil (Brooker et al., 2007). In addition, heavy hookworm infection can lead to the loss of significant amounts of plasma protein, resulting in hypoalbuminemia, hypoproteinemia, and protein malnutrition. The basis by which chronic hookworm infection and disease results in growth and cognitive delays in children is not fully understood, but is conjectured to be related to the nutritional consequences of the chronic blood loss (Brooker et al., 2004). Hookworm-associated malnutrition may also be a contributing factor in the observed adverse impact on childhood education, including school performance and attendance (Miguel and Kremer, 2004), and economic development (Bleakley, 2007) that is associated with this disease.

IMPACT OF ANTHELMINTIC CHEMOTHERAPY ("DEWORMING")

New awareness of the important health, educational, and economic consequences of chronic hookworm infection and other STHIs have led the UN agencies to develop disease-control programs in endemic countries. In children, hookworm infection frequently occurs concomitantly with ascariasis, trichuriasis, and schistosomiasis, and there is evidence that hookworm may promote susceptibility to these other helminth infections (Fleming et al., 2006). Because school-aged children harbor the highest helminth burdens of any single group (Bundy, 1988; World Bank, 2003), the UN agencies have developed a strategy for targeting this population by administering a single dose of a benzimidazole agent (i.e., mebendazole or albendazole) and a single dose of praziquantel annually in order to "deworm" the children of their STH and schistosome infections, respectively (Savioli et al., 2002). The health and educational benefits of frequent and periodic deworming have recently been reviewed (World Bank, 2003; WHO, 2005; Hotez et al., 2004b, 2006b) and include improvements in physical growth, cognition, and host iron and hemoglobin status. In addition, deworming has the potential to interrupt transmission of *A. lumbricoides* and *T. trichiura* (de Silva et al., 2003). Accordingly, in 2001, the 54th World Health Assembly adopted resolution 54.19 urging member states to deworm at least 75% of all at-risk school-aged children annually by the year 2010 (*www.who.int/wormcontrol*).

Whether resolution 54.19 will be successful in controlling hookworm-related morbidity is not as obvious as it is for some of the other helminthiases (Hotez et al., 2004a, 2005, 2006a). There are multiple reasons for this concern:

1. As opposed to the other STHs, high-intensity hookworm infections occur in both adult and pediatric populations, so that school-based deworming programs are not expected to significantly reduce hookworm transmission (Chan, 1997) nor have an impact on other vulnerable populations such as pregnant women (Christian et al., 2004).
2. High rates of posttreatment hookworm reinfection occur in areas of intense transmission. In some cases, infection returns to pretreatment levels within 4–12 months (Albonico et al., 1995).
3. Single-dose mebendazole has a high failure rate in reducing hookworm burdens (Bennett and Guyatt, 2000; de Clercq et al., 1997).
4. The efficacy of mebendazole has been shown to diminish with frequent use (Albonico et al., 2003), and there are concerns that anthelmintic drug resistance could emerge because of large-scale and widespread use (Albonico et al., 2004). Resistance to benzimidazoles has been well documented for the nematode parasites of sheep and cattle (Albonico et al., 2004).

These concerns have brought into question the sustainability of hookworm control programs that rely on regular administration of currently available anthelmintic drugs (WHO, 2005), and have stimulated the search for alternative or complementary control tools such as new anthelmintic drugs and vaccines.

THE CASE FOR A VACCINE AGAINST HOOKWORM

The high rates of hookworm reinfection that occur following anthelmintic treatment with benzimidazoles suggest that previous infection does not confer protective immunity. The absence of naturally acquired immunity is also supported by epidemiological studies in endemic regions of China and Brazil, which show increasing community prevalence and intensity of infection with age (Liu et al., 1999; Gandhi et al., 2001; Bethony et al., 2002; Fleming et al., 2006).

The lack of naturally acquired protective immunity suggests that successful vaccine development could prove to be more challenging than it was for existing vaccines that employ live-attenuated viruses such as those for measles and polio. In this sense, hookworm vaccine development could be considered as complex as the development of vaccines for malaria, tuberculosis, or even HIV-AIDS. However, during the first-half of the twentieth century, William Cort's group at the John Hopkins School of Hygiene and Public Health successfully developed vaccines containing live hookworm larvae that protected laboratory animals against challenge infections with the canine hookworm *A. caninum* (reviewed by Hotez et al., 1996). This provided "proof-of-principle" that development of a hookworm vaccine was feasible. Both humans and dogs become infected with hookworm when third-stage infective larvae (L3) penetrate the skin or are ingested orally. Subsequently, the larvae enter the peripheral circulation and migrate to the lungs where they break into the alveolar space, ascend the bronchial tree, pass over the epiglottis, and then enter the gastrointestinal tract where they develop into adult hookworms. Studies by McCoy (1931) and Foster (1935) showed that dogs could be rendered resistant to larval challenge by

first administering multiple doses of small numbers of live L3. Dogs "immunized" with live L3 tolerated challenges of several thousand larvae without developing anemia, even though the dogs did not develop complete or sterilizing immunity. Instead, vaccine-induced protection was evidenced by significant reductions in host hookworm burden (as measured by fecal egg counts), to the point where vaccinated dogs were protected against significant blood loss and canine hookworm disease.

Ultimately, the canine challenge model was standardized through the use of subcutaneously injected L3 (Otto and Kerr, 1939; Otto, 1941); using this model, vaccination with irradiation-attenuated L3 (irL3) reliably resulted in protection as measured by significant reductions in hookworm burden (Miller, 1971). These studies prompted the development of a commercial canine hookworm vaccine consisting of irradiation-attenuated live *A. caninum* L3, which was licensed and marketed initially in Florida and then in the Eastern United States during the 1970s (Miller, 1971, 1978). Although the irL3 vaccine was effective in preventing canine hookworm disease, it was ultimately removed from the market because of high production costs, the need for the L3 to remain alive during storage, and difficulties in explaining to pet owners and veterinarians how the vaccine could be effective without eliciting sterilizing immunity (Miller, 1978).

The immunological basis of the protection derived from live L3 and irL3 vaccines was subjected to intense study during the decades between 1930 and 1970 (reviewed by Hotez et al., 1987, 1996). These studies pointed to the importance of antibodies directed against antigens secreted by invading L3 (Cort and Otto, 1940). A partial breakthrough in the understanding of the humoral immunity elicited by hookworm vaccines was the discovery and description of the "Sarles phenomenon" by Merrit Sarles and William Taliaferro at the University of Chicago who demonstrated that serum recovered from rodents immunized with *Nippostrongylus brasiliensis* L3 formed immune precipitations around the oral openings of L3 when incubated with them in vitro (Sarles and Taliaferro, 1936; Sarles, 1938). This phenomenon, together with studies demonstrating protection of nonvaccinated dogs by the passive transfer of antibodies obtained from dogs immunized with either *A. caninum* L3 or irL3 vaccines (Otto, 1940; Miller, 1967), highlighted the important role of antibodies directed against L3 antigens. A recent reexamination of the immunity induced by the *A. caninum* irL3 vaccine confirmed that protection is associated with Th2-type responses against specific L3 secreted antigens and that anti-L3 antibody inhibits larval tissue penetration and migration in vitro (Fujiwara et al., 2006).

LARVAL ANTIGEN DISCOVERY AND SELECTION

The mid-20th century studies highlighting the importance of immune responses to L3 antigens in mediating vaccine protection identified them as potential human hookworm vaccine antigens (Hotez et al., 1996, 1999, 2003). With respect to secreted antigens, *A. caninum* L3 have been shown to release enzymes with protease and hyaluronidase activities, which likely facilitate larval migration through tissues (Hotez et al., 1990, 1992). However, the isolation and biochemical characterization of the major L3 secreted antigens were hampered by the minute quantities of protein produced in L3 secretions. This limitation was overcome by Hawdon and Hotez (1996), who were able to obtain abundant amounts of secreted antigens by incubating *A. caninum* L3 in vitro with a cocktail of glutathione (or its derivatives) and an ultrafiltrate of canine serum. It was presumed that these in vitro conditions mimicked the milieu encountered by larvae during invasion of human tissues.

Three of the major L3 macromolecules released after in vitro stimulation have been cloned and sequenced. Two of these proteins, known as *Ancylostoma* secreted proteins-1 (ASP-1) and -2 (ASP-2), are members of the pathogenesis-related protein (PRP) superfamily (Hotez et al., 1999). The PRPs are produced in response to infection with pathogens and other stresses, and consist of unique cysteine-rich PR domains folded in an alpha helix–beta sheet–alpha helix sandwich (Asojo et al., 2005a). ASP-1 is a 45-kDa protein containing two PR domains (Hawdon et al., 1996; Asojo et al., 2005b), whereas ASP-2 is a 20–22 kDa single PR domain protein (Hawdon et al., 1999; Asojo et al., 2005a). The function of the ASPs is unknown, although X-ray crystallographic studies suggest the possibility that they are proteases or immunomodulatory proteins (Asojo et al., 2005a). A third secreted antigen is the 62-kDa metalloprotease known as MTP-1 (Zhan et al., 2002a, 2002b). All three antigens, which were originally described in *A. caninum*, are also conserved in the human hookworms, *N. americanus* and *A. duodenale* (Zhan et al., 2000; Asojo et al., 2005a, 2005b; Goud et al., 2005).

In addition to the secreted L3 antigens, two proteins found on the surface of invading larvae, *Ac*-SAA-1 and *Ac*-16 (also referred to as *Ac*-SAA-2), have also shown potential as larval-stage vaccine antigens and are currently being developed as alternative larval vaccine antigens (Diemert et al., 2008; Fujiwara et al., 2007; Zhan et al., 2004). Although it is a component of both the larval and adult stages of the

hookworm life cycle, *Ac*-16 has been shown to be an immunodominant larval surface protein that results in reduced blood loss and fecal egg counts when used as a vaccine in the canine parasite challenge model (Fujiwara et al., 2007). The *N. americanus* homolog of *Ac*-16 has already been identified and work is currently underway to identify an ideal expression system to produce it as a recombinant protein for clinical trials.

Studies have been undertaken to determine whether ASP-1, ASP-2, MTP-1, SAA-1, and SAA-2 might be suitable vaccine candidates for subsequent process development, manufacture, and clinical testing. Because inadequate quantities of natural products are available for immunological studies, it was necessary to produce these proteins as recombinant antigens in genetically engineered expression hosts. Expression of cysteine-rich ASPs in bacterial expression systems resulted in production of insoluble recombinant protein products that could not be resolubilized or refolded. Similarly, recombinant MTP-1 as expressed by *Escherichia coli* was an insoluble product. Instead, with the exception of the two surface antigens, successful expression of soluble and properly folded larval recombinant proteins required eukaryotic expression systems such as yeast (Asojo et al., 2005a, 2005b; Goud et al., 2004, 2005) or insect cells (Bethony et al., 2005).

Studies of the induced humoral immune responses in dogs vaccinated with irL3 *A. caninum* determined that among the secreted antigens, the resultant antibody responses are preferentially directed against ASP-2, suggesting that this is the immunodominant antigen associated with such vaccines (Fujiwara et al., 2006). This evidence advanced ASP-2 as a plausible lead candidate antigen. When recombinant *A. caninum* ASP-2 (*Ac*-ASP-2) was formulated with the GlaxoSmithKline Adjuvant System 03 (AS03) and used to vaccinate dogs (Bethony et al., 2005), or when recombinant *A. ceylanicum* ASP-2 (*Ay*-ASP-2) was formulated with Quil A and used to vaccinate hamsters (Goud et al., 2004; Mendez et al., 2005a, 2005b), high levels of antigen-specific antibody were elicited, which recognized the corresponding native antigen (Bethony et al., 2005). In both cases, the vaccines elicited high levels of protection in terms of reduction in adult worm burdens, fecal egg counts, and host blood loss, as compared to animals immunized only with adjuvant (Bethony et al., 2005; Goud et al., 2004; Mendez et al., 2005b). Additionally, both anti-ASP-2 and anti-L3 antisera from dogs were shown to inhibit larval invasion in vitro (Bethony et al., 2005; Fujiwara et al., 2005). The proposed mechanism of action of ASP-2 vaccines is that they elicit antibody responses that inhibit larval invasion and thereby reduce the number of L3 that develop into adult worms that inhabit the host's gastrointestinal tract, resulting in reduced host worm burdens, fecal egg counts, and blood loss (Bethony et al., 2005; Loukas et al., 2006).

The animal hookworm studies outlined above suggested that ASP-2 is a promising vaccine antigen. Additionally, studies of hookworm infection conducted in endemic areas of Brazil and China determined that individuals who naturally acquire anti-ASP-2 antibody responses following chronic exposure to hookworm larvae exhibit a significant reduction in the risk of acquiring heavy hookworm infections (Bethony et al., 2005). Therefore, ASP-2 was the first larval antigen selected for further development based on the promising evidence from the cumulative in vitro, animal challenge, and human immunoepidemiological studies (Hotez et al., 2005, 2006a). Based on its efficacy in the canine model and the ease with which it can be produced as a recombinant protein (Fujiwara et al., 2007), *Na*-SAA-2 (the *Necator* orthologue of *Ac*-16) has been selected as the second-line larval antigen and is currently undergoing early-stage process development and scale-up expression.

PROCESS DEVELOPMENT AND MANUFACTURE OF *Na*-ASP-2 AND *Na*-SAA-2

After selecting the *N. americanus* ortholog of ASP-2 (*Na*-ASP-2) and SAA-2 (*Na*-SAA-2) as the lead larval antigens for further development, an organization had to be created in order to oversee process development and cGMP manufacture of these two recombinant protein vaccines. As with other neglected tropical diseases, the development of a vaccine against hookworm infection is impeded by the absence of a viable commercial market (Hotez and Ferris, 2006). Although North American and European vaccine manufacturers may be sympathetic to developing vaccines for neglected tropical diseases, most are not in a financial position to invest in such development given their need to produce a profit and satisfy shareholders. Ultimately the development of *N. americanus* larval antigens into vaccines for humans required the creation of an entity now known as a product development public private partnership (PD-PPP) (Hotez et al., 2005; Bottazzi et al., 2006). PD-PPPs began to emerge during the late 1990s in response to a growing demand for nonprofit organizations with the capacity to produce health products for developing countries (Hotez et al., 2006d). Similar to traditional pharmaceutical manufacturers, the PD-PPPs use industry practices and maintain a portfolio of products, but with

the goal of improving public health rather than generating profits or reporting to shareholders (Widdus and White, 2004). The PD-PPP known as the Human Hookworm Vaccine Initiative (HHVI) was established in 2000, and is based at the Sabin Vaccine Institute in Washington, DC. The HHVI's process development and quality control is conducted at the laboratories of the Department of Microbiology, Immunology, and Tropical Medicine at The George Washington University (GWU), whereas cGMP manufacture is performed at the Walter Reed Army Institute of Research (WRAIR) and Instituto Butantan, a public sector vaccine manufacturer located in São Paulo, Brazil. The Oswaldo Cruz Foundation (FIOCRUZ) in Brazil was selected to undertake clinical development of the vaccine, with additional support from the London School of Hygiene and Tropical Medicine. The Sabin Vaccine Institute provides sponsorship of the product and program management of the HHVI.

Na-ASP-2 was selected as the first larval antigen for process development and cGMP manufacture based on the reasons listed above. Early efforts to express *Na*-ASP-2 in *E. coli* resulted in the production of insoluble inclusion bodies that resisted attempts at either resolubilization or refolding. A similar experience has been reported for antigen 5, a PR protein from yellowjackets and paper wasps (Monsalve et al., 1999), which may result from the protein's high cysteine content and subsequent aberrant disulfide bond formation. Early success was achieved with insect cell expression of *Ac*-ASP-2 (Bethony et al., 2005) although the yields and expense of this expression host were considered inappropriate for further vaccine development. Both *Ay*-ASP-2 and *Na*-ASP-2 were successfully expressed in the methanol-utilizing yeast, *Pichia pastoris* (Goud et al., 2004, 2005).

The recombinant ASP-2 proteins were shown to be soluble and secreted by *P. pastoris* at high yields; in the case of *Na*-ASP-2, approximately 400 mg of purified protein were obtained per liter of fermentation broth (Goud et al., 2005). Recombinant *Na*-ASP-2 is a 21.3 kDa protein with an N-terminal acidic tag (EAEAEAF), the presence of which increases expression yield. The recombinant protein has a single O-linked monosaccharide, but no N-linked carbohydrates. Antibodies generated against the recombinant protein in rats both recognize native *Na*-ASP-2 on Western blots and inhibit larval invasion in vitro (Goud et al., 2005). Moreover, X-ray crystallographic analysis of the recombinant protein reveals that it contains a PR-1 domain with an alpha helix–beta sheet–alpha helix sandwich, which is characteristically found in other PR proteins (Asojo et al., 2005a). Together, these data suggest that recombinant *Na*-ASP-2 is correctly folded and displays conformational epitopes in a manner similar to the native molecule.

Because *Na*-ASP-2 is highly stable and is secreted in abundance by *P. pastoris*, a purification process was developed that is relatively straightforward and simple. The purification steps include ultrafiltration and microfiltration, two ion-exchange chromatography steps, and a final purification step using gel filtration chromatography (Goud et al., 2005).

Process development at the 10 L scale was followed by a 60 L fermentation and 1/12th-scale purification before the research seed stocks were transferred from GWU to WRAIR for production of the master and production cell banks, and cGMP manufacture at the 60 L scale. The final drug substance passed lot release criteria for identity, sterility, purity, immune recognition, and stability using qualified assays, as well as additional testing for residual DNA, monosaccharide analysis, residual methanol, N-terminal amino acid sequencing, host cell protein, and endotoxin content. Recombinant *Na*-ASP-2 was formulated with Alhydrogel® based on previous studies showing that *Na*-ASP-2 bound to this aluminum-containing substrate was immunogenic in rats and other laboratory animals (Goud et al., 2005; Fujiwara et al., 2005). The formulated drug product also passed lot release criteria for color and appearance, pH, identity, stability, and immunological potency in rats. An investigational new drug (IND) application was submitted to the Food and Drug Administration (FDA) in December 2004, and a phase 1 human trial of the vaccine was completed in 2006.

CLINICAL DEVELOPMENT OF THE Na-ASP-2 HOOKWORM VACCINE

The overall goal of the HHVI program is to develop a safe, efficacious, and low-cost human hookworm vaccine that will contribute to reducing the global burden of disease caused by this infection by reducing the likelihood of developing heavy infections in individual vaccine recipients. The pathway chosen by the HHVI for the clinical development of candidate hookworm vaccines is to first test them in uninfected, healthy adults in the United States, followed by age de-escalation studies in hookworm-endemic areas, culminating in "proof-of-principle" efficacy studies in children exposed to hookworm infection. Following demonstration of a meaningful biologic effect on hookworm infection, further product and clinical development will be transferred to partners in endemic countries with the capacity to develop and manufacture new

vaccines, such as Brazil, India, or China (Bottazzi et al., 2006; Hotez et al., 2006a; Loukas et al., 2006). The HHVI has chosen Brazil as its first such partner, and an agreement is now in place that provides a blueprint for Instituto Butantan, one of Brazil's largest public sector vaccine manufacturers, to continue product development and for the Brazilian government to continue the clinical development of a human hookworm vaccine once proof-of-principle is established in a phase 2 clinical trial. The agreement also includes provisions for the eventual industrial-scale manufacture of the vaccine and sponsorship of pivotal phase 3 efficacy studies.

Following submission of the IND application for the recombinant *Na*-ASP-2 Hookworm Vaccine to the FDA in December 2004, and a clinical trial evaluating the safety, reactogenicity, and immunogenicity of this vaccine in healthy adults without evidence of hookworm infection and living in the United States was started in March 2005 and completed in June 2006. Thirty-six adults were enrolled in this randomized, double-blind, dose-escalation phase 1 study comparing three different concentrations of the *Na*-ASP-2 protein (10, 50, or 100 μg of recombinant protein) adjuvanted with Alhydrogel® to a saline placebo (Diemert et al., 2008). Individuals were administered according to a 0-, 2-, and 4-month schedule by intramuscular injection and participants were followed until 6 months after the final vaccination. The *Na*-ASP-2 Hookworm Vaccine was well tolerated and did not induce any significant vaccine-related adverse events. The most frequently observed adverse events were injection site reactions including mild-to-moderate pain, swelling, erythema, and pruritus. Additionally, significant antigen-specific antibody and cellular immune responses were observed.

Because this initial phase 1 study of the *Na*-ASP-2 Hookworm Vaccine demonstrated an acceptable safety profile and encouraging immunogenicity in a naïve population, a phase 1 trial of the *Na*-ASP-2 vaccine conducted in a hookworm-endemic area of Brazil in healthy adult volunteers with documented evidence of previous hookworm infection was initiated in June 2007 and is currently underway. In this study, the same dose concentrations and vaccination schedule will be used as in the initial phase 1 trial conducted in the United States. This first study of a hookworm vaccine in an endemic area will also be a randomized, double-blind study comparing the safety and immunogenicity of the *Na*-ASP-2 vaccine to the hepatitis B vaccine. A second phase 1 study in adults is necessary as neither the safety nor the immunogenicity of the vaccine in individuals chronically exposed to hookworm can be confidently extrapolated from studies performed in unexposed populations.

Assuming the phase 1 trial in Brazilian hookworm-exposed adults yields no significant safety concerns, clinical testing of the *Na*-ASP-2 vaccine will proceed into the pediatric population in which an eventual proof-of-principle study will be conducted; that is, in preschool and/or primary school-aged children. This target age group has been chosen for a number of reasons, but primarily because studies have shown that although high intensities of infection and presumably intestinal blood loss occur in both adults and children, the health impact of hookworm infection in terms of host blood loss resulting in anemia is greatest in children (Stoltzfus et al., 1997a, 1997b). In addition, future implementation of an effective human hookworm vaccine would likely be integrated into existing helminth control programs, which are currently based on the delivery of anthelmintics to preschool and school-aged children (Savioli et al., 1992). For these reasons, we believe that children are an appropriate study population for a phase 2 study of the *Na*-ASP-2 vaccine.

The study design of the proof-of-principle phase 2 trial will consist of assessing the rate and intensity of hookworm infection in vaccinated children, in comparison to those administered an active comparator such as the hepatitis B vaccine. An important component of the study design of the phase 2 trial will be pretreatment of infected individuals with either albendazole or mebendazole in order to eliminate the adult hookworms that are already present in the gastrointestinal tract of study participants, prior to vaccination (Diemert et al., 2008).

Estimation of vaccine efficacy will be assessed by measuring the impact on worm burden, which will be indirectly assessed by quantitative fecal egg counts. Because a larval hookworm vaccine is unlikely to provide completely sterilizing immunity, but may instead limit the number of invading L3 that reach the gastrointestinal tract and subsequently develop into adult worms, the worm burden (i.e., number of worms per individual) represents the most appropriate efficacy endpoint (rather than the presence or absence of infection). Due to the difficulties in obtaining adult worm expulsions, a commonly employed indirect measure of infection intensity is the quantitative fecal egg count. Measuring fecal egg counts is considered an appropriate indicator of the health impact of hookworm infection because of the demonstrated correlation between egg counts and host worm burden, as well as the relationship between egg counts and host blood loss as estimated by measuring the quantity of heme in fecal samples (Stoltzfus et al., 1997a). Fecal egg counts, host hematological indices such as hemoglobin concentration, and fecal heme measurements will accordingly be critical endpoints for assessing the potential

efficacy of an experimental hookworm vaccine in a proof-of-principle study (Brooker et al., 2005; Diemert et al., 2008). Following demonstration of proof-of-principle, a phase 3 study will be required to demonstrate the impact of vaccination on clinical endpoints such as episodes of anemia.

In summary, the aim of the HHVI's clinical development of the *Na*-ASP-2 hookworm vaccine is focused upon showing, in a proof-of-principle study, that the vaccine is effective in reducing the intensity of reinfection with hookworm and the clinical outcomes of hookworm disease (e.g., intestinal blood loss and iron deficiency anemia) following anthelmintic treatment of hookworm-infected children from an endemic area of Brazil. The scope, scale, and design of the project will potentially provide sufficient evidence for a middle-income country such as Brazil to continue the clinical development of the vaccine. *Na*-SAA-2 is at an earlier stage of development and will be advanced depending on the results of the initial clinical trials of the *Na*-ASP-2 antigen in Brazil.

DEVELOPMENT OF ANTIGENS TARGETING ADULT HOOKWORMS

As outlined above, it is anticipated that a vaccine based on a larval antigen such as *Na*-ASP-2 will reduce the number of L3 entering the host gastrointestinal tract, thereby reducing host worm burdens, fecal egg counts, and blood loss (Goud et al., 2005). However, in the event that the vaccine is only partially effective in preventing infection, some L3 will still reach the gastrointestinal tract and develop into blood-feeding adult hookworms. In anticipation of this scenario, the HHVI has initiated a second antigen discovery program to identify macromolecules that are required by adult hookworms in order to utilize human blood as a food source (reviewed by Hotez et al., 2003). It is hypothesized that antibodies against these antigens, some of which are enzymes, would interfere with parasite feeding and thereby augment the reductions in blood loss and fecal egg counts resulting from vaccination with *Na*-ASP-2. This hypothesis is a modern-day version of the antienzyme antibody hypothesis first proposed by Professor Asa Chandler in the 1930s (Hotez and Cerami, 1983; Hotez et al., 1987). It is proposed that the second antigen would be added to a larval antigen in order to develop a bivalent hookworm vaccine.

From the HHVI antigen-discovery efforts, three candidate antigens have emerged. Two of these candidate antigens are proteases (hemoglobinases) that line the parasite alimentary canal and function to degrade host hemoglobin (Williamson et al., 2004). The third antigen is a glutathione S-transferase (GST-1) that detoxifies host heme (Zhan et al., 2005). The aspartic protease-hemoglobinase, APR-1, and the cysteine protease-hemoglobinase, CP-2, have both shown promise as protective antigens in laboratory dogs in terms of reduced host blood loss and fecal egg counts (Loukas et al., 2004, 2005). In addition, vaccination of dogs with APR-1 or GST-1 (with GlaxoSmithKline's AS03 adjuvant) or hamsters with these same antigens formulated with Alhydrogel® has also resulted in significant host worm burden reductions (Loukas et al., 2005; Xiao et al., 2007). Activities are now being concentrated on advancing at least one adult-stage antigen, such as either *Na*-APR-1 or *Na*-GST-1, through process development, cGMP manufacture, and phase 1 clinical testing. Currently, GST-1 has been manufactured according to cGMP at the 60 L scale, and should be ready for clinical testing in early 2009.

INDICATIONS AND USE OF THE HUMAN HOOKWORM VACCINE

The current aim of the HHVI is to develop a bivalent Human Hookworm Vaccine that contains an antigen targeting the larval stage of the life cycle of *N. americanus* and a second antigen targeting the adult worm. This two-component vaccine is being developed as an intramuscular injectable product for the prevention of disease—primarily anemia and protein malnutrition—related to infection with this helminth. The vaccine will most likely be used as part of an integrated hookworm control program, with areas of high transmission being targeted to obtain the greatest public health impact against this disease. The WHO defines high-transmission areas as those in which the prevalence equals or exceeds 70% or when the prevalence of moderate or heavy hookworm infections (defined as greater than or equal to 2000 hookworm eggs per gram of feces) is equal to or greater than 10% (WHO, 2002).

Administration of the Human Hookworm Vaccine to at-risk populations following deworming with a benzimidazole anthelmintic agent (e.g., albendazole or mebendazole) is being explored. The idea of prevaccination deworming with an anthelmintic is derived from observations that: (1) larval-stage vaccines will not target adult hookworms already present in the intestine (Zhan et al., 2003), and (2) in laboratory animals the presence of adult hookworms in the intestine reduces the immunogenicity of ASP-2

vaccines (Ghosh et al., 2006). Therefore, incorporation of the Human Hookworm Vaccine into existing deworming programs is under consideration (Hotez et al., 2005; Loukas et al., 2006; Hotez et al., 2006b). The concept of linking anthelmintic deworming with anthelmintic vaccination has also been proposed for the future control of schistosomiasis (Bergquist et al., 2005). In the major STHI-endemic countries, deworming is either conducted in schools or as a part of "child health days" in order to target school-aged and preschool children, respectively.

ENSURING GLOBAL ACCESS TO A HUMAN HOOKWORM VACCINE

Critical to the success of the HHVI is the ability to not only complete proof-of-principle testing in humans, but also develop plans for the licensure, industrial-scale manufacture, and distribution of hookworm vaccines. Given the large number of individuals at risk for hookworm infection and the observation that almost all of them live in rural areas without easy access to the cold chain, these goals will not be easily attainable. Equally challenging is the absence of a viable commercial market for hookworm vaccines, given that the vaccine recipients would be comprised almost exclusively of individuals who live on less than $2 per day (Hotez et al., 2005). Mahoney and Maynard (1999) point out that there was a lag time of more than two decades before hepatitis B vaccine was widely used from the time of its initial development, so it is highly desirable to identify mechanisms that could potentially shorten this time frame.

An important component of the global access strategy of the HHVI is to develop partnerships with vaccine manufacturers in middle-income countries with endemic hookworm infections (Hotez et al., 2005, 2006a; Bottazzi et al., 2006). Several of these nations are known as *innovative developing countries* (IDCs), which are characterized by evidence of innovation that exceeds expectations based on economic growth (Morel et al., 2005). Among the criteria for innovation are patents, peer-reviewed papers, and ability to manufacture drugs and vaccines. The HHVI has focused its initial efforts on tropical regions of the Americas, especially in Brazil where proof-of-principle testing of experimental hookworm vaccines will take place. Brazil is an IDC with two major vaccine manufacturers, FIOCRUZ Bio-Manguinhos and Instituto Butantan. Through signed memoranda of understanding, the HHVI is transferring hookworm vaccine development and manufacturing technology to Instituto Butantan, with clinical testing to be conducted by FIOCRUZ. In turn, the Brazilian government will commit to the purchase and distribution of the hookworm vaccine for its own country with an option to export the vaccine throughout the Americas. To date, Instituto Butantan has successfully produced GMP-grade *Na*-ASP-2.

Also of relevance to global access is the importance of improving health delivery systems (Loukas et al., 2006). As noted above, a Human Hookworm Vaccine could be integrated into existing deworming programs, even though it would mean that vaccination would be conducted outside of the infant-based Expanded Program on Immunization framework. Therefore, discussions with the WHO and other UN agencies are already underway to explore the compatibility of vaccination and deworming, thereby ensuring that an eventual Human Hookworm Vaccine is integrated into large-scale control programs, either as a part of school-based deworming programs or preschool based child health days, as soon as possible after its development. Such early-stage efforts are considered critical in order to avoid the hurdles that prevented the timely deployment of the hepatitis B vaccine in resource-limited settings. Despite the enormous challenges in developing, testing, and distributing a vaccine for a neglected tropical disease such as hookworm, success in this endeavor could be a significant public health breakthrough. Moreover, this would represent an important step in achieving several Millennium Development Goals (MDGs) for sustainable development including specific MDGs in the areas of infectious diseases, poverty reduction, and child and maternal health (Hotez and Ferris, 2006).

KEY ISSUES

- Over 500 million people worldwide are infected with the hookworms *Necator americanus* and *Ancylostoma duodenale*.
- The major health impact of hookworm infection is due to the resultant iron deficiency anemia and protein malnutrition.
- Current disease control efforts that focus on periodic mass administration of anthelmintic medications in endemic areas are not sustainable.
- High rates of anthelmintic drug failure and the potential emergence of drug resistance necessitate the development of new and alternative control tools.
- An efficacious vaccine would provide a powerful control tool when integrated into existing mass chemotherapy programs.

- Antigen discovery has concentrated on identifying targets found in both the larval and adult stages of the worm's life cycle.
- The goal of current hookworm vaccine development activities is to produce a vaccine that is a combination of a larval with an adult-stage antigen.
- Hookworm vaccine antigens are being produced as recombinant proteins expressed in either *Pichia pastoris* or *Escherichia coli*.
- The first hookworm vaccine formulation to enter clinical trials is a larval antigen adjuvanted with Alhydrogel, which is currently undergoing phase 1 testing in an endemic area of Brazil.

OUTLINE

ABSTRACT

Human onchocerciasis is a serious neglected tropical disease caused by *Onchocerca volvulus* and an important cause of blindness and chronic disability in the developing world. Through mass drug administration of ivermectin, onchocerciasis has been recognized by the World Health Organization as a potential candidate for global elimination. However, formidable technical and logistical obstacles must be overcome before the goal of elimination in Africa can be attained. In addition to difficulties of compliance in this region, evidence is building for the existence of *Onchocerca* resistance to the drug ivermectin, which is at present the only drug used for the mass treatment of this population. Therefore, additional tools are critically needed and include the need for a vaccine against onchocerciasis to "complement" the present control measures and thus potentially eliminate this infection from humans. An *Onchocerca* vaccine targeting the infective stage larvae could reduce adult worm burden

and thus the number of microfilariae produced by the adult female worms, and the causative stage of pathology. Importantly, protective immunity against *Onchocerca* larvae has now been definitively demonstrated in humans, cattle, and mice, thereby providing the conceptual underpinnings that a vaccine can be produced against this infection. Moreover, several recombinant *Onchocerca* antigens have been identified that are capable of inducing a partial but significant reduction in the survival of a larval challenge using an experimental mouse model. Thus, the research community is in an ideal position to proceed with the preclinical research needed in order to accelerate the product development of an *Onchocerca* vaccine for human use.

INTRODUCTION

Human onchocerciasis (river blindness) is a serious neglected tropical disease caused by the filarial nematode parasite *Onchocerca volvulus* and an important cause of blindness and chronic disability in the developing world. Presently, it is estimated that 37 million people carry *O. volvulus*, with 90 million at risk in Africa. Morbidity at present is estimated at 987,000 disability-adjusted life-years and there are 46,000 new cases of blindness annually. Through mass drug administration of the donated drug ivermectin (Mectizan®), onchocerciasis has been recognized by the World Health Organization as a potential candidate for global elimination, with a World Health Assembly goal to establish community-based sustainable treatments in areas of meso- and hyperendemicity by 2010 (www.apoc.bf/en). However, formidable technical and logistical obstacles must be overcome before the goal of elimination can be attained, and additional tools are critically needed to support the control measures and thus potentially eliminate this infection as a public health problem. These new control tool requirements include a need for a vaccine against onchocerciasis to "complement" the present control measures and further the goals of the existing control programs (Cook et al., 2001; Dadzie et al., 2003; Hoerauf and Steel, 2004).

The rationale for why a vaccine is in critical need includes the observations that: (a) the present control measures are not going to succeed in the elimination of *O. volvulus* infection by themselves (Dadzie et al., 2003); (b) evidence for emerging resistance to ivermectin, the only drug used for mass treatment of onchocerciasis (Osei-Atweneboana et al., 2007); and (c) practical considerations in treating people for 14–35 years (Winnen et al., 2002; Boatin and Richards, 2006). Importantly, protective immunity against *Onchocerca* infective larval stages, also known as third-stage larvae or L3, has now been definitively demonstrated in humans, cattle, and mice, thereby proving the conceptual underpinnings that a vaccine can be produced against this infection (Abraham et al., 2002; Lustigman et al., 2003; Tchakoute et al., 2006).

The value of developing a vaccine against *O. volvulus* infection was recognized by the Edna McConnell Clark Foundation. Their 15 years of support (1985–1999) provided the research foundation for antigen discovery and development of animal models for testing the efficacy of vaccine candidates. This chapter will highlight the current status of vaccine development against onchocerciasis and the potential for being able to accelerate vaccine development to provide this crucial element required for the successful elimination of onchocerciasis. Reduction in worm burden after vaccination, even if not absolute, will reduce the number of microfilariae produced by the adult female worms, and thereby reduce both pathology and the rates of transmission within endemic regions.

DISEASE

Epidemiology

Onchocerciasis or "river blindness" is a human disease caused by the filarial worm *Onchocerca volvulus* (Nematoda: Secernentea; Spirurida; Filariidae; Onchocerca). Adult worms can live for over a decade in nodules under the skin and release millions of microfilariae that are responsible for the morbidity associated with infection. When the microfilariae die, they cause skin rashes, lesions, intense and debilitating itching, and changes in skin pigmentation. Microfilariae also migrate to the eye and can cause ocular lesions resulting in blindness (Richards et al., 2001).

The distribution of onchocerciasis has been determined using rapid epidemiological mapping of onchocerciasis in which the levels of endemicity are assessed by onchocercal nodule prevalence in the endemic adult population (Ngoumou et al., 1994; Noma et al., 2002). More than 22,000 villages in Africa (outside the Onchocerciasis Control Programme (OCP) in West Africa) had been surveyed, allowing the identification of many new foci (Basáñez et al., 2006). Presently, it is estimated that 37 million people carry *O. volvulus*, with 90 million at risk in Africa (APOC, 2005). The geographic distribution

includes 28 countries in tropical Africa, where 99% of infected people live, isolated foci in 6 countries in Latin America and in Yemen (WHO, 2002) (Fig. 67.1). Morbidity at present is estimated at 987,000 disability-adjusted life-years (www.who.int/tdr/diseases/oncho/diseaseinfo.htm). Onchocerciasis causes 46,000 new cases of blindness annually (www.apoc.bf/en) resulting in 270,000 individuals being blinded and an additional 500,000 with visual impairment, making onchocerciasis the second leading cause of infectious blindness worldwide. Although the importance of *Onchocerca*-induced blindness has long been recognized, it was only in 1995 that research funded by The Special Programme for Research and Training in Tropical Diseases demonstrated that *Onchocerca* skin disease had an even greater impact on human health. Severe itching now accounts for 60% disability-adjusted life-years. Other skin manifestations are not included in the disability-adjusted life-years estimates, even though they are highly prevalent and have a major psychosocial and economic impact.

Based on the complexity of the life cycle and the chronic nature of the disease progression, it is judged that *O. volvulus* is not a potential biothreat agent.

Life Cycle

Onchocerciasis is associated with fast flowing rivers where *Simulium* blackfly vectors breed. When a parasitized female blackfly takes a blood-meal from a human host, the infective *Onchocerca* larvae, pass from the blackfly into the host's skin and enter the host's subcutaneous tissue, where they migrate, induce nodule formation, and mature into adult worms over a period of 6–12 months (Fig. 67.2). Female worms measure 33–50 cm in length and 270–400 μm in diameter, while males measure 19–42 mm by 130–210 μm. The lifespan of adult worms is up to 15 years. Developing female adult worms either induce new nodules or enter existing nodules and cluster together with the resident female worms, while the smaller male worms migrate between nodules to mate. Fertilized eggs develop into microfilariae that actively exit from the female worm. A female worm may produce up to 1000 microfilariae per day and the microfilarial lifespan is 1–2 years, which results in millions of microfilariae residing in the subcutaneous tissues. When the infected host is bitten by female blackfly, microfilariae are transferred from the host to the blackfly where they develop into

FIGURE 67.1 World distribution of onchocerciasis. Currently 35 countries around the world are affected by onchocerciasis; 28 in tropical Africa, isolated foci in 6 countries in Latin America and Yemen.

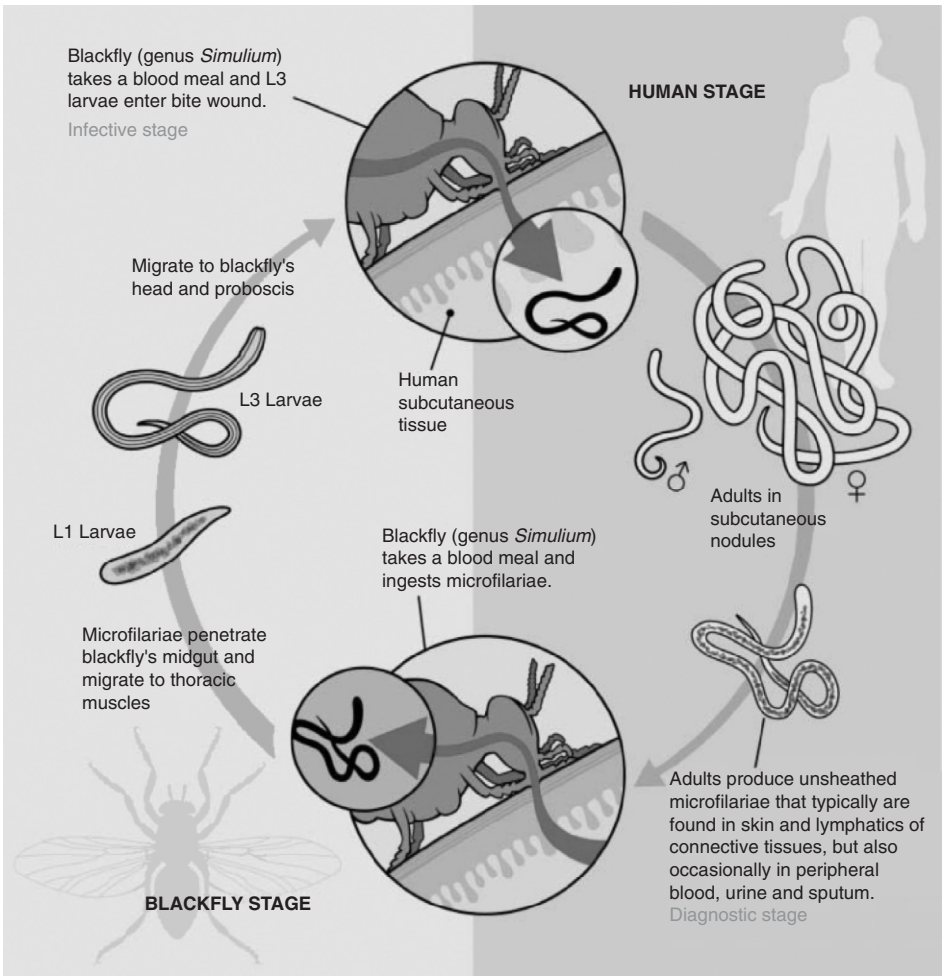

FIGURE 67.2 Life cycle of *O. volvulus*. The illustrator of this figure is Giovanni Maki (*Source*: Basáñez et al. (2006)). From: River Blindness: A Success Story under Threat? Basáñez, M.G., Pion, S.D.S., Churcher, T.S., Breitling, L.P., Little, M.P., et al. *PLos Medicine* Vol. 3, No. 9, e371 doi:10.1371/journal.pmed.0030371

infective larvae over a period of 6–12 days, which can then be transmitted to a new human host when the blackfly feeds again (www.dpd.cdc.gov/dpdx/html/Filariasis.asp?body = Frames/A-F/Filariasis/body_Filariasis_o_volvulus.htm).

Pathogenesis

Disease manifestations in the skin, lymphatics, and eye are all caused by immune responses to the parasite (Ottesen, 1995; Hoerauf and Brattig, 2002; Brattig, 2004; Pearlman and Gillette-Ferguson, 2007). Adult worms remain in subcutaneous nodules, which do not lead to morbidity or significant disfigurement in the human host. Nodule development occurs over a period of years and persists for decades. Nodules measure between 2 mm and 6 cm depending on the immune status of the host and the number of worms within the nodule. The principal cells of the granuloma surrounding the nodule are macrophages that mature into epithelioid cells and fuse to multinucleate foreign body giant cells. In addition, the granuloma is comprised of neutrophils, eosinophils, mast cells, lymphocytes, and NK cells (Buttner and Racz, 1983; Brattig, 2004).

The pathology of chronic onchocerciasis is a consequence of long-lasting host inflammatory responses directed at the microfilarial stage and the obligatory symbiont *Wolbachia* (Ottesen, 1995; Pearlman and Gillette-Ferguson, 2007). The skin is the principal site of infection, containing the mass of microfilariae. Live microfilariae appear to be unnoticed by host cells, whereas degenerating microfilariae are often surrounded by inflammatory cells that adhere and degranulate resulting in fragments of the worms being phagocytized by the adjacent cells (Buttner and Racz, 1983). The disease seen in the skin typically consists of intense itching, swelling, and inflammation. A grading system was developed to categorize the degree of

skin involvement: acute papular dermatitis—scattered pruritic papules; chronic papular dermatitis—larger papules, resulting in hyperpigmentation; lichenified dermatitis—hyperpigmented papules and plaques, with edema, lymphadenopathy, pruritus, and common secondary bacterial infections; skin atrophy—loss of elasticity, skin resembles tissue paper, "lizard skin" appearance; depigmentation—"leopard skin" appearance, usually on anterior lower leg. Onchocerciasis represents a disease comprising a spectrum of manifestations and host responsiveness. The majority of *O. volvulus* infected persons present the common generalized form of onchocerciasis presenting mostly varying mild or moderate skin dermatitis. These patients are considered to be hyporeactive and patients with high microfilarial loads show no obvious capacity to effectively reduce the number of microfilariae and adult filariae, while patients with lower microfilarial densities intermittently present dermatitis with signs of antimicrofilarial defense reactivities. Patients may also have the rare hyperreactive form (sowda) which exhibits extensive reactivity and skin pathology. These patients show a severe chronic papular dermatitis and hyperpigmentation, lichenification, and lymphadenopathy. The number of parasites in these patients is very low and histological studies reveal massive perivascular infiltration in the large nodules, the regional lymph nodes and the affected skin sites (Buttner and Racz, 1983; Mackenzie et al., 1985; Brattig, 2004).

Most importantly, visual impairment and blindness develop as a result of microfilariae migrating into the conjunctiva, the cornea, and the posterior regions of the eye. Increasing numbers of degenerating microfilariae in the eye leads to inflammatory responses that result in bilateral blindness. In the area that is damaged, punctate keratitis occurs, which clears up as the inflammation subsides. However, if the infection is chronic, sclerosing keratitis can occur, making the affected area become opaque. Over time the entire cornea may become opaque, thus leading to blindness (Brattig, 2004).

All developmental stages and individual parasites of *O. volvulus* are infected with an obligatory symbiont rickettsia, *Wolbachia*. The adult worms harbor the *Wolbachia* in the hypodermis and in the female reproductive organs, where the bacteria are essential for the development of microfilariae within the female adult worm (Hoerauf et al., 2003; Taylor et al., 2005). The role of *Wolbachia* in the pathogenesis of filarial disease has been implicated by observations made after antifilarial therapy. Elevated *Wolbachia* DNA and even intact *Wolbachia* are detected in the blood and are associated with pro-inflammatory cytokines seen in patients with posttreatment side effects (Cross et al., 2001; Keiser et al., 2002). Furthermore, *Wolbachia* are required for recruitment of neutrophils to the *Onchocerca* nodules, as the number of neutrophils in nodules from individuals treated with doxycycline to eliminate *Wolbachia* is greatly reduced compared to untreated individuals (Brattig et al., 2001). Production of TNF-α and nitric oxide by mouse macrophages stimulated with filarial extracts is clearly associated with the presence of *Wolbachia* (Taylor et al., 2000). Using a mouse model of *O. volvulus* keratitis, it has been demonstrated that the endosymbiotic *Wolbachia* bacteria are essential for the pathogenesis of *O. volvulus* keratitis, as extracts from *O. volvulus* worms depleted of *Wolbachia* by antibiotic treatment do not induce corneal inflammation (Saint Andre et al., 2002).

Epidemiological, clinical, and genetic data all suggest that *O. volvulus* exists as two strains in Africa with the severe strain inducing ocular disease in a large proportion of the infected population, while the mild strain induces little ocular disease. It appears that the pathogenic differences seen in severe and mild strains *O. volvulus* are a function of the relative *Wolbachia* burden in the parasite with the median ratio of *Wolbachia* DNA to nuclear DNA significantly greater in the severe strain of parasites than in the mild strain (Higazi et al., 2005). Therefore, the pathogenesis of onchocerciasis is dependent on the host immune response to the microfilarial stage and to the endosymbiotic *Wolbachia* bacteria. The degree of pathology that develops is dependent on the number parasites and on the intensity and type of immune response that the patient develops to the infection. Finally, the pathology develops predominantly in chronic infections and is not associated with the infective stage larvae.

Diagnosis

The demonstration of microfilariae in skin biopsies (WHO, 1995) is the classic and definitive method for diagnosis of onchocerciasis as well as determining the intensity of infection. The use of techniques that are based on polymerase chain reaction (PCR) using species specific probes for the "Oncho-150" repeat have been shown to be effective for diagnosing *O. volvulus* infection by detecting parasite DNA in routine skin snips (Zimmerman et al., 1994). The technique is more sensitive in detecting low-level infections than standard skin-snip methods, but does not give any indication of the number of skin microfilariae. PCR methods are also used for surveillance of control measures, by identifying *O. volvulus* infections in the blackfly or the human host (Pischke et al., 2002; Rodriguez-Perez et al., 2006). Immunodiagnostic tests that are capable of detecting early infections have also developed (Harnett et al., 1998). These tests were of special interest

for identifying new infections in areas under vector control (particularly the OCP area) and as a tool for onchocerciasis surveillance (Lipner et al., 2006). For larger epidemiological surveys such as "rapid epidemiological mapping of onchocerciasis," palpation for nodules, a less invasive diagnostic procedure, is being used (Ngoumou et al., 1994; Noma et al., 2002). The diethylcarbamazine patch test has been also shown to constitute a valuable tool to evaluate the levels of endemicity of onchocerciasis and to follow the intensity of transmission of *O. volvulus* (Ozoh et al., 2007).

Treatment and Control Measures

International programs supported by the World Health Organization and many other organizations have worked to control the impact of onchocerciasis using vector control with insecticides beginning in 1974 and mass drug administration with ivermectin (Mectizan) beginning in 1987 (Peters and Phillips, 2004). Ivermectin is a highly effective microfilaricide and inhibits female worm microfilarial production for several months. Annual mass drug administration reduces morbidity (Ejere et al., 2001; Tielsch and Beeche, 2004) and lowers transmission (Collins et al., 1992; Boussinesq et al., 1997). The Onchocerciasis Control Programme (OCP) in West Africa (1974–2002) greatly decreased *O. volvulus* transmission in the 11 OCP countries (Molyneux, 1995; Basáñez et al., 2006; Boatin and Richards, 2006). Ivermectin without vector control has been the principal tool for the Onchocerciasis Elimination Program in the Americas (OEPA, 1992–present) (Boatin and Richards, 2006) and the African Programme for Onchocerciasis Control (APOC, 1995–present). In the Americas, where *O. volvulus* is less common, OEPA has substantially reduced transmission and is on track to eliminate the disease (Boatin and Richards, 2006). APOC has extended treatment to 19 countries beyond OCP through sustainable community-directed ivermectin treatment (Remme, 1995; Richards et al., 2001). By the end of 2005, 400 million treatments had been supplied in Africa by Merck's Mectizan Donation Program (www.mectizan.org), with an estimated 40 million people treated by nearly 300,000 community distributors (www.apoc.bf).

Although vector control and periodic administration of ivermectin have resulted in significant reductions in disease rates in many regions of Africa (Abiose et al., 2000), the present programs, relying only on periodic administration of ivermectin, still have severe limitations. Ivermectin is only effective against microfilariae, which cause blindness and dermatitis, but has little activity against the long-lived adult worms. Drugs that eliminate *O. volvulus* adult worms by targeting the endosymbiotic *Wolbachia* bacteria have been developed, but they have limited populations in which they can be used (Taylor, 2000; Richards et al., 2001). Moreover, it is estimated that at least 25 years of annual treatment at 65% total population coverage would be necessary to eliminate infection in areas of medium to high levels of infection, and more dire model predictions suggest that durations exceeding 35 years would be required if there was heterogeneity in exposure to *S. damnosum* vector bites (Winnen et al., 2002; Boatin and Richards, 2006). The predictions that annual ivermectin treatments will need to be given for anything from 14 to 35 years or more, not only creates significant logistical obstacles, but also has lead to a concern that resistance to ivermectin in *O. volvulus* will eventually emerge. The potential emergence of drug-resistant strains of the *O. volvulus* parasite have been suggested initially by reports that showed incidence of patients with onchocerciasis who failed to respond to ivermectin treatment (Awadzi et al., 2004a, 2004b). Significantly, a recent report from Ghana has provided the first proof of ivermectin resistance in *O. volvulus* in humans (Osei-Atweneboana et al., 2007). Additionally, studies have associated ivermectin resistance with genetic markers (Huang and Prichard, 1999; Kohler, 2001; Ardelli and Prichard, 2004; Ardelli et al., 2005, 2006a, 2006b; Eng and Prichard, 2005; Bourguinat et al., 2006), particularly the β-tubulin gene in human *O. volvulus* and the livestock nematode parasite *Haemonchus contortus* (Eng and Prichard, 2005; Eng et al., 2006). A report by Bourguinat et al. (2007) showed that not only the *β-tubulin* genotype has changed after 4 or 13 ivermectin treatments but also female fertility was affected. The finding that ivermectin treatment selected for *β-tubulin* heterozygotes and that this selection was dependent on dose raises important concerns for the current river blindness control programs.

PROTECTIVE IMMUNITY AGAINST *O. volvulus* IN HUMANS AND ANIMAL MODELS

Human

Protective Immunity in Humans is Associated with Th1 and Th2 Responses against O. volvulus L3

Two distinctive expressions of anti-L3 protective immunity within the *O. volvulus* endemic population have been described: (a) which impedes the development of a patent infection (microfilaria positive) in the putatively immune (PI) individuals (Gallin et al.,

1988; Ward et al., 1988; Elson et al., 1994; Turaga et al., 2000); and (b) concomitant immunity to *O. volvulus* L3 that develops in the patently infected (INF) individuals with increasing age, and which is independent of the immune responses that are induced by the adult worms and microfilaria associated with patent infection. Concomitant immunity is believed to prevent most of the newly acquired L3 infections from developing, and results in a stable adult worm burden in the INF (Duke and Moore, 1968; Schulz-Key, 1990; MacDonald et al., 2002).

Studies of the mechanisms of acquired immunity against *O. volvulus* infection in humans have focused on identification of defined cellular and humoral responses in the PI individuals as compared to responses in the INF as well as in those associated with concomitant immunity (reviewed in McCarthy and Nutman (1996) and Hoerauf and Brattig (2002)). Some of the initial studies produced conflicting results (Turaga et al., 2000; Hoerauf and Brattig, 2002) in terms of Th1 or Th2 dominance of cellular responses in the PI to adult worm antigens. This may have been due to examining immune responses against adult worm antigens, which contain female, male, and microfilariae stage antigens. However, when antigens from L3, L3 in the process of molting into the fourth-stage larvae (mL3), isolated female worms (F-OvAg), and skin microfilariae (Smf) were used in studies with PI and INF, an interesting differential cytokine profile emerged. First, although an IL-5 response was present in both the PI and the INF toward L3 and mL3 antigens, the PI had significantly elevated IL-5 responses to both L3 antigens. Second, a subgroup of these individuals also had significantly elevated IFN-γ responses toward L3 (27%) and mL3 (54.5%) antigens, thus indicating an overall response of a mixed Th1/Th2 profile. This raises the possibility that some of the PI have more than one mechanism of anti-L3 protective immunity. In contrast, the F-OvAg and Smf antigens induced only a Th2 type response in the PI. However, the IL-5 response to F-OvAg in this group was significantly higher than that in the INF, a group that as a whole, exhibited only a Th2 phenotype in response to all antigens. Moreover, while the PI produced significantly higher levels of GM-CSF toward L3 and mL3 compared to the INF, there was no difference in the GM-CSF response between the two groups toward the other antigens.

These observations demonstrated that the two groups, PI and INF, although similar in their anti-F-OvAg and Smf responses, are distinct in their anti-L3 and mL3 immunity. It also appeared that the PI could be divided into two subgroups; those with elevated anti-L3/mL3 IL-5 (e.g., Th2) and GM-CSF responses, and those with elevated anti-L3/mL3 IL-5 and IFN-γ (e.g., mixed Th1/Th2), and GM-CSF responses. These studies confirmed the hypothesis that immunological studies of the PI could lead to the identification of immune mechanisms that play a role in anti-L3 protective immunity (Turaga et al., 2000).

Age-dependent resistance to super-infection (Day et al., 1991), and acquired concomitant humoral (Kurniawan-Atmadja et al., 1998) and cellular (Sartono et al., 1997) immunity in infected individuals has been described in lymphatic filariasis. The existence of anti-larval immunity that is separate and distinct from that directed against adult worms and microfilariae (concomitant immunity) has also been observed in individuals infected with *O. volvulus.* Studies have shown that the proliferative responses to L3 increased significantly with age, while there was a downward trend in response to F-OvAg. The responses in the INF group against L3, mL3, F-OvAg, and Smf antigens in the infected group were predominantly of the Th2-type (higher frequency of IL-5 producers than IFN-γ producers). However, when the cytokine responses were analyzed in relation to age of the PBMC donors (=years of exposure to *O. volvulus*), it appeared that a differential stage-specific IL-5 response in the infected group was observed. It appeared that a distinct IL-5 response was acquired with age against the L3 stages and this response was independent of that induced by F-OvAg and Smf antigens, which are associated with patent infection. The responses against F-OvAg and Smf antigens significantly decreased with age. Moreover, in INF individuals who had GM-CSF responses to L3, the amounts secreted were positively correlated with IL-5. Thus, older INF, like the PI subjects as a whole (Turaga et al., 2000), had predominantly IL-5 responses to L3 and mL3 antigens, which were accompanied by elevated GM-CSF. Similarly, a Th1 response was also present in a subgroup of the INF (MacDonald et al., 2002).

A Role for Antibodies in Protective Immunity Against O. volvulus Larvae in Humans

Data from several studies support the view that antibodies are part of the effector mechanism against *O. volvulus* larvae. These include the correlation between elevated antigen-specific IgG1 and/or IgG3 responses and the immune status of exposed individuals (Boyer et al., 1991; Soboslay et al., 1994, 1997; Ottesen, 1995; Stewart et al., 1995; Faulkner et al., 2001). When sera from INF and PI individuals were analyzed by Western blots, significant differences between their antibody responses to a broad range of crude *O. volvulus* larval and adult stage antigens

were also observed (Boyer et al., 1991; Luder et al., 1996; Irvine et al., 1997; Soboslay et al., 1997). Whereas both groups recognized many common antigens, the PI sera reacted with some stage-specific antigens uniquely (Irvine et al., 1997). In addition, a positive correlation was seen between anti-L3-specific IgG3 and IgE cytophilic antibody responses and increasing age of the infected subjects as well as elevated IgG1 response regardless of age (MacDonald et al., 2002). L3 surface-specific antibodies were seen in 80% of putatively immune individuals and in 83% of those infected. Moreover, antibodies that bind specifically to the surface of L3 but not to the surface of microfilariae were found in sera from infected subjects, and the intensity of L3 surface recognition was positively correlated with their age, thus suggesting a role for antibodies also in concomitant immunity (MacDonald et al., 2002). Similar results were also obtained in individuals infected with lymphatic filariasis (Kurniawan-Atmadja et al., 1998) where concomitant immunity is more clearly defined (Day et al., 1991). In vitro antibody-dependent killing of *O. volvulus* L3 and inhibition of molting of L3 to fourth-stage larvae has been observed to be dependent on granulocytes and antibody from putatively immune and/or infected individuals (Greene et al., 1985; Leke et al., 1989; Johnson et al., 1994).

Animal

O. volvulus in Chimpanzees

The chimpanzee is the only species aside from humans that is susceptible to infection with *O. volvulus*, although without the development of significant pathology (Duke, 1980). Studies have been performed in chimpanzees to determine the immunological responses that develop following primary and challenge infections. Antibody responses were measured after primary infections with L3 against antigens solubilized from adult worms and against recombinant *O. volvulus* antigens (Weiss et al., 1986; Eberhard et al., 1991, 1995; Soboslay et al., 1992; Luder et al., 1993). When the infections developed, the number of individual antigens recognized increased as determined by Western blot analyses. In addition, antibody responses in animals with microfilariae in the skin could be distinguished from responses in nonpatent animals (Soboslay et al., 1992). Lymphocyte proliferation assays were performed with cells from infected chimpanzees and it was observed that, after a strong early response to parasite antigens, a reversible cellular hyporesponsiveness developed (Soboslay et al., 1991; Luder et al., 1993).

A single study was performed to determine whether or not chimpanzees could be immunized against infection with *O. volvulus*. Four chimpanzees were immunized with irradiated L3 followed by infection with L3. After 11–26 months, three out of the four immunized chimpanzees developed microfilariae in the skin, whereas all four of the control animals became patent. There were no significant differences in the number of microfilariae found in the skin of the immunized chimpanzees when compared with the infected controls (Prince et al., 1992). This experiment is difficult to interpret because adult worm burdens cannot be determined in live chimpanzees, hence protective effects could be obscured by microfilariae production from very few adult worms. The reason why the one vaccinated animal did not develop microfilariae in the skin could have been a result of a failure to get infected by the challenge L3 (not all chimpanzees develop patent infections after primary challenge (Eberhard et al., 1991; Soboslay et al., 1991)) or could have been the result of some immune protection. This animal developed an antibody response to 11–12 kDa L3 antigens of *A. viteae* (Luder et al., 1993). Serum from this immunized and protected chimpanzee was used for immunoscreening and resulted in the cloning and identification of *Ov*-CPI-2 (Lustigman et al., 1991, 1992a), one of the 15 protective recombinant *O. volvulus* antigens (r*Ov*Ags) (Lustigman et al., 2002).

Protective Immunity to Onchocerca ochengi in Cattle

O. ochengi infection of cattle is an excellent analog of human *Onchocerca* infection (Trees et al., 2000). Epidemiological evidence demonstrates crossreactivity between antigens from *O. volvulus* and *O. ochengi* that extends to cross-protection of humans against *O. volvulus*, by exposure to infected larvae of *O. ochengi* (Wahl et al., 1998). The superficial location of the adult worms of *O. ochengi* contained within nodules in the infected cows has enabled studies measuring adult parasite worm burdens. Treatment of cattle infected with *O. ochengi* with ivermectin (Njongmeta et al., 2004), melarsomine (Tchakoute et al., 2006), or oxytetracycline (Nfon et al., 2007) to control the infection did not effect the susceptibility of these cattle to re-infection. Field studies, however, have provided evidence that immunity develops in cattle to both microfilariae and larval stages. Whereas adult burdens increased with age in naturally infected cattle, microfilarial loads decreased in older cattle despite the continuing fecundity of excised, adult, female worms (Trees et al., 1992). Cattle have been identified in a number of studies

that have naturally developed protective immunity to infection and are considered putatively immune. The cattle were maintained in endemic areas yet were not infected with *O. ochengi*, based on the absence of nodules with adult worms and microfilariae in the skin (Hoch et al., 1992; Trees et al., 1992; Wahl et al., 1994). Putatively immune cattle were significantly less susceptible to challenge infections as compared to naïve cattle based on acquisition of *O. ochengi* nodules. The density of microfilariae in the skin was substantially lower in the putatively immune cattle as compared to their naïve counterparts. Furthermore, cattle immunized with *O. ochengi* irradiated third-stage larvae were significantly protected against both experimental (100% reduction in median nodule load) and field challenge (64% reduction in median nodule load) infections (Tchakoute et al., 2006). Finally, calves immunized with live *O. volvulus* larvae and subsequently challenged with *O. ochengi* larvae had significantly fewer adult *O. ochengi* parasites as compared controls (Achukwi et al., 2007). In summary, these experiments demonstrate the feasibility of vaccinating a natural host against *Onchocerca* infection and support the feasibility of developing a vaccine against the infection in humans.

Immunity against Onchocerca spp. Microfilariae

Vaccination of cattle with microfilariae of *O. lienalis* was shown to enhance the clearance of microfilariae subsequently transplanted into the same animal (Townson and Bianco, 1982a). Moreover in natural infections of cattle with *O. ochengi*, skin microfilarial density falls with age in spite of increasing numbers of fecund female worms, which suggests that a level of stage-specific microfilarial immunity may develop (Trees et al., 1992). Mice have also been used as surrogate hosts to investigate immunity against *Onchocerca* spp. microfilariae. Mice can support the survival of inoculated microfilariae for 3–4 months. Microfilariae injected subcutaneously at the nape of the neck, concentrate in the ears, therefore recovery of microfilariae from the ears post-mortem can be used as a measure of parasite survival (Townson and Bianco, 1982b; Carlow et al., 1986). Using this model with *O. lienalis*, significant protective immunity was conferred by live, homologous primary infection, immunization with microfilariae extracts and with live infections that were abbreviated by drug treatment (Townson et al., 1984; Carlow et al., 1986). Some protection was also conferred by heterologous stages and species but at a lower level (Townson et al., 1985; Carlow and Bianco, 1987). Significantly, protection against *O. volvulus* microfilariae was also demonstrated in mice immunized with live homologous or heterologous (*O. lienalis*) microfilariae (Bianco et al., 1991). The mechanisms of protection have been extensively studied using *O. lienalis*. Eosinophils are crucial and IL-5 is dominant in the expression of microfilarial immunity (Folkard et al., 1996; Hogarth and Bianco, 1999b). Using gene knockout mice, clearance of microfilariae following primary and secondary infections was independent of IL-4 (Hogarth et al., 1995, 1998). Exogenous IL-12 was used to ablate parasite-induced IL-4 responses without eliminating the protective IL-5-dependent responses (Hogarth and Bianco, 1999a).

Protective Immunity to O. volvulus Larvae in Mice

A mouse model has been developed to study protective immunity against *O. volvulus* larvae. Although *O. volvulus* L3 do not develop into adult worms in mice, it is possible to study the effects of anti-L3 immunity by placing *O. volvulus* L3 in subcutaneous implantable diffusion chambers, which are porous to host antibody and cells. L3 develop equally well, for a short period of time, in resistant hosts (such as mice) as they do in the susceptible chimpanzee host when implanted within diffusion chambers (Abraham et al., 1993). To study protective immunity in this mouse model, mice were immunized by injection of normal, irradiated, or freeze-thaw-killed *Onchocerca* spp. larvae, and then received challenge infections of L3 contained in diffusion chambers. There was a significant reduction of ~50% in the survival of challenge parasites in all the experimentally immunized mice (Lange et al., 1993).

The mouse model was also used to establish the mechanism of immune-mediated killing of *O. volvulus* L3 in diffusion chambers in mice immunized with irradiated L3. IL-5, but not IFN-γ, was found in diffusion chambers of immunized mice coincident with the time of parasite killing. Elimination of either IL-5 or IL-4 by monoclonal antibody treatment significantly reduced the protective effects of vaccination against *O. volvulus* L3 (Lange et al., 1994). The dependency on Th2 cytokines was further corroborated in cytokine-deficient mice. Immunized IL-4-deficient mice did not develop protective immunity, whereas IFN-γ deficient animals developed immunity comparable to immunized wild-type mice (Johnson et al., 1998). The finding that immunity was dependent on IL-4 and IL-5 suggested a dependency on the antibody isotypes IgG1 and/or IgE. Two mouse strains, μMT mice that lack all mature B cells and Xid mice that have deficiencies in their B-1 cells, were used to determine if antibody was required for protective immunity in

mice immunized with irradiated L3. Immunity did not develop in μMT mice but did develop in the Xid mice. Furthermore, mice treated to eliminate IgE from the blood did not develop protective immunity. The role of granulocytes in protective immunity was also determined in mice immunized with irradiated L3. Immunity did not develop in mice if granulocytes, including both neutrophils and eosinophils, were eliminated nor did it develop if only eosinophils were eliminated (Abraham et al., 2004).

Wolbachia from *O. volvulus* contains molecules with LPS-like activity that induce an inflammatory response from monocytes (Brattig et al., 2000). Various studies suggest that TLR4 is an important mediator in the response to the *Wolbachia* endosymbiont and that immunity to *Wolbachia* may be an integral component of the immune response to the L3 of *O. volvulus* (Taylor et al., 2000; Brattig et al., 2004). TLR4-mutant mice were immunized against *O. volvulus* with irradiated L3 and it was observed that antibody responses to *Wolbachia* were absent in both wild-type and TLR4-mutant mice. Protective immunity, however, did not develop in the TLR4-mutant mice even though the Th2 immune response was intact (Kerepesi et al., 2005). It can therefore be concluded that immunity induced by irradiated L3 in mice is dependent on: (a) a Th2 response through IL-4 and IL-5; (b) a B-2 cell response through production of parasite-specific IgE; (c) eosinophils as effector cells; and (d) signaling through TLR4. Protective immunity to the larvae of *O. volvulus* is not, however, dependent on an immune response to *Wolbachia.*

VACCINES

The development of an *Onchocerca* vaccine has been the focus of research supported by the Edna McConnell Clark Foundation who funded from 1985 to 1999 research projects aimed at the development of a vaccine against infection with *O. volvulus* L3 (Cook et al., 2001; Richards et al., 2001; Abraham et al., 2002; Hoerauf and Brattig, 2002; Lustigman et al., 2002; Nutman, 2002; Williams et al., 2002). This approach has also been endorsed in 2002 during a "Conference on the Eradicability of Onchocerciasis" at the Carter Center (Dadzie et al., 2003) and later at a conference convened in 2004 on the global program to eliminate lymphatic filariasis (Hoerauf and Steel, 2004). Vaccines are still the most economical, efficient, and effective tool to control infectious diseases and might be the only way to guarantee elimination of onchocerciasis as initially envisioned by the World Health Organization. The ultimate goal of such a vaccine would be to complement the existing control programs and thus to combine it with drug treatments in a program of vaccine-linked chemotherapy (Hotez and Ferris, 2006; Hotez, 2007). The objective is to induce protection that is not necessarily sterile against the incoming infective third-stage larvae but rather that reduces adult worm burden. This will result in a reduction in the number of microfilariae produced by the adult female worms, a reduction in the development of pathology in the skin and in the eye, and a decrease in the potential for disease transmission. It is anticipated that continual natural exposure of the immunized individuals to infective larvae from black flies would sustain the protective immunity induced by immunization with recombinant vaccine proteins, and that ultimately the combination of vaccination with long-term chemotherapy with ivermectin could accelerate the eradication of onchocerciasis from sub-Saharan Africa.

Importantly, protective immunity against *O. volvulus* L3 has now been definitively demonstrated in humans, cattle, and mice, thereby proving the conceptual underpinnings that a vaccine can be produced against this infection (Abraham et al., 2002; Lustigman et al., 2003; Tchakoute et al., 2006). Studies of other filarial worms have clearly shown that the targets of the protective host immune response were the L3 and the molting L3 (Eisenbeiss et al., 1994; Le Goff et al., 2000), and that excretory–secretory proteins from the developing parasites induce protection (Lucius et al., 1991). These studies also suggested that the protective immune responses could inhibit the development of L3 to L4 (Horauf and Fleischer, 1997; Le Goff et al., 2000; Abraham et al., 2001). Assuming that there are common protective mechanisms against filariae and that the target antigens are similar, it advocated pursuing *O. volvulus* L3, mL3, and excretory–secretory antigens, and to also include larval proteins that are homologous to the other filarial protective antigens.

Although irradiated larvae serve as successful immunogens for inducing protective immunity in mice, it is clear that these larvae could never be used in a vaccine for use in humans because of safety and practicality issues. A more reasonable approach for immunization would be to use recombinant antigens as the basis for the vaccine. The experimental *O. volvulus* mouse model was subsequently used to screen recombinant antigens and protection was defined by significant reduction in the survival of L3 following two immunizations with 25μg of respective purified recombinant protein in the presence of an adjuvant.

While vaccine-induced immunity may function by a different constellation of mechanisms than those seen in PI and the individuals with concomitant immunity, it is likely that some of the mechanisms

developed naturally over time in humans will be also induced by the recombinant *O. volvulus* protective antigens. The objective of an *Onchocerca* vaccine will be to elicit in individuals living in endemic areas defined anti-larvae immune responses similar to those present in the PI and the individuals with acquired concomitant immunity that will enable them to control effectively incoming *O. volvulus* L3 infections.

Identification of Protective O. *volvulus* Larval Antigens

Two basic strategies were used to identify and clone *Onchocerca* larval target-antigens to be tested as possible vaccine candidates. The first strategy was based on the potential involvement of antibodies in protective immunity. Attempts were made to identify the target proteins by immunoscreening cDNA libraries using immune sera from human or animal hosts. Although this approach was used with success, it did not take into account carbohydrate and other nonprotein determinants shown to be important in other helminth systems (Ellis et al., 1994; McVay et al., 1998, 2000; van Der Kleij et al., 1999), and which could be crucial to the generation of protective immunity. The success of the immunoscreening effort relied mostly on the source and specificity of the antibodies used and, hence, was done mostly with serum samples from PI with the goal of identifying antigens that were preferentially recognized by the PI in comparison with the INF. In addition, sera from vaccinated or immune animals (chimpanzees, mice, or cows), polyclonal antibodies raised against *O. volvulus* L3 or monoclonal antibodies developed against specific parasite antigens were used to screen the cDNA libraries, initially using cDNA libraries constructed from adult worm stages of *O. volvulus* and later using cDNA libraries constructed from *O. volvulus* larval stages, L3, mL3, and L4 (Joseph et al., 1997, 1998; Lizotte-Waniewski et al., 2000).

Immunoscreening of the adult cDNA libraries resulted in the identification and characterization of >26 recombinant proteins. Because some of these proteins were also expressed in larval stages as determined by in situ hybridization analysis, immunolocalization, stage-specific Western blot or PCR, they were tested in the *O. volvulus* experimental mouse model for vaccine efficacy. Immunoscreening of the larval cDNA libraries resulted in the cloning of additional proteins that were successful in stimulating significant protection in mice (Abraham et al., 2001). Altogether, out of 26 recombinant antigens that were identified by immunoscreening and tested in the *O. volvulus* mouse model, 12 induced partial but significant protection (39–69%) in the presence of Block Copolymer, alum, or Freund's Complete Adjuvant (Table 67.1). Eight of them, *Ov*-CPI-2, *Ov*-RAL-2, *Ov*-RBP-1, *Ov*-103, *Ov*-B20, OI5/OI3, *Ov*-CAL-1, and *Ov*-TMY-1 were cloned from the adult library, and four of them *Ov*-ALT-1, *Ov*-FBA-1, *Ov*-ASP-1, and *Ov*-B8 were cloned from the L3 cDNA library. Only two of the protective antigens, *Ov*-CPI-2 and *Ov*-RAL-2, were cloned from both libraries. Five of the protective antigens (*Ov*-CPI-2, *Ov*-ALT-1, *Ov*-RAL-2, *Ov*-FBA-1, and *Ov*-B8) were protective in multiple experiments. The level of protection with each recombinant protein was in the same range as that induced by immunization with irradiated L3 (Lange et al., 1993; Taylor et al., 1994; Johnson et al., 1998). Moreover, it appeared that immunization with the recombinant antigens *Ov*-CPI-2, *Ov*-ALT-1, and *Ov*-B8 also induced significant reduction in the molting of L3 (Abraham et al., 2001).

The second strategy was to isolate molecules thought to be vital in the infection process. These would include proteins with vital metabolic functions or defense properties, which permit the parasite to survive in immunocompetent hosts. Targeting such molecules would block the establishment of the parasite in the host. In addition, antigens that are not normally seen by the host but that are nevertheless accessible to host immune-effector molecules and cells, the "hidden antigens," were also thought to be potentially useful as vaccine targets (Sher, 1988). Isolation of the gene encoding a protein of interest was achieved by either: (a) screening a cDNA library using a heterologous probe (Henkle-Duhrsen and Kampkotter, 2001); (b) PCR cloning using degenerate primers (Henkle-Duhrsen and Kampkotter, 2001); (c) purifying the protein followed by partial amino acid sequencing and molecular cloning (Wu et al., 1996); or (d) identifying the gene of interest by searching the *O. volvulus* expressed sequence tag (EST) database or the EST databases generated by the Filarial Genome Project (Lizotte-Waniewski et al., 2000).

Out of 18 recombinant antigens that have been cloned using the second strategy and tested in the *O. volvulus* mouse model, four (*Ov*-ALT-1, *Ov*-CHI-1, *Av*-ABC, and *Av*-UBI) induced partial but significant protection (48–63%). *Ov*-ALT-1, *Av*-ABC, and *Av*-UBI were protective in the presence of alum or Freund's Complete Adjuvant (Table 67.1). Chitinase, *Ov*-CHI-1, effectively induced protection using DNA immunization (Harrison et al., 1999). *Av*-ABC and *Av*-UBI that were used for immunization have been cloned from the rodent filarial parasite *Acanthocheilonema viteae* as the *Onchocerca* homologue of *Av*-ABC has not been cloned as yet and the *Av*-UBI of *A. viteae* is completely identical to *Ov*-UBI (Wu et al., unpublished).

TABLE 67.1 Portfolio of the O. *volvulus* protective larval proteins

Characteristics of the ***O. volvulus*** protective protein (Lustigman et al., 2002)						Protection in animal models		
Antigen (kDa)	**Identity (Function)**	**Localization[a]**	**Immunogenicity[b]**	**Number of ESTs[c] L3/mL3**	**In vitro killing assays[d]**	**Protection in *Ov* mouse model (%)[e] (adjuvant)**	**Protection in lymphatic filariae models**	**Protection in other helminth models**
Ov-CPI-2 (17)	Onchocystatin, (cysteine protease inhibitor)	Hypodermis; basal layer of cuticle; separation of L3/L4 cuticles; secretory vesicles; ES	Chimpanzee anti-*Ov*-xL3; PI sera; CI sera	59/9	Anti-*Ov*-CPI-2 and *Ov* L3 (Lustigman, unpublished)	43–49% (alum)	*Ls*-cystatin (Pfaff et al., 2002)	*Ac*-cystatin (Hotez, unpublished)
Ov-ASP-1 (25)	Novel, homolog of vespid venom allergen 5 and the PR-1 protein family	Granules of glandular esophagus; ES	PI sera CI sera mice anti-*Ov*-xL3	50/1	anti-*Bm*-ASP-1 and *Bm* L3 or Mf (Anand et al., 2006)	44% (alum) 42% (FCA)	*Bm*-ASP-1 (Anand et al., 2006)	*Ac*-ASP-2 (Goud et al., 2004)
Ov-RAL-2 (17)	Novel, nematode specific	Hypodermis	PI sera CI sera mice anti-*Ov*-xL3	6/4	Anti-r*As*16 and Ascaris L3 (Tsuji et al., 2004)	51–60% (FCA)	r*Wb*-SXP (Ramachandran et al., 2004) r*Bm*-SXP-1 (Wang et al., 1997)	r*As*16 (Tsuji et al., 2001, 2003, 2004) r*Ac*-16 (Hotez, unpublished)
Ov-ALT-1 (15)	Novel, filariae specific	Granules of glandular esophagus; cuticle; channels	PI sera CI sera	223/18	Anti-*Bm*-ALT-2 and *Bm* L3 or Mf	39–62% (alum)	*Bm*-ALT-1 (Gregory et al., 2000) *Bm*-ALT-2 (Anand et al., 2006)	ALT-1 is a filariae-specific protein
Ov-103 (15)	Novel, nematode specific	In L3: Basal layer of the cuticle; hypodermis; basal lamina; channels; multivesicular bodies. In Mf: surface	PI sera	5/0	Anti-*Ov*-103 and *Ov* Mf (Lustigman et al., 1992b)	30–69% (alum)	ND[f]	*Ac*-SAA-1 (Zhan et al., 2004)
Ov-B20 (52/65)	Novel, nematode specific	Cuticle; hypodermis; ES product	Cattle anti-*Ol*-xL3	3/2	ND	39% (alum)	*Ov*-B20 in *Av* model (Taylor et al., 1995; Jenkins et al., 1996)	ND
Ov-RBP-1 (20/22)	Novel, nematode specific; retinoid binding protein	Body wall; ES product	ND	1/2	ND	42% (BC)	*Ov*-RBP-1 in *Av* model (Taylor et al., 1995; Jenkins et al., 1996)	ND
Ov-CHI-1 (75)	Chitinase	Cuticle, granules of glandular esophagus	ND	0/0	ND	53% (DNA)	*Bm*-chitinase (Adam et al., 1996; Wang et al., 1997)	ND
Ov-FBA-1(41)	Fructose 1,6 biphosphate aldolase	Basal layer of cuticle; channels; basal lamina	PI sera mice anti-*Ov*-xL3	29/7	ND	51–54% (FCA)	ND	ND
Ov-TMY-1 (42)	Tropomyosin	Body wall; ES product	Cattle anti-*Ol*-xL3	15/3	ND	44% (alum)	ND	ND

OI5/OI3 (>200)	Novel	Hypodermis; cuticle	PI sera	0/0	ND	35% (BC)	ND	ND
Ov-B8 (66)	PHD-finger protein	Basal lamina; secretory vesicles	PI sera	0/0	ND	37–46% (alum)	ND	ND
Av-ABC (18)	ATP-binding-cassette transporter	Cuticle; glandular esophagus	ND	0/0	ND	63% (alum)	ND	ND
Av-UBI (30)	Ubiquitin	Glandular esophagus; body wall	ND	0/0	ND	48% (FCA)	ND	ND
Ov-CAL-1 (45)	Calponin	Longitudinal muscles	ND	0/2	ND	42% (BC)	ND	ND

Abbreviations: *Ov*, *O. volvulus*; *Ol*, *O. lienalis*; *Bm*, *B. malayi*; *Wb*, *W. branconfti*; *Ls*, *L. sigmodontis*; *Av*, *A. viteae*; *Ac*, *A. ceylanicum*; *As*, *Ascaris Suum*; BC, block copolymer; ES, excretory–secretory product.

[a] Localization based on the native protein in larval stages (L3 and mL3) as determined by IEM.

[b] Immunogenicity based on data obtained from protected humans, putatively immune individuals (PI), infected individuals who developed concomitant immunity (CI), and/or antibodies from xL3 animal models (xL3 mouse model, cows, or chimpanzees).

[c] The number of ESTs were determined by BLAST-searching the L3 and mL3 EST datasets (3510 and 5165 entries, respectively) using each individual gene sequence. A gene was considered upregulated if the ESTs occurred at least five times in a particular stage.

[d] Using in vitro cytotoxicity assays few antigens were shown to be a target for antibodies raised against the recombinant antigens of ***Ov*-CPI-2** (Lustigman, unpublished) and ***Ov*-103** (Lustigman et al., 1992b). Although antibodies against the other vaccine candidates were not tested in vitro for their ability to inhibit molting or kill larvae, it appeared that immunization with the recombinant antigens ***Ov*-CPI-2** and ***Ov*-ALT-1** also induced significant reduction in the molting of L3 (Abraham et al., 2001). Moreover, studies using antibodies from mice immunized with the *B. malayi* homologous recombinant proteins of ***Ov*-ALT-1 (*Bm*-ALT-2)** and ***Ov*-ASP-1 (*Bm*-ASP-1)** have shown that anti-***Bm*-ALT-2** antibodies elicited 71–72% cytotoxicity in vitro against both L3 and Mf, while anti-***Bm*-ASP-1** antibodies induced 61–62% cytotoxicity in vitro against both L3 and Mf (Anand et al., 2006). Interestingly, antibodies against the homologous proteins of ***Ov*-103** in hookworms (*Ac*-SAA-1) and ***Ov*-RAL-2** in Ascaris (rAs-16), when used in vitro inhibit invasion of L3 through dog skin or caused cytotoxicity in vitro against L3, respectively (Zhan et al., 2004; Hotez, unpublished).

[e] Protection was determined in mice after two immunization with 25 μg of protein in the presence of an adjuvant or using a DNA vaccine , followed by challenge with 25 L3 within diffusion chambers, and is defined by a significant ($p < 0.05$) percentage of reduction of L3 survival in the immunized mice vs. control mice.

[f] ND, not determined.

Protection Induced by Recombinant *O. volvulus* Antigens in Mice is Associated with Th2 and/or Th1 Responses

The mechanism of adaptive protective immunity induced by immunization with r*Ov*Ags in mice was studied by observing the type of adjuvant that effectively induced protective immunity and by analyzing the isotypes of the antibody response (Abraham et al., 2001; Lustigman et al., 2002, 2003). Freund's Complete Adjuvant has been shown to preferentially induce a Th1 response characterized by IgG2a antibodies, and alum preferentially induces a Th2 response characterized by IgG1, IgE, and eosinophilia (Kenney et al., 1989; Forsthuber et al., 1996; Yip et al., 1999). Four antigens, *Ov*-CPI-2, *Ov*-ALT-1, *Ov*-B8, and *Ov*-103, induced protective immunity only in the presence of alum. Unlike mice immunized with irradiated L3, there was no increase in either eosinophil numbers or levels of eotaxin in the diffusion chambers. The antibody responses to each of these antigens were dominated by IgG1 and IgE antibodies, which suggested a Th2 response (Abraham et al., 2001). Two other antigens, *Ov*-FBA-1 (McCarthy et al., 2002) and *Ov*-RAL-2 (Lustigman et al., 2002), induced protective immunity of ~50%, only when injected in Freund's Complete Adjuvant, with an apparent Th1 response based on the adjuvant type and an elevated IgG2a antibody response. *Ov*-ASP-1 induced significant levels of protective immunity when administered with alum (42%) or Freund's Complete Adjuvant (44%) (MacDonald et al., 2004). The mechanisms of protective immunity induced by the two adjuvants and *Ov*-ASP-1 differed in that IgG1 dominated the response induced by alum and IgG2a dominated that induced by Freund's Complete Adjuvant. Hence, individual r*Ov*Ags can induce immunity through Th1, Th2, or both Th1 and Th2 responses.

Based on these results it can be concluded that the mechanisms of protective immunity induced with the protective r*Ov*Ags are different from those induced with irradiated L3; some of the r*Ov*Ags utilize a Th1 or a mixed Th1/Th2 response, and those that use a Th2 response do not appear to require the collaboration of eosinophils. The protective immunity elicited by irradiated L3 is Th2 and eosinophil-dependent. Although the discrepancies between responses to irradiated L3 and r*Ov*Ags may be due to differences in the immunization protocols, it was hypothesized that they may reflect intrinsic properties of these antigens. This is also supported by observing that some of the target L3 native proteins recognized by r*Ov*Ag-specific antibodies were not labeled by anti-irradiated L3 antibodies (Abraham et al., 2001). However, they are recognized by antibodies from PI or individuals who developed concomitant immunity (Lustigman et al., 2003), thus confirming that the r*Ov*Ags induce responses in mice that are more similar to those operating in humans.

The protection induced by DNA immunization corresponding to *Ov*-CHI-1 was associated with an IgG1-dominant response. Moreover, antibodies from the vaccinated mice reacted with the cuticle of postinfective L3 larvae, implying that this may be the site of immune attack following secretion of chitinase (Harrison et al., 1999).

Characteristics of the Protective r*Ov*Ags

The characteristics of the parasite proteins corresponding to 15 protective r*Ov*Ags have been reviewed previously (Abraham et al., 2001; Lustigman et al., 2002) and are also described in Table 67.1. Eight of the proteins, *Ov*-ALT-1, *Ov*-B8, *Ov*-RAL-2, *Ov*-B20, OI5/OI3, *Ov*-CHI-1, *Ov*-RBP-1, and *Ov*-103 are parasite-specific antigens, whereas *Ov*-ASP-1 is a member of the vespid venom allergen-like protein family (Tawe et al., 2000). Six of the protective proteins are homologs to recognized proteins of higher organisms. *Ov*-CPI-2 (onchocystatin), *Ov*-TMY-1 (tropomyosin), *Ov*-FBA-1 (aldolase), *Ov*-CAL-1 (calponin), *Av*-ABC (ATP-binding cassette protein transporter), and *Av*-UBI (ubiquitin) have 32%, 31%, 69%, 42%, 71%, and 98% amino acid identity, respectively, with human proteins. An important concern associated with vaccine antigens belonging to conserved gene families (e.g., enzymes, muscle proteins) is the risk of crossreactions with host or environmental antigens.

Whereas it was expected that many of the protecting antigens would be larval stage specific, only two were actually L3 specific (*Ov*-ALT-1 and *Ov*-CHI-1) (Wu et al., 1996; Joseph et al., 1998) and one (*Ov*-B20) was limited to L1–L4 stages (Taylor et al., 1995); all the other proteins were expressed in all stages of the parasite. Many of the protective antigens are potentially upregulated in L3 and/or mL3 as determined by the abundance of the transcripts of the protein in stage-specific *O. volvulus* cDNA libraries, following large-scale EST sequencing and clustering (Lizotte-Waniewski et al., 2000), which suggests their importance during the initial steps of infection in humans. Moreover, localization of their corresponding native proteins in L3 and mL3 has indicated that all the protective antigens are found in one or more of the regions in the larvae where antibodies from irradiated L3-immunized mice and/or PI bound. These include the different layers of the cuticle, channels

connecting the esophagus to the cuticle, and the basal lamina surrounding the body cavity (Abraham et al., 2001). In addition, many of the proteins were found in secretory vesicles within the hypodermis and/or in the granules of the glandular esophagus (Table 67.1) which is significant because the glandular esophagus is thought to be important for the molting process (Joseph et al., 1998).

When the antibody responses to some of the recombinant proteins were analyzed with PI and INF serum, it appeared that both groups recognized all protecting antigens similarly. Recognition of antigens by PI and INF groups should not eliminate these antigens as vaccine components because it appears that in the INF concomitant immunity is acquired with age. Importantly, analysis of the immunoglobulin class and subclass responses to some of the protecting antigens revealed that these proteins induced mainly cytophilic antibodies, IgG1, IgG3, and/or IgE in PI and INF (Bradley et al., 1995; MacDonald et al., 2002). For example, elevated cytophilic antibodies (IgG1, IgG3, IgE) and complement-fixing (IgG3) responses were observed in infected subjects to the L3-specific recombinant antigen *Ov*-ALT-1, of which the IgG3 and IgE responses increased with age (MacDonald et al., 2002). In additional unpublished studies the IgG1, IgG3 against *Ov*-ASP-1, and IgG3 against *Ov*-CPI-2 and *Ov*-RAL-2 increased with age in the infected human population (Lustigman et al., unpublished results). Further support to the possibility that such antibodies may have a role in antibody-dependent cellular cytotoxicity effector mechanisms, came from observing that human neutrophils inhibited molting of L3 by 96–100% in the presence of purified human antibodies against *Ov*-CPI-2 (Lustigman et al., unpublished results). *Ov*-CPI-2 is known to be essential for molting of L3 (Lustigman et al., 1996), and the molting of the L3 challenge was inhibited in protected mice (Abraham et al., 2001).

Importantly, many of the protective r*Ov*Ags have homologs that have been shown to also induce protection in other filariae host–parasite systems: (a) the *Ov*-ALT-1 homolog from *D. immitis* is specifically recognized by antibodies from protected dogs (Frank et al., 1996); the *Bm* homolog (*Bm*-ALT-1) induced 76% reduction in parasite survival in the presence of Freund's Complete Adjuvant (Gregory et al., 2000); the closely related r*Bm*-ALT-2 induced in the presence of alum 74% reduction of L3 viability within a diffusion chamber implanted in jirds. When r*Bm*-ALT-2 was combined with r*Bm*-ASP-1 (the homolog of *Ov*-ASP-1) for immunization they induced in jirds a 76% reduction in worm burden that was associated with increased IL-4 production and the presence of cytotoxic antibodies (Ramachandran et al., 2004; Anand et al., 2006); (b) the *L. sigmodontis Ov*-CPI-2 homolog, *Ls*-cystatin, induced in mice in the presence of alum or Pam_3Cys reduction in the numbers of patent infections, i.e., less infections with microfilaremia were observed in vaccinated animals (Pfaff et al., 2002). Previous studies in *O. volvulus* have shown that cystatin is present in the eggshell surrounding the microfilariae and thus potentially functions during microfilarial development (Lustigman et al., 1991, 1992a), which may explain the results obtained in the *L. sigmodontis* model; (c) the *Bm* homolog of *Ov*-RAL-2, *Bm*-SXP-1, in the presence of Freund's Complete Adjuvant induced in mice 30% reduction in *B. malayi* L3 survival when the challenge infections were contained in diffusion chambers (Ramachandran et al., 2004). In another study, immunization of jirds with *Bm*-SXP-1 in the presence of Freund's Complete Adjuvant or alum reduced microfilaremia and, in some experiments, also adult worm burdens by 35% (Wang et al., 1997); (d) the *A. viteae* chitinase was identified as the main target for antibodies from protected jirds after vaccination with irradiated L3 (Adam et al., 1996). Moreover, immunization of jirds with the *Bm*-chitinase induced 48% reduction in worm burden and >90% in the number of circulating microfilariae (Wang et al., 1997); and (e) the *O. volvulus* recombinant proteins *Ov*-RBP-1 and *Ov*-B20 were shown to also induce protection against a challenge with *A. viteae* in jirds (Taylor et al., 1995; Jenkins et al., 1996).

Moreover, homologs of four of the r*Ov*Ags were tested for protection in other nematode host–parasite systems, such as hookworm infection in dogs and *Ascaris* in pigs, and were shown to elicit reduction in worm burden or other protective measures: (a) the *Ov*-ASP-1 homolog in hookworms, *Na*-ASP-2, is a highly protective excretory–secretory protein (Ghosh et al., 1996), and is in the process of testing for efficacy in humans as part of the Human Hookworm Vaccine Initiative (see Chapter 66) (Goud et al., 2005; Hotez et al., 2006); (b) the hookworm homolog of *Ov*-103, Ac-SAA-1, induced partial protection against hookworm infection (25%), 64% reduction in egg count and significant reduction in blood loss (Zhan et al., 2004); (c) *Ac*-cystatin, the hookworm homolog of *Ov*-CPI-2 elicited 22% reduction in worm burden in dogs (Hotez, unpublished); and (d) rAc-16, the hookworm homolog of *Ov*-RAL-2 induced in dogs 25% reduction in worm burden, 64% reduction in egg counts, and a significant reduction in anemia (Hotez, unpublished). Moreover, a homolog of *Ov*-RAL-2 from *A. suum*, rAs16, also induced in mice a 64% reduction of recovery of larvae when coupled with cholera toxin

B subunit for immunization (Tsuji et al., 2001, 2003). Pigs vaccinated with rAs16 coupled with cholera toxin were also protected from migration of *A. suum* larvae through the lungs, as indicated by a 58% reduction in the recovery of lung-stage L3, compared with that in nonvaccinated controls (Tsuji et al., 2004). Notably, anti-rAs16 antibodies inhibited survival of L3 and interrupted the molting of lung-stage L3 (Tsuji et al., 2004).

PROSPECTS FOR THE FUTURE

Although it was previously considered that *O. volvulus* infection was on the cusp of being controlled using ivermectin distribution, it is becoming increasingly clear that without additional modalities, such as drugs which kill or permanently sterilize the adult worms or a vaccine, elimination of onchocerciasis from sub-Saharan Africa will remain an unfulfilled goal. A vaccine aimed at preventing infection (anti-L3) or blocking transmission and/or pathology (anti-microfilariae) could be the essential supplement for the successful control or elimination of onchocerciasis. The process would be to link the vaccine with drug treatments in a program of vaccine-linked chemotherapy (Hotez and Ferris, 2006; Hotez, 2007). Although the ultimate goal of a vaccine against onchocerciasis has not yet been achieved, fortunately, through the commitment of the Edna McConnell Clark Foundation and researchers in the field of filariasis, appropriate scientific infrastructure is now in place to meet this challenge. Research on vaccine development has provided the foundation for antigen discovery and development of animal models for testing the efficacy of vaccine candidates, and consequently resulted with at least 15 vaccine candidates that were shown to induce partial but significant protection against an L3 challenge using an experimental mouse model. Moreover, protective immunity against *O. volvulus* L3 has now been definitively demonstrated in humans, cattle, and mice thereby proving the concept that a vaccine can be produced against this infection (Abraham et al., 2002; Lustigman et al., 2003).

Future steps for vaccine development would initially use the *O. volvulus* L3 mouse model to select a subset of highly immunogenic antigens from the 15 recombinant vaccine candidates for further development and assessment. This subset of r*Ov*Ags would be then moved to product development and scale up applicable for human use. The bovine *O. ochengi* model has proven the feasibility of immunoprophylaxis against *Onchocerca* using irradiated L3 (Tchakoute et al., 2006) and would therefore be a superb secondary screen to verify the potency of recombinant vaccines developed in the mouse model.

The availability of the *O. volvulus* EST database (Williams et al., 2002), the complete sequencing of the *Brugia* genome (Ghedin et al., 2004) and *Caenorhabditis elegans* (www.wormbase), as well as the rapidly expanding technologies in proteomics, functional genomics, and bioinformatics could provide the needed tools for integrated comparative functional genomics and result in the identification of additional *Onchocerca* larval proteins that could be used as potential vaccine candidates (Hashmi et al., 2001). For example, 47 essential *C. elegans* molting genes (>90% reduction in molting due to gene-specific RNA interference) belonging to the categories: novel, proteases, protease inhibitors, peroxidases, extracellular matrix, sterol-sensing domain, DNA binding, nucleic acid interacting, signaling, WD domains, and others have been identified (Frand et al., 2005). It appears that 46 of them are also potentially encoded by filarial transcripts (Lustigman, unpublished), and may prove to be excellent vaccine antigens.

An alternative approach that could be taken would be to develop a vaccine targeting the microfilaria stage. The microfilaria is responsible for the development of pathology and for transmission of the disease. Therefore, a vaccine against this stage would be a terrific asset for control of the infection. A caveat for this vaccine is the possibility that vaccination against microfilariae would exacerbate disease development caused by microfilariae. A possible way to circumvent this issue would be to immunize people with parasite antigens and not with *Wolbachia*-derived antigens.

It is anticipated that the vaccine against onchocerciasis will be administered to populations that may have been treated for many years with ivermectin. Therefore, longitudinal studies examining the immune responses following long-standing ivermectin treatment need to be performed. Attempts to define the nature of the targets of the posttreatment responses should be undertaken by surveying all possible available antigens. With the advent of antibiotic therapy against *Wolbachia*, studies following the changes in immune responses following this treatment should also be executed.

In conclusion, the human studies of onchocerciasis patients have suggested that protective immunity can develop in humans. The experimental and natural infections of animals have demonstrated that protective immunity does develop and that vaccines can protect animals from infection under natural conditions. The foundation studies on antigen screening have been accomplished and now the challenge is to optimize and formulate vaccines suitable for human

usage. The development of drug resistance to the only treatment available for control of onchocerciasis has rejuvenated the impending critical need for a vaccine against onchocerciasis.

KEY ISSUES

- Human onchocerciasis is a serious neglected tropical disease caused by *O. volvulus* and an important cause of blindness and chronic disability in the developing world.
- Great progress has been made in reducing disease burden through mass drug administration of ivermectin.
- Technical and logistical obstacles must be overcome before the goal of elimination of this infection as a public health problem can be attained.
- Evidence for the existence of *Onchocerca* unresponsiveness or resistance to the drug ivermectin is building up. Therefore, additional tools are critically needed and include the need for a vaccine against onchocerciasis to "complement" the present control measures and thus further the goals of the existing control programs.
- An *Onchocerca* vaccine targeting the infective stage larvae could reduce adult worm burden and thus the number of microfilariae produced by the adult female worms.
- Protective immunity against *Onchocerca* larvae has now been definitively demonstrated in humans, cattle, and mice, thereby providing the conceptual underpinnings that a vaccine can be produced against this infection.
- Several recombinant *Onchocerca* antigens have been identified that are capable of inducing a significant but partial reduction in the survival of a larval challenge using an experimental mouse model.
- The foundation studies on antigen screening have been accomplished and now the challenge is to optimize and formulate vaccines suitable for human usage.
- It is anticipated that continual natural exposure of the immunized individuals to infective larvae from black flies would sustain the protective immunity induced by immunization with recombinant vaccine proteins, and that ultimately the combination of vaccination aimed at preventing infection (anti-L3) with long-term chemotherapy with ivermectin could accelerate the eradication of onchocerciasis from sub-Saharan Africa.
- An alternative approach will be to develop a vaccine against microfilariae, which is aimed at blocking transmission and/or pathology.
- It is anticipated that the vaccine against onchocerciasis will be administered to populations that may have been treated for many years with ivermectin. Therefore, longitudinal studies examining the immune responses following long-standing ivermectin treatment need to also be performed.

CHAPTER

68

Schistosomiasis

Christopher L. King
Center for Global Health and Diseases, Case Western Reserve University School of Medicine, Cleveland, OH, USA

OUTLINE

ABSTRACT

Schistosomiasis is one of the most important tropical diseases chronically infecting over 200 million people worldwide, and an estimated 774 million people are at risk. It is the most important human helminth infection in terms of morbidity and mortality. Frequently, individuals are coinfected with schistosomiasis, HIV/AIDS, tuberculosis, and/or malaria, and increasing evidence indicates that schistosomiasis impacts the course of disease and transmission of these important infections. A safe and highly effective drug for the treatment of schistosomiasis is praziquantel. The mainstay of schistosomiasis control has been mass treatment programs that have reduced the

burden of disease. However, individuals become rapidly reinfected, and drug cost and the infrastructure to sustain repeated treatment may be unsustainable.

Currently, no effective vaccine exists for schistosomiasis, and only one vaccine candidate is being tested in humans with no evidence for any efficacy yet. In spite of this slow progress, there has been about 40 years of research toward development of a schistosome vaccine. A strong rationale exists for development of a schistosome vaccine. There are good animal models for studying human schistosomiasis. High levels of protective immunity can be induced in animals with radiation-attenuated infective larval stage of the parasite. Humans develop partial immunity to schistosomiasis. Importantly, the parasite does not replicate in humans, and a vaccine with partial efficacy can reduce the intensity of infection and therefore the burden of disease.

Initially, vaccine candidates were targeted toward preventing infection. Increasingly, attention has focused on vaccine candidates that impair the fecundity of adult worms since the release of ova that become trapped in host tissues is the primary cause of disease. It is the granulomatous responses to these ova and ensuing fibrotic changes and chronic inflammation that cause organ failure, particularly the liver and kidneys, and the chronic anemia that are the hallmarks of schistosome disease. Reducing fecundity will also reduce transmission.

Many different approaches have been undertaken to identify vaccine candidates producing a long list of antigens delivered as recombinant antigens and DNA constructs with a variety of adjuvant formulations. These antigens present a range of proteins from glycolytic enzymes (e.g., glutathione S-transferase), myofibrillar proteins since schistosomes are highly motile organisms (e.g., paramyosin), proteins generated by the parasite that may modulate the host response to the parasite (such as superoxide dismutases, which may impair neutrophil O_2—killing of parasites), and integral membrane proteins expressed on the parasite surface, such as tetraspanins. The levels of protection have rarely exceeded 50% to any of these molecules or formulations and most have been less than 40%, suggesting that there are fundamental characteristics about the parasite biology to avoid host immune responses that need to be better understood in order to generate a more effective vaccine. In spite of these limitations, the recent sequencing of the schistosome genome, and characterization of the parasite transcriptome and proteome in different life-cycle stages, has identified many novel proteins. The analysis of these proteins firmly based on the physiological process of the parasite has begun to yield a new generation of exciting vaccine candidates.

INTRODUCTION

Schistosomiasis is likely an ancient disease of humans. Earliest records of human infection document the presence of schistosome ova in tissues of Egyptian mummies ~1500 BC, and earlier etchings from Egyptian temples show individuals urinating blood, which is characteristic of human urinary schistosomiasis. It was not until 1852 that Theordor Bilharz, working in Egypt, first described the disease and the initial elements of its transmission. It was termed bilharzia and later referred to as schistosomiasis.

Five species infect humans; *Schistosoma haematobium*, *Schistosoma japonicum*, *Schistosoma mansoni*, *Schistosoma mekongi*, and *Schistosoma intercalatum. S. mansoni* and *S. haematobium* are predominately human parasites while *S. japonicum* is zoonotic in a wide range of domestic animals as well as humans these species. Closely related *Schistosoma bovis*, *Schistosoma spindale, Schistosoma margrebowiei*, and *Schistosoma mattheei* infect domestic livestock. Several of animal-specific species can accidentally infect humans, notably *S. bovis* and *S. margrebowiei*. The infective stage of the parasite, referred to as cercariae, from other nonhuman schistosome parasites, particularly bird parasite (e.g., *Trichobilharzia* sp.) may penetrate human skin but fail to penetrate deeper and die. This can give rise to an allergic condition called swimmer's itch, or cercarial dermatitis, caused by release of antigens in the skin.

Biology and Life Cycle

The life cycle is shown in Fig. 68.1. Unlike other trematode infections, schistosomes have separate sexes (dioecious). Adult parasites generally range from 0.8 to 1.6 cm in length, featuring two terminal suckers, a complex tegument, a blind digestive tract, and reproductive organs. The body of the male worm forms a grove, or gynaecophoric channel, into which the longer and thinner female body is embedded (Gryseels et al., 2006; Ross et al., 2002). The male worm provides important nutrients to the female and helps to anchor the worm pair inside the vessel with prominent anterior and ventral suckers.

The mammalian host becomes infected when free-swimming larvae released from freshwater snail intermediate hosts directly penetrate the skin. The cercariae forces its way through the initial squamous cells of epidermis, and further penetration of skin is facilitated by release of an elastase and a series of proteolytic enzymes produced by specific glands in the anterior

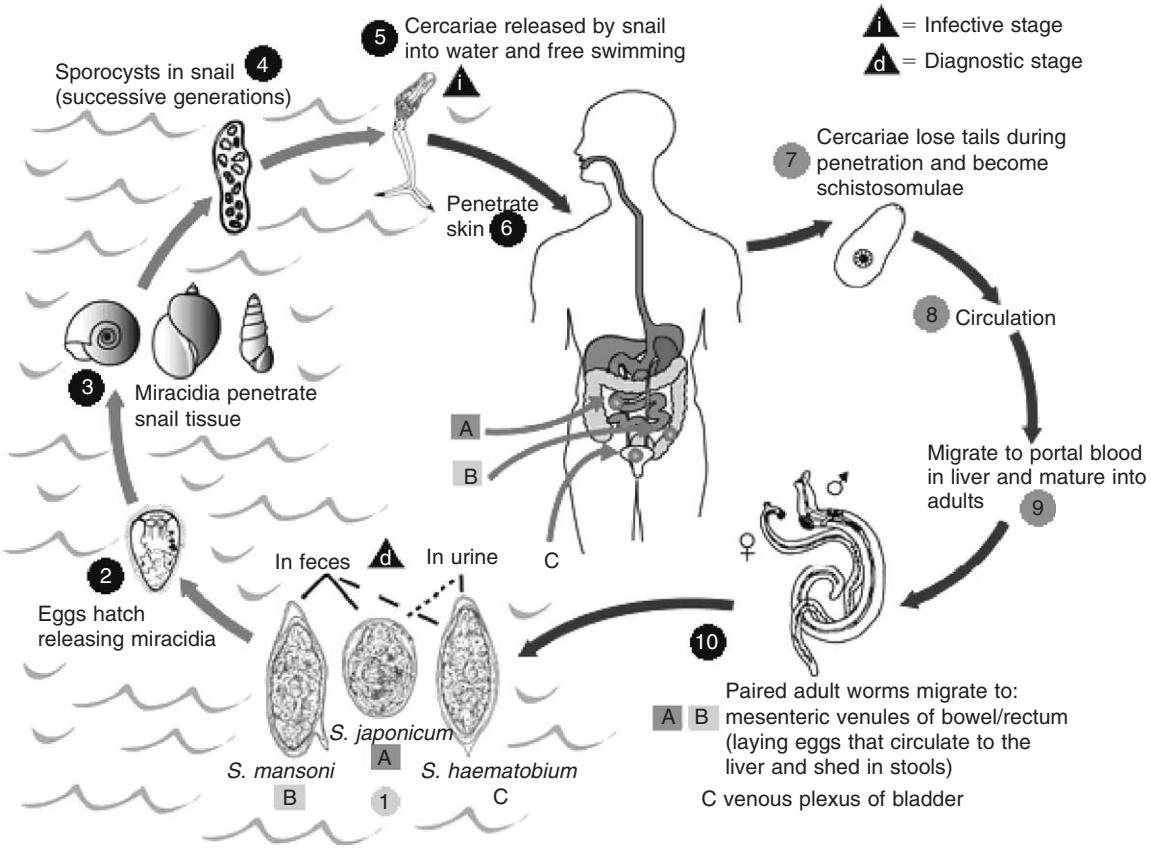

FIGURE 68.1 Life cycle of *S. masoni*, *S. japonicum*, and *S. haematobium* (Reprinted from DPDx, the Centers for Disease Control and Prevention website for parasite diseases, http://www.dpd.cdc.gov/dpdx/HTML/Schistosomiasis.htm).

portion of the parasite. After larvae successfully penetrate the skin, they transform into a tissue-migratory larval stage, or schistosomula, which are about 300 μm in size, whereupon the larvae undertake a complex intravascular migration in which they eventually accumulate in the vessels of the hepatic portal system. Initially, the parasite migrates in the skin for 1–4 days until they reach the venous circulation, are carried to the lungs where they shift to the arterial circulation and eventually concentrate in the liver, travel to the portal vein, and mature into adult worms. Migration of larvae from the skin to liver requires about 7–10 days, and maturation to adult worms requires 3–6 additional weeks. The worm pairs migrate distally into the mesenteric veins, that is, superior mesenteric veins for *S. mansoni* and inferior mesenteric and hemorrhoidal veins for *S. japonicum*. For *S. haematobium,* adult worms migrate past the hemorrhoidal veins into the venus plexus surrounding the bladder and adjacent organs. Females produce hundreds of ova each day (*S. mansoni* and *S. haematobium*) to thousands per day (for *S. japonicum*) for the life span of the worms that can be up to 30 years. These eggs release potent proinflammatory molecules that disrupt tissue barriers and enable the ova to transit from the endovascular space into the lumen of gut (*S. mansoni* and *S. japonicum*) or bladder (*S. haematobium*), where ova are excreted with stool or urine into the environment and then hatch and infect snails to complete the life cycle. Primarily the ova released into host tissues, especially those that fail to exit into the feces or urine, cause the pathology and disease associated with schistosomiasis. Infection intensity depends on exposure because the parasite does not replicate in the human host. The life cycle is completed when ova are passed in the urine or feces and come into contact with fresh water, whereupon they release miracidia, a ciliated highly motile form of the parasite, which infect freshwater snails. *S. haematobium* infects *Bulinus* species, *S. mansoni* infects *Biomphalaria* sp., and *S. japonicum* infects *Oncomelania* sp. The distribution of schistosome species depends on the ecology of their respective snail hosts. After infection of the snail, parasites undergo asexual replication to produce thousands of cercariae per snail that are shed in the water to complete the life cycle.

Schistosomiasis transmission is highly dependent upon water resource use and sanitation, usually

associated with agricultural practices. Environmental changes linked to water resource development (e.g., large- and small-scale dams), and irrigation, migration, and population growth have led to an increase in the prevalence of schistosomiasis and spread into areas where it was not previously endemic (Gryseels et al., 2006; Ross et al., 2002; Li et al., 2007). The Diama dam on the Senegal River introduced *S. mansoni* into Senegal and Mauritania. The Aswan High Dam in Egypt spread *S. mansoni* into Upper Egypt, which was already infected with *S. haematobium* (Malek, 1975). The spread of small ponds for collection of seasonal rainfall throughout many areas of African have led to the spread of *S. haematobium* since its snail intermediate host is able to estivate in the mud, when the pond dries up, until the next rainfall. The soon-to-be-completed Three Gorges Dam on the Yangtze River in China is near to a *S. japonicum* endemic area that could lead to further spread of this parasite (Li et al., 2007).

Epidemiology and Significance

Schistosomiasis is estimated to have infected 207 million individuals in 74 countries worldwide, and ~1 billion individuals are at risk (Gryseels et al., 2006). It is likely these estimates significantly underestimate worldwide prevalence because of the poor sensitivity of existing diagnostic methods. Infections occur throughout much of topical and subtropical areas of the world (Fig. 68.2). The burden of infection occurs in rural communities; however, with increasing travel, residents of major cities in China and Brazil often become infected. North American and European travelers are often at risk and occasionally become infected. The heaviest burden of infection and disease is among adolescent children. Therefore, children under the age of 4 years, in whom schistosome infections are uncommon, would be an important target population for a schistosome vaccine.

Disease

Most diseases arise from inflammatory responses directed to ova trapped in tissues, especially the liver or gut (Wilson et al., 2007). These trapped eggs release 40 different proteins (Jang-Lee et al., 2007) that produce marked CD4+ T-cell-dependent inflammatory responses, resulting in the recruitment of primarily eosinophils, monocytes, and B cells to produce a granuloma around the egg. Importantly, the chronic granulomatous inflammation promotes collagen deposition with the consequence that ova trapped in the liver, bladder, or ureters can impair organ function, notably the liver, resulting in hepatic periportal

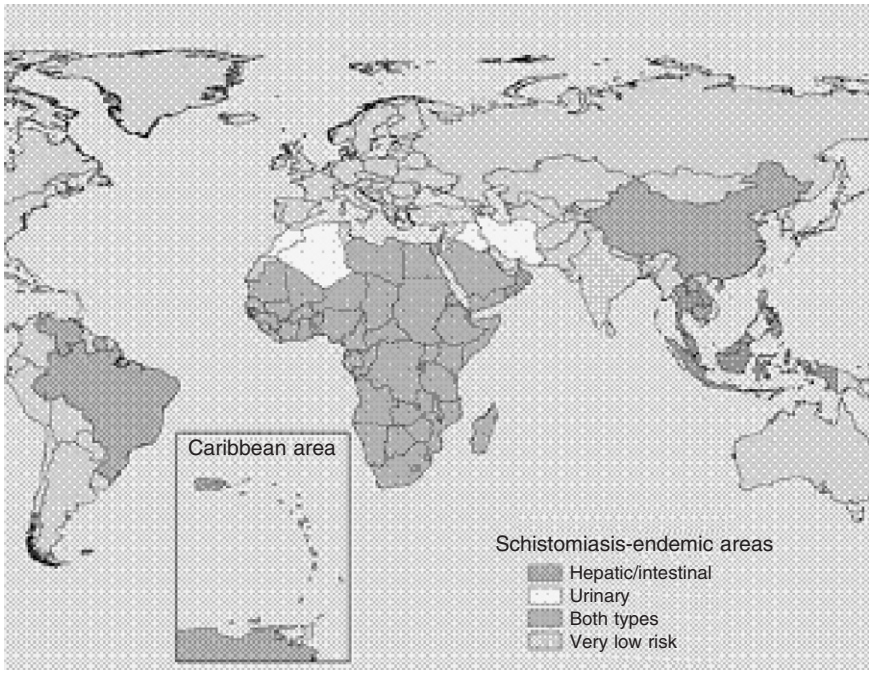

FIGURE 68.2 The global distribution of schistosomiasis. *S. mansoni*, *S. japonicum*, and *S. mekongi* represent hepatic/intestinal species and *S. haematobium* and *S. intercalatum* urinary schistosomiasis (Reprinted from DPDx, the Centers for Disease Control and Prevention website for parasite diseases, http://www.n.cdc.gov/travel/image.ashx?i=263).

(Symmer's) fibrosis and cirrhosis, or obstruction of the ureter, leading to obstructive hydronephrosis and renal failure (King et al., 1988). Chronic schistosomiasis has been associated with hepatocellular carcinoma and bladder cancer. An important aspect of disease is when adult worms develop or migrate to other organs. The residence of worms in veins surrounding the bladder, prostate, uterus, and vagina or near the central nervous system are notable. The release of ova from these aberrant sites produces inflammation in critical tissues with devastating effects. Transverse myelitis and seizures from the schistosomiasis, for example, can be difficult to diagnose and produce permanent neurological impairment (Pittella, 1997; Betting et al., 2005).

Recently, it has been appreciated that light infections can also produce significant morbidity. Symptoms such as diarrhea, dysentery, and dysuria, which cause chronic pain, can be disabling as well as the consequence of anema, undernutrition, exercise intolerance, stunting of growth, and learning and developmental delays (King et al., 2005). All these conditions can also lead to increased absences of schools, which compound learning and development. Schistosomiasis is a chronic infection, and coinfections are common with other important infections, notably HIV/AIDS, tuberculosis, and malaria. Since schistosomes can cause profound immune modulation in its host (Wilson et al., 2007; King et al., 1996), there is growing evidence that schistosomiasis can affect the natural course of these co-infections and potentially increase the transmission such as HIV/AIDS (Gallagher et al., 2005; Brown et al., 2005, 2006; Kallestrup et al., 2005, 2006; Booth et al., 2004; Lyke et al., 2005, 2006). Schistosomiasis also has an impact on the efficacy of vaccine of children born to infected women (Malhotra et al., 1999) and among older individuals infected with schistosomiasis (Elliott et al., 2007).

The number of deaths attributable to schistosomiasis in sub-Saharan Africa is estimated at 280,000 per year (van der Werf et al., 2003), with 1.7 million disability-adjusted life years (DALYs) from chronic infections (Mathers et al., 2007). Thus schistosomiasis has been recognized as the second most important human parasite disease, following malaria, as a cause of human suffering.

Treatment and Control and the Importance of a Vaccine

Schistosomiasis can be treated with a single dose of praziquantel (PZQ) to achieve over 90% cure rates as determined by individuals becoming egg negative. However, it is not known whether some worms survive treatment and transiently stop releasing ova. PZQ is safe with few side effects and has become increasingly less expensive. The widespread use of PZQ has led to reduction in severe disease; nonetheless, because individuals become rapidly infected, the overall prevalence of schistosomiasis has actually increased 7–12% in the past decade in spite of mass chemotherapy programs (Fenwick and Webster 2006). Although clinically significant PZQ resistance has not been reported in humans, resistance to drugs related to PZQ already exists in domestic animals (Bennett et al., 1997), and a low efficacy of PZQ treatment has been reported in Egypt and Senegal (Fallon et al., 1997; Ismail et al., 1999). No safe, broad-spectrum alternative drugs for treatment exist. Nearly all countries have an existing infrastructure for vaccine delivery but few for drug delivery. Therefore, a vaccine that produces even a partial reduction in worm burdens could considerably reduce pathology and limit parasite transmission. .

PROTECTIVE IMMUNITY

Animal Models

Most of what is known about protective immunity and vaccine testing has been obtained in the laboratory mice and baboons, which are the favored nonhuman primate models (Nyindo and Farah, 1999; Siddiqui et al., 2008). Human schistosome parasites can infect these animal models. Both of these animal models develop patent infections and pathology similar to that observed in humans. Studies of protective immunity and vaccine testing in rats and other nonhuman primates, notably the rhesus, have also been performed; however, both of these models spontaneously cure their infection (Moore and Meleney, 1952; Ritchie et al., 1963; Maddison et al., 1979). The mechanism by which these latter hosts can spontaneously eliminate infections may provide novel vaccine targets for parasite elimination.

Since schistosome parasites do not multiple in the mammalian host, protective immunity is primarily measured as the reduction in adult worm burden of vaccinated animals relative to controls. Typically, this is assessed by euthanasia of animals followed by perfusion of the portal vasculature to flush out the worms. Surrogates of worm burdens, such as assessing the fecal and urine egg numbers and circulating antigen concentrations, have been insensitive and only partially correlate with the actual worm burden (Wilson et al., 2006). This has been a major impediment for studying the levels of protective immunity in humans and will complicate

assessment of vaccine efficacy in human trials. For a vaccine to be protective, it need not generate sterile immunity because a significant reduction in the number of worms would reduce the number of eggs produced, and thus morbidity and transmission. Indeed, even if vaccine had little effect on the adult worm population but markedly reduced worm fecundity, it would have a similar effect. This antifecundity effect can be measured by reduction in egg output in the feces or urine and tissue burden per adult worm pair. The effect on transmission would be assessed by reduced viability of released ova, using a miracidial hatching assay. Miracidia released from hatched ova in water infect the snail intermediate host to complete the transmission cycle.

A difficulty for measuring protective immunity in animal models is the long delay from the time an animal is challenged following immunization and measurement of protection by portal perfusion, which requires an interval of 5–6 weeks to allow maturation of parasites. An in vitro assay of immune-mediated protection would be of great value. One such assay measured antibody-dependent cellular cytotoxicity of schistosome larvae in vitro, using serum and cells from vaccinated animals, to predict vaccine potential (Butterworth et al., 1974, 1982). Although it has been used for decades, its ability to predict vaccine potential is limited, and the discordance of ultrastructural changes associated with larval killing in vivo and in vitro (McLaren et al., 1978; McLaren and James 1985) has led the majority of researchers in the field to consider this as a poor surrogate for protective immunity.

Radiation-Attenuated Parasites Induce Protective Immunity

The majority of studies that have evaluated mechanisms of protective immunity to schistosomiasis have focused on studies of radiation-attenuated (RA) cercariae that infect various animal models but fail to mature to sexually mature adults. Such studies have reliably demonstrated 60–70% reduction in worm burdens following challenge (Coulson, 1997). Certain mouse strains produce even higher levels of protection, and sterile immunity has been achieved when exposure to irradiated cercariae is combined with immunization with recombinant IL-12 (Wynn et al., 1995).

The mechanisms by which RA larvae confer protection in murine models have been evaluated in considerable detail (Coulson, 1997; Wilson et al., 1996). The optimal radiation dose permits parasites to infect the mouse skin but delays their migration to host vessels and, as a consequence, provokes more intensive inflammatory responses in the skin and draining lymph nodes compared to normal larvae. This has the effect of boosting cell-mediated immunity, particularly Th1-type immune responses. Upon challenge infection with normal larvae, the primary site of attrition is in the lung. Interestingly, this attrition does not appear to result from killing of the lung-stage larvae; instead, a primarily mononuclear infiltrate develops in the pulmonary capillaries upon challenge infection, which impairs onward migration of the larvae (Smythies et al., 1992). Some of the larvae enter pulmonary alveoli and thus ends their intravascular journey. The production of IFN-γ and TNF-α is essential for this effecter immune response (Wilson, 1998; Street, et al., 1999), and protection occurs in μMT mice, which cannot make an antibody response (Anderson et al., 1999), and emphasizes the cell-mediated basis for protection.

If mice are repeatedly immunized with RA cercariae, usually three times, similar levels of protective immunity are achieved compared to singly immunized mice; however, this tends to involve a substantial humoral component. Adoptive transfer of IgG antibodies from multiple immunized mice can confer protection to naive receipts, whereas singly vaccination mice cannot (Delgado and McLaren, 1990). The maximal levels of protection in nonhuman primates requires at least 5 exposure to RA cercariae producing up to 84% reduction in worm burden (Kariuki et al., 2004). The strong correlation of the IgG antibody level directed to larval stage antigens with levels of protection implies that humoral immunity is a critical component of protective immunity (Kariuki et al., 2004). Protection waned to an average of 72–53% if animals were challenged 3 versus 12 weeks following vaccination with irradiated cercariae. Although this was a single experiment, it highlights that the duration of immunity to a schistosome vaccine may be short, and approaches will be needed to sustain significant levels of protection.

The use of irradiated larvae as a human vaccine followed the demonstration of the effectiveness of similar irradiated sporozoite vaccines against malaria (Hoffman et al., 2002). The use of irradiated cercariae as a vaccine has two important drawbacks. First, if irradiation fails to attenuate all larvae and some develop into adults, this could result in patent infection, egg production, and ensuing disease as described above. This concern is significant because individuals would likely require exposure to thousands of larvae (Eberl et al., 2001), and even if only 1–5% were to mature to adults, this would represent a heavy infection with potentially adverse consequences. The second impediment has been the short life span of irradiated larvae and impracticality for their use in most endemic areas. Therefore, attempts have been made to cryopreserve RA larvae.

Cryopreserved larvae produce significantly lower and highly variable protection in nonhuman primates and mice (Bickle and James, 1978; Murrell et al., 1979; Damian et al., 1984; Lewis et al., 1984). The lack of reproducibility for cryopreservation eventually resulted in individuals loosing interest for this approach two decades ago. The recent success in the cryopreservation or lyophilization of RA *Theilera parva* sporozoites for subsequent successful vaccination suggests that reexamination of this approach for schistosomiasis is warranted (Marcotty et al., 2003; Mbao et al., 2006). The cryopreservation of unicellular *Theilera* parasites versus the more complex multicellular schistosome larvae may make this translation difficult.

Humans

Humans gradually acquire partial immunity to further infection following years of exposure such that adults generally have lower prevalence and intensity of infection compared to children and adolescents (Butterworth et al., 1985; Hagan et al., 1991; Roberts et al., 1987; Medhat et al., 1998; Karanja et al., 2002). Repeated treatment of individuals with PZQ accelerates naturally acquired protective immunity, suggesting that repeated priming of parasite antigens released upon worm killing can boost the host immune responses (Karanja et al., 2002). However, the level of protection acquired has been difficult to measure because of the surrogates to assess the presence and intensity of infections mentioned above, for example, fecal and urine egg counts, and serum markers of infection, are insensitive and imprecise. Another complication is the difficulty to measure human exposure. These same issues will also make vaccine testing in humans challenging and point to the necessity for developing additional tools to better assess exposure and biomarkers of infection.

In spite of these complications, human population studies have demonstrated increased levels of crude adult-driven IL-4, IL-5, IFN-γ, and other cytokines in human serum in recall responses by peripheral blood mononuclear cells with parasite protection to reinfection (Medhat et al., 1998; Roberts et al., 1993; Caldas et al., 2000). Other studies have shown that parasite-specific IgE directed to crude preparation of adult worms (Hagan et al., 1991; Rihet et al., 1991) and, in some cases, certain recombinant antigens, for example, Sm22.6 (Fitzsimmons et al., 2004) also correlated with protection. Despite the protective role of IgE, high levels of IgG_4 are also produced during infection and potentially blocking the protective effects of other immunoglobulins because IgG_4 lacks opsonizing and complement fixation capacity of other IgG subclasses (Hagan et al., 1991; Caldas et al., 2000; Rihet et al., 1992). The initial induction of IgE and IgG_4 require IL-4 and IL-13; however, the production of IgG_4 also requires IL-10. IL-10 plays a crucial role in the immunoregulation of host immune responses against schistosomiasis. Although the dissociation of IgE and IgG_4 production might be feasible by differential regulation of IL-4/IL-13 and IL-10, this might be difficult. Studies have also showed that eosinophilia, particularly activated eosinophils (assessed by increased expression of FcεRI-β chain), correlate with protection (Ganley-Leal et al., 2006a, 2006b). IgA antibodies may also have a protective role based on a series of correlation studies with protective immunity in different parts of the world (Caldas et al., 2000; Mutapi et al., 1997). Taken together, these studies support the development of a schistosome vaccine and indicate that such a vaccine will likely require both cellular and humoral effector mechanisms. The development of a vaccine that elicits IgE and eosinophilia is unlikely to be pursued because they risk developing atopic diseases. Because of obvious constrains for study of vaccines in humans, the bulk of work in schistosome vaccine development has centered on animals models.

SUBUNIT VACCINES

Given the difficulties for mass production, storage, and distribution of irradiated larvae and the complex heterogeneity of producing a vaccine based on crude parasite antigens, the focus has shifted to identification of individual parasite proteins as vaccine candidates.

Crude Parasite Extracts for Identification of Potential Protective Antigens

The immunization of mice with crude schistosomula larval extracts typically produced 51% protection against cercarial challenge when administered subcutaneously to C57BL/6 mice with BCG as an adjuvant (James, 1985). Immunity was primarily cell mediated and required potent adjuvants such as BCG to elicit protection (James, 1987). Similar levels of protection were observed with crude adult worm extracts.

Paramyosin

In order to identify which fractions were most important for eliciting protection, the crude antigen was fractionated by gel filtration to identify the antigens responsible for protection. This approach identified a

fraction that contained a 97-kDa protein that was subsequently identified as paramyosin, an invertebrate muscle protein (Lanar et al., 1986). The native protein was subsequently purified and shown to induce about 30% protection with BCG as an adjuvant (Pearce et al., 1988) and similar levels of protection (up to 53%) without any adjuvant (Flanigan et al., 1989). We subsequently expressed the full-length Sm-97 using a vector provided by Dr. Charles Schoemaker but failed to achieve more than 30% protection using BCG or alum as an adjuvant (unpublished observations).

At about the same time, *S. japonicum* paramyosin obtained from a Philippines strain of the parasites demonstrated strong protection against cercarial challenge when administered intraperitoneally without adjuvants (62–86%) (Ramirez et al., 1996). Native and recombinant paramyosin proteins or DNA constructs from China confer protection against *S. japonicum* in mice, water buffaloes, and other mammalian hosts (Wu et al., 2005; Chen et al., 2006). Recent studies of human antibody (Nara et al., 2007) and Th2-type immune responses (Leenstra et al., 2006) to *S. japonicum* paramyosin correlate with protection providing support for the protein as a leading *S. japonicum* vaccine candidate. More recently, several studies have indicated that the exogenous form of paramyosin may act to bind Fc fragments of immunoglobulins (Loukas et al., 2001) and inhibit the terminal complement cascade (Deng et al., 2003, 2007), thus indicating an immunomodulatory role for the parasite. Therefore, paramyosin may further act as a potential vaccine candidate; unfortunately, the protein is poorly expressed in soluble form. To improve expression, various fragments have been cloned and the protein expressed, although protection has been less than the full-length molecule (Zhang et al., 2006).

GSTs

A different approach to identify antigens from crude extracts was used to identify glutathione S-transferases (GSTs) independently from two laboratories. In these experiments, crude adult worm extracts were used to immunize rats and then the immune sera to immunoprecipitate native proteins, one of which was the 28-kDa GST (Balloul et al., 1985). Antiserum raised to this protein was able to induce cytotoxic activity of schistosomula in vitro and subsequently shown to reduce worm burdens from 52% to 67% with cercarial challenge following immunization with Freund's complete adjuvant or aluminum hydroxide (Balloul et al., 1987a, 1987b). A great advantage for this protein is that the native protein can be readily prepared using immobilized glutathione to which it binds with high affinity. The 28-kDa GST was formulated with aluminum hydroxide and generated from 0% to 80% protection in baboons (mean 38%) (Boulanger et al., 1991). This study also noted for the first time an antifecundity effect of immunization with Sm28GST. There were a significantly reduced number of eggs per worm pair recovered from the tissues of the exposed animals. This antifecundity effect was confirmed in mice by immunization with recombinant protein as well as antigenic peptides (Charrier-Ferrara et al., 1992).

In a separate research study, a 26-kDa GST was identified from *S. japonicum.* It was cloned, expressed, and shown to elicit a small level of protection against adult worms (21%) but much greater antifecundity effect (59% reduction in number of eggs per adult worm pair) in pigs (Liu et al., 1995). The *S. japonicum* GSTs have subsequently shown inconsistent protection in mice (Scott and McManus, 2000) but obtained significant protection in sheep, water buffalo, and cattle with various formulations—including BCG, Freund's adjuvant, and/or keyhole limpet hemocyanin (KLH)—with levels of protection up to 70%, although most reduction in worm burdens were more in the range of 30–40% (Wu et al., 2005; Shi et al., 2001, 2002; Xu et al., 1995; Taylor et al., 1998).

The research focus for GST as a potential vaccine candidate shifted to an emphasis on its antifecundity effect, which would reduce both morbidity and transmission. It was also tested in the patas monkey, which is an animal model used for *S. haematobium* or urinary schistosome infections. Vaccination with the heterologous Sm28GST induced marked and persistent reduction in egg excretion in the urine and feces by 55% and 74%, respectively; however, it had no effect on worm burdens (Boulanger et al., 1995). When the *S. haematobium* homologue to GST was cloned and expressed, it also generated a similar reduction in egg excretion following vaccination of patas monkeys using BCG and Freund's complete adjuvant but no effect on worm burden (Boulanger et al., 1995). This antifecundity effect could also be observed following vaccination of cattle against *S. bovis* (Bushara et al., 1993), but not in goats or sheep, although it produced a significant reduction in worm burdens (Boulanger et al., 1994, 1999). The protective effect on different species, particularly the antifecundity effect of GST, has resulted in this antigen moving forward to human vaccine trials (described below).

Fatty Acid-Binding Proteins

Fasciola hepatica is a trematode parasite in the same family as schistosomes and shares cross-reactive antigens with schistosomes. A 12-kDa *F. hepatica* antigen was identified with cross-reactivity to *S. mansoni* and,

when used to immunize mice, induced 52–77% protection against a heterologous challenge with *S. mansoni* (Hillyer et al., 1988). Subsequently, a fatty acid-binding protein (Sm14) was cloned using polyclonal sera from mice immunized with a saline extract of *S. mansoni* adult worms. This recombinant protein induced 37–67% reduction in worm burden in mice following cercarial challenge and 100% protection against *F. hepatica* challenge (Tendler et al., 1996). This protein was subsequently identified to have 44% sequence identity to the fasciola Sm12 antigen. This raised the possibilities that this vaccine could protect against both schistosomiasis and liver flukes (Hillyer, 1995). Although the *S. japonicum* homologue has 91% identity to Sm14, the recombinant antigen has consistently failed to elicit significant protection in mice against *S. japonicum* (Scott et al., 2000). A difficulty may be that the antigen is not surface expressed and appears to be localized in internal tissues.

Detection of Antigens Using Protective Monoclonal Antibodies

With the advent of hybridoma technology to develop monoclonal antibodies (MAbs), mice were injected with various preparations of schistosome extracts—eggs, larvae, adult worms—or vaccinated with irradiated cercariae. From these studies, MAbs were generated that could confer significant passive protection in vivo to cercarial challenge (Smithers et al., 1989). The antigens that these MAbs recognized were identified by immunoaffinity purification of parasite extracts. Three such antigen targets were subsequently evaluated in detail in protection experiments.

Sm23 and Tetraspanins

The MAbs that recognized Sm23 was made by cell fusion following immunization with schistosomula (Harn et al., 1985). The MAb reacted with newly transformed larvae or schistosomula, 5-day schistosomula, but not lung-stage larvae. The antigen was subsequently identified as a membrane tetraspanin with two highly immunogenic extracellular domains. Tetraspanins are four-transmembrane-domain proteins homologous to receptors on T and B cells. Mapping B and T epitopes (Reynolds et al., 1992) identified the immunogenic domains. The epitopes were synthesized as a multiple antigenic peptide (MAP), which was then shown to produce significant protection in mice (Harn et al., 1995). Subsequently, a recombinant form of the molecule administered with aluminum hydroxide failed to elicit protection in mice (Da'dara et al., 2003), although a DNA vaccine formulation injected alone or with plasmids encoding IL-4 or IL-12 elicited 21–44% protection (Da'dara et al., 2001). Administration of a *S. japonicum* homologue (Sj23) in various formulations either failed to elicit protection or induced variable protection levels of generally <40% (Waine et al., 1999; Zhu et al., 2003). However, a DNA formulation injected with plasmids encoding IL-12 was found to induce 51–59% protection in pigs to *S. japonicum* cercarial challenge (Zhu et al., 2004). Similar levels of protection were observed in water buffaloes, using a similar DNA vaccination formulation with IL-12. The focus for these studies was to develop a vaccine that reduced infection intensity in one of the major animal reservoirs for this infection in China (Williams et al., 2002). Recently, the extracellular domains of two additional tetraspanins, referred to as tsp1 and tsp2, were expressed and administered to mice with Freund's adjuvant, tsp2 induced 57–64% reduction and tsp1 34–52% reduction in worm burden (Tran et al., 2006). This antigen is expressed on the surface of adult worms but was not tested to determine if it was also surface expressed in the larval stages. Putatively resistant humans had significantly higher IgG antibodies directed to tsp2 compared to *S. mansoni* infected but not resistant individuals. Together these data support tetraspanins as potentially valuable vaccine candidates for future studies.

Triose Phosphate Isomerase (TPI)

This 28-kDa protein was identified as the target of the MAb that conferred partial protection in mice (41–49%) (Harn et al., 1992). This antigen is present on all stages of the parasite but only transiently expressed on schistosomula. Similar to Sm23, T and B cell epitopes were identified, and a MAP constructed (Reynolds et al., 1994) with 45–65% protection was reported (Harn et al., 1995). A DNA construct of *S. japonicum* homologue of TPI failed to induce protection in mice (Zhu et al., 2002). However, a DNA construct administered with or without a plasmid encoding IL-12 induced 46–48% reduction in worm burden following cercarial challenge, although this reduction in worm burden was greater for female worms (54–60%) (Zhu et al., 2006). TPI is a ubiquitous glycolytic enzyme, is intracellular, and is not surface expressed, however it undergoes exocrine release from the cercarial preacetabular glands, during skin penetration.

9B-Ag

The MAb that recognized this antigen was originally generated from mice chronically infected with

S. mansoni and boosted with a cercarial glycoprotein; the MAb was able confer ~42% protection upon passive transfer (Hazdai et al., 1985). Isolation of the native protein, which is multimeric and consists of 30- and 45-kDa subunits, conferred 40–50% protection in mice from cercarial challenge (Tarrab-Hazdai et al., 1998, 1999; Arnon et al., 2000). This antigen has not been cloned, but various formulations of peptides and mimotopes all gave similar levels of protection.

Identification of Vaccine Candidates from Expression Libraries

New technologies spawned additional efforts for vaccine candidate discovery, and when recombinant DNA technology became available in the early 1980s, a series of antigens were identified by screening schistosome cDNA expression libraries from different parasite stages and by immune sera obtained from mice vaccinated with RA sera or from putatively immune humans. Two notable antigens emerged from this approach.

IrV5

This antigen was identified using immune sera from mice vaccinated with irradiated cercariae and immunoaffinity-purified antigens (Dalton and Strand, 1987) that were then used to immunize rabbits (Soisson et al., 1992). One such antiserum recognized an antigen on the surface of newly transformed schistosomula and was then used to screen a larval expression library to identify a 62-kDa fragment of a larger 200-kDa protein. This protein was found to be a myosin heavy-chain protein, designated IrV5. The recombinant 62-kDa fragment administered with a meningococcal outer membrane protein as an adjuvant induced 75% protection in mice (Soisson et al., 1992). Vaccination of baboons with a similar formulation elicited a variable range of protection in animals from no protection to 54% (Soisson et al., 1993). The subsequent expression of the *S. japonicum* myosin protein fragment failed to induce significant protection in mice or pigs, thus holding out little promise for this molecule as a significant vaccine candidate (Zhang et al., 1998).

GAPDH

This antigen was initially identified by Western blot analysis of serum from putatively immune individuals (Dessein et al., 1988). The protein was subsequently purified, and antisera raised in rabbits were used to screen an adult expression library that identified a molecule as glyceraldehyde 3-phosphate dehydrogenase (GAPDH) (Goudot-Crozel et al., 1989). Interestingly, immune sera raised to this protein identified a motif on the larval surface, which is surprising considering that this is also an abundant glycolytic enzyme. It is possible that an isoform of this molecule may be expressed on the larval surface or possibly taken up from the host (Charrier-Ferrara et al., 1992). The dominant T and B cell epitopes for this molecule were identified and, when coupled to ovalbumin in Freund's adjuvant, produced modest protection (Argiro et al., 2000). Protection was boosted to 32–38% when the MAP was co-adsorbed to granulocyte-macrophage colony-stimulating factor (GM-CSF) and alum (Argiro et al., 1999).

Superoxide Dismutase (SOD)

Serum from putatively immune humans infected with schistosome was used to screen an adult cDNA library and found to recognize a gene encoding a schistosome superoxide dismutase with a signal peptide (SP-SOD) (Smyth et al., 2003). Prior studies have shown that granulocytes release oxygen radicals that have been shown to be toxic for schistosome ova. The addition of exogenous SOD can inhibit the granulocyte toxicity for schistosome ova as measured by their metabolic activity and hatching (Kazura et al., 1985). Therefore, it was reasoned that production of SOD by schistosomes might protect themselves from host granulocyte-mediated killing by oxygen radicals. Antibodies raised to cDNA encoding a cytosolic SOD (CT-SOD) were immunolocalized to the tegument and subtegumental tissues in adult worms (Mei and LoVerde, 1997). Proteomic studies of tegument of adult worms and larvae have shown that SOD is localized below the tegumental plasma membrane (van Balkom et al., 2005; Braschi et al., 2006). A DNA vaccine expressing the CT-SOD produced 44–60% reduction in worm burden following cercarial challenge (Shalaby et al., 2003; Cook et al., 2004). Although protection studies using a recombinant CT-SOD or the SP-SOD that is expressed on the tegument have not been performed, they show potential promise.

SECRETORY AND MEMBRANE PROTEINS AS VACCINE TARGETS

The availability of new technologies such as proteomics and microarray analysis along with the recent sequencing of the *S. mansoni* and *S. japonicum* genomes has opened new avenues for discovery of vaccine candidates (Ashton et al., 2001). This has led to a focus on

identifying secreted antigens and tegumental antigens as possible vaccine candidates.

Secreted Proteins

Molecules that are secreted by the parasite are likely to be crucial enzymes for penetration of the epidermis and migration through host tissues. The acetabular glands at the anterior portion of the parasite release elastase, which has been cloned and expressed (McKerrow et al., 1985). More recently, proteomic analysis of cercarial secretions has also identified novel metalloproteinases, a dipeptidyl peptidase, a serine protease inhibitor, and several additional molecules that have homologies to potentially immunomodulatory molecules (Curwen et al., 2006). Although these proteins may be critical for invasion of the skin, they may not represent ideal vaccine candidates since they are primarily active in the epidermis before vascular entry, which is not immediately accessible to the host immune response. A potentially better target would be contents of the head glands, which appear to release their contents following skin penetration (Crabtree and Wilson, 1985) and transformation to schistosomula. Indeed, such proteins may facilitate migration within the dermis and penetration of the vessel wall (Curwen and Wilson, 2003). Although there is a lack of information on such secretions, examination of proteins released by larval stages of the parasite through proteomic analysis can potentially accomplish this task. Both the cercariae and schistosomula appear to release potentially immunomodulatory molecules, such as Sm16, which has been shown to inhibit neutrophil migration and lymphocyte proliferation in the dermis (Rao et al., 2002; Rao and Ramaswamy, 2000). Such molecules may be crucial for blocking host effector immune responses to larval stages of the parasites, and by inhibiting such molecules, host immunity may be much more effective in eliminating parasites. Immunomodulatory molecules released by adult worms, such as SOD as mentioned above, may also be important. Other potential immunomodulatory molecules, such as serine protease inhibitors that could block the host clotting mechanism on the adult surface (Blanton et al., 1994) or complement regulatory protein homologues that could inhibit host complement (Skelly, 2004).

Tegumental Antigens

Antigens expressed on the parasite tegument is an obvious source of putative protective antibodies since it is readily accessible to host immune responses and likely expresses molecules critical for the host survival within the host (Skelly and Wilson, 2006). Schistosome parasites are prodigious consumers of glucose, for example, and consume their dry weight in glucose in 4 h. Several schistosome glucose transporter molecules have been identified, cloned, and expressed on the larval surface (Skelly et al., 1994). These recombinant antigens could be useful vaccine candidates and have the further advantage that an in vitro assay could be developed to examine whether functional antibodies are generated following vaccination. Functional antibodies would be evaluated to determine if they block uptake of labeled glucose by parasites in culture.

The ability of tegumental antigens to induce protective immunity in mice has been approached by isolation of the tegument surface of parasites. The purity and degree of enrichment of these fractions is unclear. However, in one instance, the parasite surface was prepared by a freeze-thaw technique (Roberts et al., 1983), which in subsequent analyses was found to contain various membrane proteins but dominated by cytosolic and cytoskeletal proteins (Braschi et al., 2006). Overall, immunization of mice with these various fractions by different studies resulted in induction of highly variable levels of protection in mice ranging from 0% to ~50%, but most were less than 30% (Smithers et al., 1989; Maddison et al., 1978; Roberts et al., 1988; Hota-Mitchell et al., 1997). The generally unspectacular protection observed by this approach may relate to the high amount of variability in the antigen preparations used; however, a number of tegument-associated proteins have been identified (including the tetraspanins described earlier) by this approach.

Calpain (Smp80)

Calpain is a calcium-activated neutral cysteine protease. The large subunit of the molecule was first identified by immunoscreening of a cDNA expression library by sera from infected humans (Andresen et al., 1991). Calpain was immunolocalized to the tegument and underlying musculature of adult worms and shown to be involved in surface membrane turnover (Siddiqui et al., 1993) and inner tegumental membrane (Braschi and Wilson, 2006). This protein was first implicated in protective immunity as the target of a CD4+ T cell clone that could induce peritoneal macrophages to kill schistosomula in vitro (Jankovic et al., 1996). The same clone, when administered intraperitoneally, conferred 65% protection in irradiated mice challenged with cercariae and IL-2, making calpain the first vaccine antigen identified based on the T cell reactivity. The large subunit of calpain was expressed and shown to induce 29–39% protection in mice

(Hota-Mitchell et al., 1997). Subsequent efforts to improve this vaccine have focused on DNA vaccine constructs, with and without Th1-type cytokine cDNAs, which increased protection to 42–57% in mice and baboons (Siddiqui et al., 2003a, 2003b). The *S. japonicum* calpain has also been cloned and the recombinant protein shown to induce 41% protection in mice along with a demonstrable antifecundity effect (Zhang et al., 2001a, 2001b; Ohta et al., 2004). Calpain is expressed in all parasite stages, including the penetration glands and secretions of *S. japonicum* cercariae (Kumagai et al., 2005).

Additional Membrane Proteins

A group of tegumental proteins with sequence homology to cytoskeletal proteins have also been assessed for protective potential. Notable is a 22.6-kDa antigen that was recognized by IgE from patients infected with schistosomiasis (Santiago et al., 1998) and has homology to Sm22.6 (20.8-kDa protein) from *S. mansoni*. The gene, in the form of a DNA construct, elicited 29–30% protection in mice (Mohamed et al., 1998). These proteins, however, exist on the cytoplasmic side of the tegument and are not surface expressed. Aside from the tetraspanins previously described, another membrane-spanning protein that is expressed on the tegument surface has been recently identified using bioinformatics and in silico analysis (Cardoso et al., 2006a, 2006b), and preliminary results indicate the corresponding recombinant protein is efficacious in mice (Loukas et al., 2007). Additional surface-expressed proteins that warrant further study as potential vaccine candidates have been identified from the surface tegument of adult worms (Braschi and Wilson, 2006). These include structural membrane proteins with large extracellular regions, such as homologues to annexins and dysferlin, and other accessible proteins on the surface with no homologues of known function, such as Sm200.

Antigen Formulation and Vaccination with Multiple Antigens

In order to enhance vaccine efficacy, combinations of antigens as well as the use of more potent adjuvants to boost immunogenicity have been studied. Unfortunately, several attempts to combine antigens to boost protective efficacy have been generally unsuccessful. A DNA vaccine encoding paramyosin, Sm23, TPI, calpain, and Sm28GST as a single polyprotein containing dominant epitopes failed to induce significant protection in mice (Yang et al., 2000). Subsequently, a cocktail DNA vaccine encoding Sj28GST, Sj14-3-3, Sj23, and 62 kDa of myosin induced between 34% and 45% protection, irrespective of adjuvants used (Zhang et al., 2001). To date, a cocktail of recombinant antigens has not been used, but current data indicate that combining antigens does not improve vaccine efficacy. Perhaps these antigens induce similar protective mechanisms, the targets are not diverse enough, or are not consistently expressed on the parasite surface, or there are certain characteristics of the host immune response induced by chronic parasite infection that limits further protection (see below).

The success of a vaccine is also dependent on generating the optimum immune response. This can be accomplished either by varying the adjuvant or routine of immunization. This enhanced response is illustrated by administering the irradiated cercariae with recombinant IL-12 to generate sterile immunity in mice (Wynn et al., 1995) or soluble extracts of lung-stage larvae to give >90% protection (Mountford et al., 1996). With respect to a single vaccine candidate antigen, the greatest effort has been undertaken with Sm28GST. MAPs have been assembled and coupled to tetanous toxoid carriers (Auriault et al., 1988) or have been incorporated in live vectors, such as *Salmonella typhimurium* (Khan et al., 1994a, 1994b), *Bordetella pertussis* (Mielcarek et al., 1997), or BCG (Kremer, et al., 1996). The recombinant protein has also been formulated in biodegradable particles (Baras et al., 1999, 2000), linked to adjuvants to facilitate mucosal administrations, such as cholera toxin B subunit, and administered intranasally. A DNA vaccine has been formulated with genes encoding IL-12, IL-18, and GM-CSF, with the aim of enhancing the cellular immune response. Motifs have been included in DNA vaccines that contain CpG motifs to augment activation of antigen presentation cells or formulated with oligonucleotides corresponding to various CpG motifs. Overall, these various formulations have not markedly enhanced vaccine efficacy to Sm28GST (or to other schistosome antigens evaluated with other various formulations). These data suggest that beyond a certain point, additional protection may not be achieved, even with the most potent adjuvants to Sm28GST or perhaps to any one single antigen.

TRANSLATION FROM ANIMAL STUDIES TO HUMAN CLINICAL TRIALS

With the optimism of identifying a number of potential vaccine candidates, the World Health Organization sponsored independent testing of several of the most

promising antigens, with the aim to move one or more to human trials. These included IrV5, Sm14, and Sm28GST as recombinant proteins, paramyosin as the native protein, and TPI and Sm23 as MAPs. The protein donors specified the adjuvants used. Unfortunately, none of the antigens achieved the target of 40% protection, and some lacked any significant protection in two independent laboratories (Anonymous, 1996). This study also highlighted the difficulty of producing protein of consistent quality in sufficient amounts for more extensive vaccine studies. In spite of these disappointing results, further studies of some of the candidate antigens were undertaken to correlate the cellular and humoral immune responses in humans with the rationale that murine studies might not predict immune responses in humans. Lymphocytes and serum were obtained from well-defined populations of putatively immune versus susceptible humans in Brazil and Egypt. Although there were distinct immune responses to these antigens, there were no clear markers for either susceptibility or resistance (Ribeiro de Jesus et al., 2000; Al-Sherbiny et al., 2003). Thus, the decision was made not to proceed with any of the candidates, putting a considerable damper on further development of schistosome vaccines.

In spite of the discouraging results, one vaccine candidate, Sh28GST or BILHVAX, progressed to clinical trials. This is the only vaccine currently studied in humans. The vaccine candidate was not tested in independent animal trials or human immune correlate studies. The rationale for moving this vaccine forward was the strong antifecundity effect it had in patas monkeys (Boulanger et al., 1995, 1999). In Phase I and II trials, the recombinant protein formulated with alum was safe and highly immunogenic (Capron et al., 2002). Phase III efficacy trials are reported to be underway (Capron et al., 2005); however, no published studies on its clinical efficacy are available at this time. It is unfortunate that more vaccine candidates have not progressed to human studies.

In order to facilitate the movement of more candidates to human studies, a better transition is required from vaccine efficacy studies in murine models to humans. This will require further testing in nonhuman primates, the best model being the baboon (Nyindo and Farah, 1999), followed by studies in chimpanzees (Eberl et al., 2001), although perfusion studies cannot be performed in the latter species. Studies of vaccine efficacy against *S. japonicum* in large animals, for example, water buffaloes, pigs, and cattle have demonstrated successful vaccine efficacy to several candidate antigens that demonstrated poor efficacy in mice. Several vaccine candidates have progressed to efficacy trials in nonhuman primates, for example, SOD and calpain, although results remain to be published.

WHY ARE HIGH LEVELS OF PROTECTION DIFFICULT TO ACHIEVE?

This question has been proposed in a recent review of schistosome vaccines by Wilson and Coulson (2006) and warrants careful consideration in approaches to a schistosome vaccine. Out of the many different vaccine candidates tested, a few have achieved greater than 40% protection under ideal conditions using potent adjuvants. It is rare for a candidate protein vaccine to break 50% protection, and such results are variable and require independent testing. Thus, for some reason, there seems to be a ceiling of about 40–50% protection induced by any single protein. There are several potential explanations. Many vaccine candidates represent cytosolic or subtegumental antigens, and it is hard to fathom how host effector immune responses recognize these parasite antigens. Protection may not actually involve direct parasite killing but rather impede parasite migration through the host, particularly through the pulmonary vasculature as has been observed in the case of RA cercariae described previously (Smythies et al., 1992). Any single antigen or group of antigens can elicit only so many T cell clones that are recruited to the lung and result in only partial blocking of their onward migration. This may also explain why individual antigens or cocktails of antigens fail to achieve the levels of protection observed with RA cercariae.

Among the antigens that are actually available on the surface of the parasite as vaccine targets, these may be only transiently expressed because the parasite goes through a series of transformations in the process of maturation to the adult stage. Once the parasite fully matures, it then rapidly turns over its tegument, shedding its surface and consistently renewing it (Skelly and Wilson, 2006). Therefore, antibodies or cells adhered to its surface may be shed before they could elicit a lethal blow to the parasite.

There are other mechanisms that the parasite might employ to mitigate the host effector immune responses. The parasite has been observed to acquire host proteins on its surface that might partially mask vaccine targets on its surface (Damian, 1965, 1987). The parasite also acquire host proteins on its surface that can mitigate the host immune responses. An example is the decay-accelerating factor (DAF), which is an inhibitor of the alternative complement pathway (Horta and Ramalho-Pinto, 1991; Pearce

et al., 1990; Ramalho-Pinto, 1987; Ramalho-Pinto et al., 1992). Similarly, paramyosin has also been shown to bind human CD59, which inhibits activation of the terminal pathway of the complement (Deng et al., 2003). Interestingly, the parasite itself may also produce homologues of human complement regulatory proteins (Braschi et al., 2006).

The parasite produces other proteins that might impair recruitment or activation of host immunity. The cercarial preacetabular and, potentially, head gland contents contain several immunoregulatory proteins. As mentioned previously, Sm16 can suppress dermal immune responses (Rao and Ramaswamy, 2000), and it is likely that others exist. For example, penetrating parasites have been shown to promote eicosanoid synthesis in the skin (Fusco et al., 1985). The vaccine candidate Sm28GST has been shown to be responsible for producing prostaglandin D2 (Herve et al., 2003), which impairs migration of Langerhan's cells from the skin and consequently antigen presentation (Angeli et al., 2001).

Another possible mechanism why vaccine candidates may not be fully effective is because they produce the wrong type of antibody. In humans, the predominant isotype synthesized and directed against schistosome antigens is IgG_4, which recognizes similar epitopes to IgE (Hussain and Ottesen, 1988) and can block IgE-mediated effector mechanisms (Hagan et al., 1991). Several MAbs of different isotypes in both rats and mice were found to block cytotoxic activity of other isotypes (Grzych et al., 1984) and murine antibodies against the same targets (Yi et al., 1986) or human infected serum (Dunne et al., 1987) for schistosomula in vitro.

It is likely that vaccines will be initially administered to children or adults previously or already infected with schistosomiasis. A defining characteristic of human schistosomiasis is the capacity to undergo immune modulation. This is manifested by impaired lymphocyte recall responses as measured by reduced lymphocyte proliferation and cytokine production to a variety of schistosome antigens. This is most pronounced as the parasites mature into adult worms and begin release of ova (Wilson et al., 2007). This limitation may also serve to impair host immune responses to vaccination (Elliott et al., 2007).

Compared to many infections, schistosomiasis presents unique challenges to produce an effective vaccine because of the multiple mechanisms the parasite has evolved to survive within its host for many years. Therefore, development of a vaccine will likely have to accompany a better understanding of how they both limit the immune responses and provoke and circumvent the host effector immune responses.

PROSPECTS FOR THE FUTURE

Overall, prospects for developing a schistosome vaccine are encouraging. There is now a much broader international effort to develop a schistosome vaccine, particularly among scientists from China and Brazil, where the disease is endemic. These countries are providing substantial financial and personnel resources to move vaccine research forward. The research community is posed to identify a new generation of vaccine candidates now that the schistosomiasis genome, transcriptome, and proteome are being defined for all life stages of the parasite. The challenge is to integrate identification of the vaccine candidates in the context of physiological processes of the parasite. For example, vaccines that can generate antibodies capable of inhibiting the function of critical molecules on the parasite surface such as glucose transport proteins, or molecules that circumvent the host immune responses. Alternatively, a logical approach may be to generate antibodies to proteins in the parasite gut that are required for digestion. We emphasize that critical targets are likely to be proteins expressed on the surfaces of schistosomula and adult worms. Additional targets include secretory proteins, which may also serve in essential physiological processes for parasite migration in the host and avoidance of the host immune response. The most vulnerable stages of the parasites should also be identified, which are likely to be tissue-migratory larval stages of the parasite.

What can be reasonably achieved for a schistosome vaccine needs to be reconsidered. A high level of protective efficacy, as observed for most bacterial and viral vaccines currently in use, is unlikely to be achieved in the near future because of the complex and probably redundant mechanisms that the parasite has evolved to survive within its host. Yet, even partial protection conferred by a vaccine can be of great benefit because the parasite does not replicate within the host. It is also likely that greater effort will be put toward vaccines that limited parasite fecundity, for example, a vaccine that protects more against disease than infection, which might be a more achievable target. In this context, schistosome vaccines will be an important component for integrated control of schistosomiasis that complements existing strategies, including chemotherapy, health education, and vector control. It should be emphasized that PZQ is the only currently anti-schistosome drug in production, and with expanding mass treatment programs, it is likely that resistance will emerge. This makes development of schistosome vaccines ever more important.

KEY ISSUES

- Only a few vaccine candidates have achieved more than 50% efficacy, with most less than 40% under ideal conditions. Why there is this ceiling to protective efficacy needs to be better understood.
- A vaccine with an even partial efficacy will be of great benefit because the parasite does not replicate within its host.
- The points in the schistosome life cycle that are most susceptible to immune attack need to be better understood.
- A better understanding of what are the host effector mechanisms that lead to parasite elimination in large animal models following vaccination with irradiated cercariae.
- The genomes of *S. mansoni* and *S. japonicum* need to be fully assembled, analyzed, and annotated. The *S. haematobium* genome should be sequenced since it is now the most prevalent human schistosome species.
- A concerted effort should be made to complete the proteome and transcriptome for each stage of life cycle for the three major human species of schistosomiasis.
- Surface-expressed or -secreted antigens from this inventory of parasite proteins identified by these new technologies are likely to be preferred vaccine candidates.

OUTLINE

ABSTRACT

Trypanosoma cruzi is the etiologic agent of American trypanosomiasis or Chagas disease. It is normally transmitted by the reduviid insect vector, and also by blood transfusion. It is estimated that 16–18 million people are infected in the American continent, with >50,000 deaths reported every year. Acute infection by *T. cruzi* can be lethal, though the majority exhibit flu-like, nonspecific clinical symptoms. The disease usually evolves into a chronic stage, in which >30% of infected individuals exhibit severe debilitation of the heart. The pathology of Chagas disease presents a complicated and diverse picture in humans. The clinically relevant pathognomonic consequences of human infection by *T. cruzi* are dilation and hypertrophy of the left ventricle walls and thinning of the apex. The major complications and destructive evolutionary outcomes of chronic infection include ventricular fibrillation, thromboembolism, and congestive heart failure. American trypanosomiasis poses serious public health care and financial concerns. The currently available drugs, though effective against acute infection, are highly toxic and ineffective in arresting or attenuating clinical disease symptoms in chronic patients. No effective vaccines are available.

Studies in animal models and human patients have revealed several mechanisms, including parasite persistence, chronic inflammatory responses to self or parasite antigens, and sustained mitochondrial dysfunction and oxidative stress, that contribute to the pathogenic outcome of Chagasic cardiomyopathy. Protective immunity against *T. cruzi* infection requires the elicitation of Th1 cytokines, lytic antibodies and the concerted activities of macrophages (ϕs), T helper cells, and cytotoxic T lymphocytes (CTLs). Several antigens, antigen delivery vehicles, and adjuvants have been tested to elicit immune protection to *T. cruzi* in experimental animals; however, most of these attempts have met with limited success, and the development of an efficacious prophylactic vaccine faces many challenges. There is a critical lack of methods for prevention of infection or treatment of acute infection or chronic disease. This chapter will summarize what is known about the parasite and the current state of knowledge of pathogenesis and protective immunity. We will discuss the research efforts in vaccine development to date and the challenges faced in achieving an efficient prophylactic vaccine against human American trypanosomiasis, as well as the future perspectives.

HISTORICAL BACKGROUND OF CHAGAS DISEASE

A detailed history of American trypanosomiasis is presented in a review (Guerra, 1970). The chronicles of colonization of the New World contain many indirect references to Chagas disease, then referred to as *Mal de Bicho* in Brazil. The first description of the reduviid insect and its blood-sucking habits was made in 1590 by a missionary priest in Tucuman, Argentina. It was ~300 years later when reduviids were shown to be carriers of *Trypanosoma cruzi*. In 1908, a physician, Carlos Chagas, was commissioned by Oswaldo Cruz, then director of Manguinhos Institute, to the Lassance region of Amazon Basin in Brazil to control a malaria outbreak. During this visit, he noted a large number of reduviid insects, referred to as "barbeiros" or "kissing bug" infesting the poorly constructed rural dwellings. He considered that these insects might be important vector of human disease, and studied them and found flagellates, resembling *Crithidia*, in their hindgut. Armed with a vector and a possible agent, he allowed the reduviid insects to feed on laboratory animals, and subsequently found flagellated parasites in their blood. The parasite was named, in honor of Oswaldo Cruz, *Schyzotrypanum cruzi*, and later renamed *T. cruzi*. Chagas continued his studies and, in 1908, documented the first case of human *T. cruzi* infection in a 2-year-old girl. Within a period of less than 2 years, he described salient characteristics of the clinical disease, named Chagas disease after him (Lewinsohn, 1979). Subsequently, Vianna, a colleague of Chagas, made the first histopathological observation of amastigote nests in tissues, and Brunmpt delineated the life cycle of *T. cruzi*. Cases of *T. cruzi* infection were reported in Panama, Argentina, and Uruguay from 1931 to 1936. The first case of transfusion-mediated parasite transmission was reported in 1952 in Sao Paulo, Brazil. During the next 10 years, it became evident that the chronic infection is associated with pathologic lesions in the heart, extensively described by Mott and Hagstrom (1965). In 1974, the first observation of anti-heart antibodies in chronically infected patients was made (Cossio et al., 1974), and concurrently, others showed the destruction of heart cells by *T. cruzi*-sensitized lymphocytes in vitro (Santos-Buch and Teixeira, 1974). These observations initiated the hypothesis of Chagas disease as an autoimmune disease.

The earliest studies documenting the immunologic control of *T. cruzi* showed: the complement-dependent phagocytosis and cytotoxicity to *T. cruzi* (Kierszenbaum and Budzko, 1973); antibody-dependent, cell-mediated cytotoxicity to bloodform trypomastigotes (Abrahamsohn and Silva, 1977); macrophage activity against *T. cruzi* (Hoff, 1975); and genetic resistance-versus-susceptibility

of different inbred mouse strains to *T. cruzi* (Trischmann et al., 1978). Much has been learned about the biology, pathogenesis, and immunity to *T. cruzi* since its first description in 1909, and the knowledge related to vaccine development against *T. cruzi* is summarized here.

VECTOR AND PARASITE

Vector Classification

The vectors of *T. cruzi* are insects of the order *Hemiptera*, family *Reduviidae*, and subfamily *Triatominae*. Of the 118 species of triatomines identified, only a few, e.g., *Triatoma infestans* and *Panstrongylus megistus* in South America; *Rhodnius prolixus* in Venezuela, Columbia, and Central America; and *T. barberi* and *T. dimidiata* in Mexico, are epidemiologically significant as vectors of *T. cruzi. T. sanguisuga* is the primary vector of *T. cruzi* in the southeastern US (Pung et al., 1998; Schofield and Dias, 1999; Guzman-Bracho, 2001) (Fig. 69.1).

Parasite Classification

T. cruzi is a hemoflagellate protozoan of the *Sarcomastigophora* phylum, *Mastigophora* subphylum, *Kinetoplastida* order, *Trypanosomatidae* family, and is characterized by the presence of one flagellum and a single mitochondrion, which contains the kinetoplast, a specialized DNA-containing organelle. *T. cruzi* isolates are grouped into two major phylogenetic groups, i.e., I and II, on the basis of zymodemes and several genetic markers. *T. cruzi* II consists of five related subgroups, IIa–IIe (Brisse et al., 2000). In South America, *T. cruzi* I is associated with a sylvatic transmission cycle and human disease north of the Amazon basin. *T. cruzi* II is predominantly distributed in the Southern Cone countries and also associated with a domestic transmission cycle and infection of placental mammals (Barnabe et al., 2001a). In Mexico and the US, the majority of human cases are linked to *T. cruzi* I (Barnabe et al., 2001b; Bosseno et al., 2002). No direct correlation between Chagas disease severity and parasite lineage has been established.

Life Cycle of *T. cruzi*

T. cruzi evolves during its life cycle into different forms that are morphologically distinct and can also be identified by the relative position of the kinetoplast in relation to the cell nucleus and flagellum emergence (Fig. 69.2) (Tyler et al., 2003). The infective, trypomastigote (15–20 $\times$ 2μm) exists as a freely swimming, extracellular, nonreplicative form in the bloodstream of mammalian hosts. It may be ingested during a bloodmeal by the triatomine insect vector. In the midgut of the insect, trypomastigotes transform into

FIGURE 69.1 Geographical distribution of triatomines of clinical importance and *T. cruzi* infection in humans.

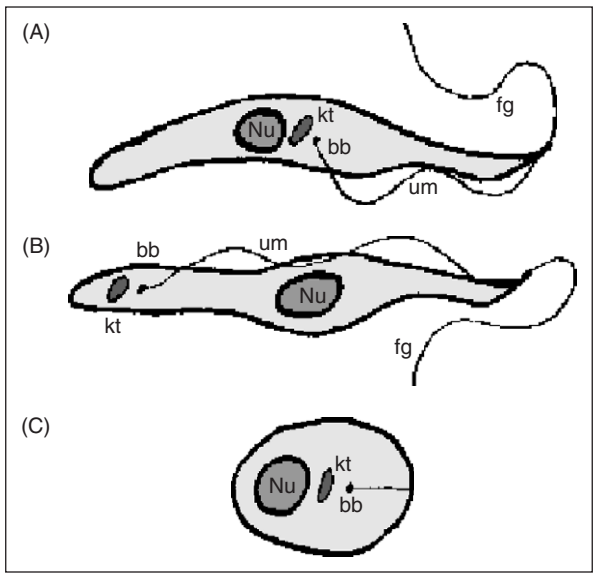

FIGURE 69.2 Different morphological forms of *T. cruzi*. (A) Epimastigote, (B) trypomastigote, (C) amastigote. Nu, nucleus; fg, flagellum; um, undulating membrane; kt, kinetoplast; bb, basal body.

epimastigotes ($20 \times 2\mu m$) that replicate by binary fission, and move to the hindgut and rectum, where they transform into infective metacyclic trypomastigotes. When an infected triatomine takes a bloodmeal and defecates, metacyclic trypomastigotes are released in the feces of the insect and may enter the body of the victim through the puncture wound caused by insect bite, or through mucosal membranes of the mouth, nose, or eyes. Trypomastigotes may also be transmitted by transplacental transmission, blood transfusion, or laboratory accident. There is local inflammation at the entry site where macrophages and/or local tissues are parasitized. Most cells can be parasitized, although there appears to be a tropism for striated muscle, smooth muscle, and neuroectodermal cells. Trypomastigotes escape from the parasitophorous vacuole into the host cell cytoplasm by an unusual mechanism involving transformation of trypomastigotes into spherical, intracellular amastigotes (2–4 μm diameter) that replicate by binary fission within the cytoplasm of the parasitized cells. Within 4–5 days, amastigotes of heavily parasitized cells convert back into trypomastigotes, which are released by cell lysis. The released trypomastigotes may infect other cells or be ingested by the vector to continue the life cycle (Fig. 69.3) (Tyler et al., 2003).

Diagnostic Measures

Parasitologic diagnosis of infection by *T. cruzi* depends upon detection of trypomastigotes by microscopic examination of blood samples. Trypomastigotes in patients may also be detected by indirect methods, e.g., xenodiagnosis and hemoculture (Chiari, 1992). The polymerase chain reaction (PCR) offers several advantages in the sense that it can be more sensitive, specific, and rapid than the above-mentioned methods. The majority of PCR assays used to detect *T. cruzi* target the amplification of kinetoplast DNA, ribosomal DNA, or mini-exon sequences (Gonzalez et al., 1994; Gomes et al., 1999; Pizarro et al., 2007).

Serological analysis is routinely conducted to determine exposure to *T. cruzi*. Generally, specific IgM to *T. cruzi* can be detected 1 week after infection, peaks by day 30, and decreases to undetectable levels in 3–4 months when IgG antibodies reach their maximum level. *T. cruzi*-specific IgG antibodies persist throughout the life of infected individuals. Anti-*T. cruzi* antibodies are detected by various methods, including complement fixation, enzyme-linked immunosorbent assay (ELISA), flow cytometry, direct agglutination or indirect hemagglutination, indirect immunoflourescence, and immunoblotting (Ferreira, 1992). *T. cruzi*-antigen-based serological analysis reagents are commercially available in the endemic countries and used for blood bank screening or seroepidemiological surveys. It is essential to perform multiple tests to confirm seropositivity. In the US, an ELISA assay that uses epimastigote lysate antigens for detection of antibodies to *T. cruzi* in serum and plasma (Ortho-Clinical Diagnostics, Raritan, NJ) has been licensed by the Food and Drug Administration, and used by American Red Cross and other blood banks for screening the donors for *T. cruzi* infection.

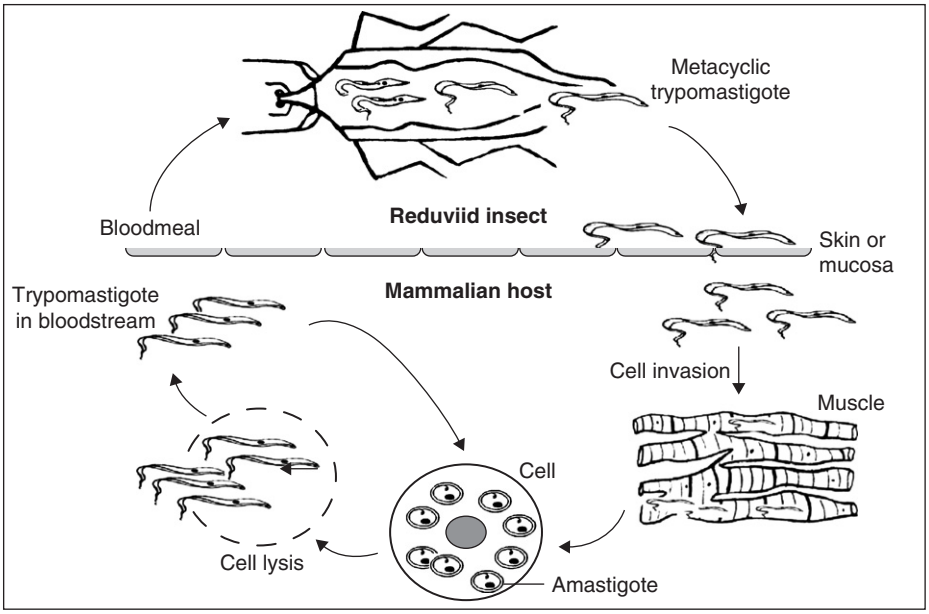

FIGURE 69.3 Life cycle of *T. cruzi*.

IMMUNE RESPONSE TO *T. CRUZI*

Protective Immune Responses

High parasitemia and wide distribution of *T. cruzi* in different organs and tissues after initial infection are a result of the parasites' ability to evade or suppress innate immune mechanisms. The acute phase ends when the host mounts a potent immune response that is largely effective in controlling the parasite. Sterilizing immunity does not exist in *T. cruzi* infection. The comparison in responses exhibited by susceptible and resistant experimental models has contributed to an understanding of protective immune responses to *T. cruzi*. Natural killer (NK) cells appear to be the first source of interferon-γ (IFN-γ) that, in turn, augments IL-12 synthesis by ϕs (Gazzinelli et al., 1992). Surface glycoproteins (mucins) and/or glycophospholipids (GIPLs) of *T. cruzi* are shown to stimulate the production of multiple cytokines, e.g., IFN-γ, TNF-α, IL-1, and IL-6; and chemokines, e.g., MCP-1, RANTES, and IP-10 by inflammatory ϕs (Almeida et al., 2000, 2001; Almeida and Gazzinelli, 2001). These cytokines induce ϕ activation and nitric oxide (NO) production that is important in the killing of *T. cruzi* (Martins et al., 1998). It is suggested that IFN-γ of NK origin and IL-12 of ϕ origin skew the differentiation of parasite-specific T helper cells toward a protective Th1 phenotype (Abrahamsohn and Coffman, 1996). Parasite-specific $CD4^+$ T cells may assist in the control of *T. cruzi* through secretion of Th1 cytokines (IFN-γ, IL-2), amplification of the phagocytic activity of macrophages, stimulation of B cell proliferation and antibody production, and differentiation and activation of $CD8^+$ T cells (Brener and Gazzinelli, 1997). *T. cruzi* antigen-specific $CD8^+$ T cells are frequently present in infected mice and humans (Wizel et al., 1997, 1998b); and may contribute to *T. cruzi* control, either by cytolysis of the infected cells or secretion of Th1 cytokines (IFN-γ) that induce trypanocidal activity (DosReis, 1997). A strong lytic antibody response enhances the opsonization, phagocytosis, and complement-dependent killing of the parasites (Krautz et al., 2000).

With progression to indeterminate and chronic disease, blood parasitemia is absent, and parasite nests are rarely detectable in cardiac tissue. The presence of parasite-specific antibodies is diagnostic of chronic *T. cruzi* infection. The mononuclear cells, ϕs, and IFN-γ-producing $CD8^+$ T cells represent the majority of the infiltrate in experimental models (Tarleton, 1996) and human cardiac biopsies (Reis et al., 1993). $CD4^+$ T cells are less prominent in the chronic myocardium of infected mice (DosReis, 1997) and human patients (Higuchi et al., 1997). It is likely that immune responses similar to those essential for control of acute parasitemia, i.e., substantial antibody response and activation of type 1 $CD4^+$ and $CD8^+$ T cells, are required to maintain control of *T. cruzi* during indeterminate and chronic phases of infection and disease. The evidence is provided from the experimental models and natural human infections demonstrating that absence or reduction in any of these immune responses through targeted depletion, immunosuppressive treatments, or infection-induced immunosuppression can result in an exacerbation of parasitemia (Sartori et al., 1995; D'Almeida et al., 1996; Tarleton et al., 1996).

Pathologic Immune Responses

Along with their immunoprotective role, $CD4^+$ and $CD8^+$ T cells are suggested to be involved in immunopathology. During acute infection in mice, $CD4^+$ T cells initiate unspecific, polyclonal activation of B cells from spleen and lymph nodes, leading to an increased number of nonspecific, IgG-secreting cells and hypergammaglobulinemia with disease progression (Minoprio et al., 1987, 1989). GIPLs, at least in part, are responsible for triggering of polyclonal B lymphocytes (Bento et al., 1996). $CD4^+$ T cells that persist in chronic hearts represent an autoreactive phenotype and are associated with myocyte death, tissue destruction, and increased animal mortality (Soares and Santos, 1999). In humans, most of the initial humoral response is dominated by antibodies to an epitope (Galα1-3Gal) expressed by glycosylphosphatidylinositol (GPI) anchored mucins of *T. cruzi* and is followed by polyclonal B cell activation and hypergammaglobulinemia with disease progression. $CD8^+$ T cells are the major T-cell subset found in the cardiac tissue of both experimental animals and human patients and are thought to be responsible for immunopathology during chronic Chagas disease (Higuchi, 1999; Higuchi et al., 2003).

Regulatory Immune Responses

Because *T. cruzi* infection elicits a strong activation of the immune system, it seems essential that immunoregulatory mechanisms be activated. IL-10 and TGF-β cytokines are important negative modulators of NO synthesis and trypanocidal activity of ϕs. A lack of IL-10 results in an overwhelming inflammatory response and animal deaths early in infection with *T. cruzi* (Hunter et al., 1997). Several mechanisms, e.g., regulation of IL-2 expression (Tarleton, 1988), ϕ activation and NO synthesis (Abrahamsohn and Coffman, 1995), and selective apoptosis of T helper cells (Lopes

and Dosreis, 1996), may act independently, or in concert, to control the $CD4^+$ T cell population in infected mice. Parasite molecules (GIPLs) are shown to block $CD8^+$ T cell activation in vitro (DosReis et al., 2002); however, no regulatory mechanisms have been defined that may control $CD8^+$ T cell population in vivo. The occurrence of such regulatory mechanisms in human patients, though expected, has not been defined.

EPIDEMIOLOGY

Transmission and Geographic Distribution

The ancient sylvatic cycle of *T. cruzi* transmission involves interaction between wild vectors and hosts in different natural ecotypes of American continent. The domestic cycle results from human–vector contact. The reservoir hosts of *T. cruzi* include >150 mammal species, mainly small animals, that play an important role in maintaining both sylvatic and domestic cycles (WHO, 2002). Humans, followed by dogs, cats, and rodents are important domestic reservoirs. *T. cruzi i*s widespread and endemic in almost all of South and Central America, and Mexico (Fig. 69.1) (Schofield et al., 2006; Cruz-Reyes and Pickering-Lopez, 2006). Several studies have shown the presence of the insect vector as well as infection of domestic dogs and wild animals in the US (Yabsley and Noblet, 2002; Beard et al., 2003; Hall et al., 2007; Hanford et al., 2007). Vector-transmitted human infections have been reported in the southern US (Herwaldt et al., 2000) (Fig. 69.1).

Profound economic and social changes have stimulated rural-to-urban migration within the endemic countries and towards the developed countries, e.g., the US and Canada. It is estimated that >300,000 infected individuals live in the city of Sao Paulo; >200,000 each in Rio de Janeiro and Buenos Aires (Dias, 1992b); and >100,000 infected immigrants from Latin America live in the US (Kirchhoff, 1993). These individuals may donate contaminated blood and thereby expose many others to the risk of *T. cruzi* infection (Dias, 1992a; Leiby et al., 1997). The infectivity risk, defined as the likelihood of infection from receiving an infected transfusion unit, is estimated to be ~20% for *T. cruzi* (WHO, 2002). Before serologic screening of blood donors for antibody to *T. cruzi* was implemented, infection rates through blood transfusion ranged from <0.1% to 4% in Argentina, Brazil, Chile, and Uruguay to >10% in Bolivia (Schmunis and Cruz, 2005). Transmission of *T. cruzi* infection by solid-organ transplantation has been evident in Latin America (Reis et al., 1995; Riarte et al., 1999).

In the US, five cases of *T. cruzi* transmission by organ transplantation from infected donors have been described (CDC, 2002a, 2006). Three blood banks, situated in California and Arizona states, have conducted a large-scale serosurvey, and documented that 1 in every 4665 blood donations was seropositive for *T. cruzi*-specific antibodies (CDC, 2002b). This study led to FDA approval of first blood donor screening test for Chagas disease in the US (CDC, 2007). Beginning January 2007, American Red Cross and Blood Systems Inc. have begun screening the blood donations for presence of *T. cruzi* antibodies and it is expected that all blood-collection establishments in the US will implement screening test for *T. cruzi* infection in near future. As of July 2007, 458 blood donations were repeat reactive by ELISA and 124 donations were confirmed positive by radioimmunoprecipitation test in the US (AABB Chagas' Biovigilance Network, http://www.aabb.org/Content/Programs_and_Services/Data_Center/Chagas/chagas.htm).

Disease Burden

According to World Health Organization estimates from 1998, >120 million people are exposed to risk of *T. cruzi* infection, ~18 million people are infected with *T. cruzi*, and ~50,000 children and adults die annually, because of the clinical complications of *T. cruzi*-induced heart disease and lack of effective treatments in endemic countries (WHO, 2002). Approximately 2–5% of fetuses carried by infected mothers are either aborted or born with congenital infection. Revenue loss, in terms of productivity declines due to sickness in prime years and medical costs, has an overwhelming effect on economic growth (WHO, 2002). It is currently estimated that the total annual cost of Chagas disease management in endemic countries is >8 billion US dollars. When considered from a global perspective, Chagas disease represents the third greatest tropical disease burden after malaria and schistosomiasis. American trypanosomiasis is recognized as a potentially emerging infectious disease in the US (Dodd and Leiby, 2004).

Potential as a Biothreat Agent

T. cruzi infection poses a minimal risk as a biothreat agent due to a latency period of incubation ranging ~10–30 years prior to development of clinical disease. Chagas disease is, however, an emerging infectious disease in the US and no longer considered a disease of the tropical, developing countries. Since January 2007, the American Red Cross and other blood banks across

the United States have implemented the donor screening for *T. cruzi* infection, highlighting the urgent need for clinicians, laboratorians, and public health professionals to understand Chagas disease, its diagnosis, and treatment.

CLINICAL DISEASE AND CONTROL MEASURES

Clinical Manifestations of Chagas Disease

Infection by *T. cruzi* elicits nonspecific symptoms, e.g., fatigue, fever, enlarged liver or spleen, swollen lymph glands, and occasionally a characteristic swelling either at the site of entry in the skin, a *Chagoma*, or in the conjuctiva of eyelid, *Romana's* sign. Most acute patients develop heavy parasitism of muscles and some symptoms of cardiac involvement that is usually unrecognized. The clinical manifestations resemble myocarditis, with slight-to-moderate cardiac enlargement. In a small proportion of acute patients (<5%), more severe right- and left-sided heart failure may occur with pulmonary and systemic congestion, tachychardia, and other cardiac insufficiencies, occasionally resulting in fatal congestive heart failure. *T. cruzi* can also invade the gastrointestinal and central nervous systems, but, in general, damage to these systems is uncommon. The signs and symptoms of acute disease resolve spontaneously in 4–8 weeks postinfection, and the majority of patients enter an indeterminate phase of infection. This phase is characterized by very low or undetectable parasitemia, high parasite-specific antibody titers, and lack of clinical symptoms. Between 10 and 20 years after an initial infection, ~40% of infected individuals become symptomatic. The systemic changes during the chronic stage commonly develop in the heart, esophagus, and rectosigmoid colon, and less often in the central nervous system (Kirchhoff et al., 2004).

Heart problems in chronic Chagasic patients are evidenced by nonspecific symptoms such as palpitations, dizziness, and syncope. Typically, manifestations of chronic disease are thromboembolism in the brain, limbs, or lungs, congestive heart failure, and sudden death—mainly due to ventricular fibrillation. Once clinical symptoms appear, the prognosis is poor, and fatality occurs within a short period (Rassi et al., 2000). The principal defects in the conduction system present as a mixture of arrythmias, e.g., tachycardia, bradycardia, ventricular fibrillation, and electrical impulse blockages, e.g., right bundle branch and left anterior fasicle block. Myocardial structural defects are mainly cardiomegaly with hypertrophy and dilation of the chambers, apical aneurism in left ventricle, and clot formation with thromboembolization (Rossi et al., 2003). The histological examination of sections from both autopsy and biopsy specimens reveal that tissue fibrosis, inflammation, and hypertrophy of cardiac fibers are the chief pathological consequences of Chagas disease. Fibrosis is most pronounced in the left ventricle and apex, and may correspond to increased collagen fiber deposition around the muscle bundles. Inflammation varies in severity and its location may be interstitial and/or diffuse. Echocardiography, serial chest radiographs, and electrocardiography are the most accurate and commonly employed methods for detecting myocardial involvement in Chagasic patients (Rocha et al., 2003).

Clinical manifestations of Chagas disease may also be correlated with defective innervation and defective contraction within the myocardium. Pathogenic changes in the parasympathetic branch of the autonomic nervous system are sometimes observed at autopsy. Specifically, a reduction, or in some cases, a complete absence of cells in the neuronal ganglia has been described and may be indicative of a role for impaired heart innervation in cardiac dsyfunction associated with Chagas disease (Marin-Neto, 1998).

In some patients, clinical manifestations of Chagas disease include development of a megaesophagus and/or megacolon. Repeated episodes of aspiration pneumonitis are common in patients with severe esophageal dysfunction. Patients with a megacolon suffer from chronic constipation and abdominal pain. Ultrasonography, computed tomography, and magnetic resonance imaging are excellent imaging modalities used to determine the extent of tumor and enlargement, but are very expensive (Mattoso, 1981).

Control Measures

Vector Control

Three multinational, government-funded programs, initiated in 1991, are underway to control the endemicity of *T. cruzi* infection in Southern Cone nations of Argentina, Bolivia, Brazil, Chile, Paraguay, and Uruguay (Schofield, 1992; Schofield and Dias, 1999). The primary focus of these programs is the elimination of the domestic insect population through insecticide use, housing improvement, and education. These efforts have been very successful in reducing the domiciliary infestation by triatomines in vast regions of the endemic countries, and subsequently reducing the prevalence of acute infection in young children (Dias and Schofield, 1999; Schofield et al., 2006). The current goal is to eliminate vectorial *T. cruzi* transmission

to humans throughout the Southern Cone by 2010. Venezuela and Colombia have also implemented parallel insecticide spray and housing improvement initiatives (WHO, 2002). However, the operational cost to sustain the insecticide spray programs, followed by constant surveillance, is one of the major obstacles in the success of the regional insecticide-based control programs. Insecticide use in the long-term may not be efficacious in blocking *T. cruzi* transmission, owing to the development of drug resistance by triatomines. Concern remains that reinfestation of homes by secondary sylvatic vectors, e.g., *Triatoma sordida*, in Brazil and other South American countries, will compromise the long-term efficacy of vector control measures (Moncayo, 2003). Successful elimination of disease as a public health problem through interruption of transmission would not eradicate the parasite due to the zoonotic nature of the disease.

Blood Supply Screening

The problem of transfusion-transmitted Chagas disease was apparent by the 1950s. However, it was only in the 1980s, with the emergence of AIDS that national and regional blood-screening programs were implemented in endemic countries. Among the 18 countries in Latin America for which data are available, the degree of blood bank screening for *T. cruzi* now reaches 100% of the donors in seven countries, ≥99% in three, 75–95% in four, and 25–34% in three (Schmunis and Cruz, 2005). In the US, an ELISA assay that uses epimastigote lysate antigens for detection of antibodies to *T. cruzi* in serum and plasma (Ortho-Clinical Diagnostics) has been licensed by the Food and Drug Administration in January 2007, and used by American Red Cross and other blood banks for screening the donors for *T. cruzi* infection.

Treatment

Two drugs, benznidazole and nifurtimox, are generally approved for the treatment of *T. cruzi* infection, and are effective in curing at least 50% of acute or recent cases of infection (Coura, 1996). Both of these drugs have serious and frequent side effects and are not available to many patients either because they are not registered in those countries or drug prices are high. Anti-parasitic drugs are not effective once the patients enter the chronic phase of infection and disease progression (Rodriques Coura and De Castro, 2002). Several other drugs, e.g., posaconazole (Liendo et al., 1998) and thioridazine (Lo Presti et al., 2004; Bustamante et al., 2007) have shown promise in curing *T. cruzi* infection in murine models, however, these drugs have not yet entered clinical trials possibly due to lack of financial support from the major drug companies for the development of new drugs against Chagas disease (Moncayo and Ortiz Yanine, 2006).

Treatment of chronic patients focuses on cardiac management (Rocha et al., 2003) that requires a specialized clinical infrastructure, and thus, is expensive and often beyond the reach of the patient. For example, in Brazil, considering that only 10% of infected individuals would develop chronic disease, the medical costs for the obligatory treatment could reach $250 million. Cardiac transplantation is an option for patients with severe cardiac disease; however, immunosuppression can lead to reactivation of infection with an intensity typical of acute Chagas disease, invasion of transplanted heart by parasites, and heart rejection.

No vaccines are currently available against *T. cruzi* infection.

PATHOGENIC MECHANISMS IN CHAGAS DISEASE DEVELOPMENT

Considerable debate exists regarding the pathomechanisms that are involved in Chagas disease development. No universally accepted model exists to explain the long latency period between infection and disease development, why a subset of individuals in the indeterminate phase progress to chronic disease, or what instigates or perpetuates the damage in the heart that ultimately results in Chagasic disease symptoms. We briefly discuss the pathomechanisms that are described in the literature.

Immune-Mediated Pathology: Autoimmunity or Parasite Persistence

A significant body of literature suggests that consistent inflammatory immune responses play a role in the development and/or propagation of pathological lesions in Chagasic hearts (Pathologic Immune Responses). In cardiac tissue, antibody- and cytotoxic T lymphocyte (CTL)-mediated responses, as well as the continuous production of cytokines and chemokines, may contribute to the selective destruction of cardiomyocytes, neurons, or endothelial cells, and the development of fibrosis in response to cytopathology (Brener and Gazzinelli, 1997). Two mechanisms, autoimmunity and parasite persistence, are proposed to sustain pathological inflammatory responses in Chagasic hearts (Soares et al., 2001).

The concept of autoimmunity is that polyclonal activation (Minoprio, 2001), molecular mimicry (Iwai et al., 2005), or the presence of cryptic epitopes shared by the host and parasites (Girones et al., 2001b) result in the recognition of self-antigens by the immune response elicited to control the parasite and, subsequently host tissue destruction. A growing number of studies have shown the pathogenic role of autoantibodies present in the serum of chronic mice and patients that react with various antigens in the heart, skeletal muscle, or nervous tissue (reviewed in Kierszenbaum (1999)). These include the β1-adrenoreceptor (Sterin-Borda and Borda, 2000), ribosomal P proteins (Kaplan et al., 1997), cruzipain (Giordanengo et al., 2000), and a novel Cha protein (Girones et al., 2001a). Common antigens between *T. cruzi* and human myocardial fibers (e.g., myosin) and auto-reactive T cells with specific cytotoxicity against myocardial fibers have been demonstrated in humans (Cunha-Neto et al., 1995; Cunha-Neto and Kalil, 2001). A cardiac myosin-specific autoimmune response and myocarditis can be induced by injecting several doses of subcellular antigens of *T. cruzi* in animals (Leon et al., 2004). The autoimmune theory, thus, suggests that the humoral and cellular immune reactions, elicited in response to *T. cruzi* infection, recognize self-antigens, are potentially harmful to the host, and contribute to the development and/or propagation of pathological lesions in Chagasic myocarditis (Leon and Engman, 2003). The lack of evidence that *T. cruzi*-induced self-reactive antibodies or T cells can induce disease upon transfer into a naïve host precludes us from defining chronic Chagasic cardiomyopathy as an autoimmune disease.

It is now recognized that human infection of many years' duration is associated with a nearly consistent low level of parasitosis (Higuchi et al., 2003). Recent studies using modern techniques, e.g., PCR, immunohistochemistry, and confocal microscopy, have detected parasite DNA or antigens in blood and heart tissue biopsies of experimental animals and chronic human patients (Anez et al., 1999; Mortara et al., 2000; Salomone et al., 2000; Caliari et al., 2002). It is proposed that parasite persistence provides sufficient, consistent antigens that work as a trigger for the hypersensitive response against myocardial fibers, leading to pathologic tissue injury, and, subsequently, to cardiac insufficiency.

Vascular Mediators in Endothelium

Yet, clinical-pathological severity is not universally correlated with the presence of parasites (Higuchi et al., 1993) and chronic inflammation (Palomino et al., 2000). This leads to the suggestion that other mechanisms must be involved. The hypothesis that vasculopathy contributes to Chagasic heart disease has developed from the observations indicating that both human and experimental infections cause a reduction in blood flow and an intense vasculitis. Bradykinin, a potent vasodilator, and endothelin 1 (ET-1), and thromboxane A2 (TXA2), two potent vasoconstrictors, have been identified in Chagasic hearts. Kinins convey the vasodilating response through their interaction with vascular receptors and lessen the detrimental effects of ischemia (Yang et al., 2001). Despite increased kinin expression, *T. cruzi*-mediated decrease in coronary flow was not normalized in infected rats, suggesting impaired kinin receptor function. Instead, activation of kinin receptors on cardiovascular cells was shown to contribute to an increased infectivity by *T. cruzi* (Scharfstein et al., 2000; Todorov et al., 2003). TXA2 and ET-1 may potentiate disease severity by promoting microvascular pathology, e.g., vasospasm, ischemia, and microthrombi (Petkova et al., 2001). Vascular mediators, in conjunction with cytokines induced by *T. cruzi* infection, may be significant to the development of microcirculatory abnormalities that are well documented in Chagasic hearts (reviewed in Mukherjee et al. (2003)).

Mitochondria Dysfunction and Oxidative Stress-Mediated Damage

Our studies suggest that Chagasic myocardium may be pre-disposed to sustained oxidative stress associated with mitochondrial dysfunction (reviewed in Garg (2005) and Zacks et al. (2005)). Cardiac tissue is extraordinarily dependent upon oxidative phosphorylation for energy to perform its functions. Accordingly, in cardiomyocytes, mitochondria are abundant. Mitochondria are the main producers of reactive oxygen species (ROS) in the heart and brain. Under normal conditions, NADH-ubiquinone oxidoreductase (CI) and ubiquinol-cytochrome c reductase (CIII) complexes of the respiratory chain release 2–4% of electrons to oxygen, resulting in superoxide (O_2^-) formation in mitochondria that is then converted to highly toxic hydroxyl ion (OH^-) and H_2O_2 by various reactions (Ide et al., 1999; Chen et al., 2003). An alteration in CI and CIII activities may result in increased ROS production in mitochondria (Ide et al., 1999; Chen et al., 2003), and is found in the myocardia of *T. cruzi*-infected mice (Vyatkina et al., 2004; Wen and Garg, 2004) and peripheral blood of seropositive Chagasic subjects (Wen et al., 2006b). Manganese superoxide dismutase (MnSOD) is the major O_2^- scavenger in mitochondria, and its decreased activity was noted during

acute-to-chronic disease development in infected murine myocardium (Wen et al., 2004). It was, therefore, proposed that a functional decline in the respiratory chain, increased ROS generation, coupled with an inability to efficiently scavenge the mitochondrial free radicals, predisposes Chagasic hearts to sustained ROS during infection and disease development.

At low levels, ROS induces cytokine and chemokine production (Rahman and MacNee, 2000), thus providing a potential mechanistic link between mitochondrial ROS generation and acute and/or chronic inflammation in Chagasic cardiomyopathy. The cytotoxicity of sustained oxidative stress is related to ROS' ability to oxidize cell constituents, including proteins, lipids, and DNA, which lead to deterioration of cellular structure and function and, ultimately, to cell death (Tsutsui, 2001; Martindale and Holbrook, 2002). The sustained occurrence of oxidative damage, as evidenced by consistent presence of protein carbonylation and lipids peroxidation products, was shown in the myocardium of an experimental model of Chagas disease (Wen et al., 2004) and in peripheral blood of human Chagasic subjects (Wen et al., 2006b; de Oliveira et al., 2007). Oxidative damage during Chagas disease may not only be due to increased ROS formation but also exacerbated by inefficient glutathione antioxidant capacity (glutathione peroxidase-GSH-glutathione reductase), as is noted in infected mice (Wen et al., 2004) and human subjects (Perez-Fuentes et al., 2003). Subsequently, recent studies have suggested that combinatorial anti-parasite/antioxidant therapies would be useful in controlling Chagas disease pathology. Treatment of experimental animals with phenylbutylnitrone antioxidant (Wen et al., 2006a) and human Chagasic patients with vitamin C and vitamin E antioxidants (Macao et al., 2007) was shown to be effective in reducing the oxidative insult–associated pathology in Chagas disease.

In summary, mitochondria are targets of a variety of endogenous and exogenous insults, including inflammatory mediators, elicited by *T. cruzi* infection. Depending upon the extent and duration of mitochondrial dysfunction, oxidative stress may initiate or contribute to destruction of heart tissue and consequent dysfunction through sustenance of inflammatory responses and oxidative damage of the cardiac components.

Other Mechanisms

Less well explored is the potential for the *T. cruzi* strain or clonal variation to account for different clinical outcomes (Tibayrenc, 1998). Human genetic differences may also contribute to the dichotomy between indeterminate and chronic disease manifestations (Williams-Blangero et al., 2003), although no conclusive evidence for genetic differences is present to date.

Summary

We conclude that the contributions of parasite persistence, autoimmunity, vascular mediators, mitochondria dysfunction, oxidative stress, and potentially, parasite strain or clonal variation and host genetics are not mutually exclusive and could contribute in part and/or act at distinct time points during *T. cruzi* infection to initiate and sustain the observed, multifaceted cardiac pathology. The sum of these factors may also determine the degree of pathophysiology the infection may evoke and the severity of chronic disease. An important implication of these studies is that preventing infection or controlling the acute parasite load below a threshold level would be effective in decreasing the tissue damage imposed by multiple pathogenic mechanisms and lead to decreased disease severity. Obviously, these observations provided an impetus for vaccine development against *T. cruzi*, which is also favored by the fact that the effector mechanisms capable of controlling parasite burden were delineated.

VACCINE DEVELOPMENT AGAINST *T. CRUZI*

Given the current knowledge about the status of protective immunity from *T. cruzi* (see section Protective Immune Responses), a successful vaccine against the parasite is envisioned to elicit a long-term, lytic antibody response, type 1 cytokines, and CTLs. There are two stages of the parasite against which vaccines can be designed. Vaccines against trypomastigotes as they enter host cells following the bite of an infected triatomine, or the burst of an infected cell, will prevent the initiation or persistence of infection, and limit the parasitemia. Vaccines against intracellular replicative amastigotes would arrest the propagation of parasite in a host and prevent the parasite from entering the blood. Both types of vaccines would arrest or attenuate disease development in humans and the reservoir mammalian host. In addition, vaccines against either stage of the parasite would prevent triatomine infection and, thus, interrupt or reduce parasite transmission in both human and reservoir populations, as well as in insects.

Historical Perspective

Early efforts in developing prophylactic vaccines against *T. cruzi* tested killed parasite preparations as immunogens. Examples include *T. cruzi* killed by: (i) chemical treatment, e.g., thimerosal, formalin, glutaraldehyde; (ii) physical methods, e.g., pulverization, freezing and thawing, sonication, or pressure disruption; and (iii) irradiation. These antigenic preparations were tested for vaccine potential in various animal models, including mice, guinea pigs, dogs, and monkeys. Vaccination with chemically treated *T. cruzi* failed to provide any protection from lethal challenge infection. Other vaccination approaches generated a degree of resistance to *T. cruzi*; immunized animals controlled acute parasitemia and survived (70–100%) acute infection (Table 69.1). Similar efforts utilizing subcellular fractions, e.g., flagellar, soluble, or membranes, as vaccines also demonstrated an elicitation of partially protective immunity. For example, immunization with crude flagellar extracts enhanced resistance to *T. cruzi*, evidenced by a 90% survival rate of mice from challenge infection (Ruiz et al., 1986). Immunization of mice with *T. cruzi* soluble extract elicited IFN-γ and prevented death from an otherwise lethal infection (Garcia et al., 2000). Most of these approaches utilized the epimastigote, the insect stage of the parasite, that was later identified as expressing different antigens from those found in the infective and intracellular stages of *T. cruzi.* An absence of immunogenic proteins in epimastigotes, or a loss of protective epitopes during inactivation and fractionation, was believed to be the cause for the limited success met in these attempts in vaccine development.

The next series of efforts tested live vaccines, consisting of *T. cruzi* strains attenuated by treatment with drugs or pharmacological agents, or by serial passage in cultures, for their potency in experimental animals (mice and dogs). These vaccines were largely effective in controlling subsequent infections by virulent strains. Vaccinated animals exhibited decreased parasitemia and increased survival rates compared to unimmunized animals (Table 69.1). The danger of reversion of the attenuated strains to a virulent form and the likelihood of increased virulence of attenuated strains in immunocompromised individuals rendered these vaccines impractical. These studies, however, showed that a prophylactic vaccine capable of eliciting protective immunity with a minimal risk of biological reversion to virulent phenotype would be useful in controlling *T. cruzi* infection and disease, and provided a foundation for the identification of target antigens of the immune responses and the development of subunit vaccines.

Efforts Toward Identification of *T. cruzi* Antigenic Targets

The antigenic targets capable of eliciting the desired immune responses (see Protective Immune Response) at a level that confers protection from infection are the best choice for subunit vaccine development. Early studies employed random approaches, e.g., screening of expression libraries with immune sera from infected animals or human patients, screening with antigen-specific monoclonal antibodies, and amplification of the antigen-encoding genes (Ruiz et al., 1990; Malchiodi et al., 1993; Low and Tarleton, 1997) for the identification of putative vaccine candidates. These approaches, though successful in characterization of a variety of *T. cruzi* proteins, often led to the discovery of antigens capable of eliciting an antibody response only.

The diploid genome (106–110 Mb) of *T. cruzi*, distributed in 35–40 chromosomal bands, contains ~22,500 proteins encoded by genes (El-Sayed et al., 2005). The complexity of the *T. cruzi* genome has necessitated the development of logical strategies to determine which parasite proteins are the likely choice for immune activation. Garg et al. (Garg et al., 1997) employed a transfection system and expressed chicken ovalbumin (OVA), the classical immunogen, in different cellular compartments of *T. cruzi*. Antigen-presenting cells infected with *T. cruzi* expressing OVA as a GPI-anchored surface protein or as a secreted protein were recognized and lysed by the OVA-specific CTLs in vitro. Also, parasites expressing GPI-anchored or secreted OVA elicited the expansion of OVA-specific CTLs and antibodies in infected mice (Garg et al., 1997; Kumar and Tarleton, 2001). It was inferred that during the process of replication and/or differentiation, *T. cruzi* releases GPI-anchored and secretory proteins in host cell cytoplasm where they are degraded by proteosome enzymes. The resulting peptides that transported to endoplasmic reticulum are associated with MHC class I molecules, and displayed on the surface of infected cells, where they can be recognized by circulating $CD8^+$ T cells. On extracellular trypomastigotes and amastigotes, these same proteins expressed in a membrane-associated form, are engulfed and processed by phagocytic cells, displayed in association with MHC class II molecules, and can be recognized by $CD4^+$ T cells that provide help for the activation and proliferation of $CD8^+$ T and B cells. These studies concluded that GPI-anchored proteins, abundantly expressed in infective and intracellular stages of *T. cruzi*, and the secreted proteins are the most likely source of peptides for immune activation.

Accordingly, during the last 10 years, several surface proteins of *T. cruzi* have been identified, and their immunogenic potential examined. The extracellular and intracellular life cycle stages of *T. cruzi* adapt to sudden changes in the environment and survive in generally unfavorable conditions by changing the composition of surface glycoproteins. Most (but not all) of these surface proteins are attached to the plasma membrane by GPI anchor, their expression is developmentally regulated, and contain stage-specific modifications that ultimately reflect their functional importance in the life cycle and provide plausible targets for vaccine development.

We briefly describe the abundantly expressed and other surface proteins of *T. cruzi* and evidence that they are recognized as antigenic targets of immune responses elicited in infected experimental animals and humans.

Abundantly Expressed Surface Antigens

Many of the GPI-anchored surface proteins are encoded by genes belonging to large families, e.g., trans-sialidase (TS) super family (737 genes), mucins (662 genes), mucin-associated surface proteins (MASPs, 944 genes), and glycoprotein 63s (GP63s, 174 genes) (El-Sayed et al., 2005). These gene families are largely *T. cruzi*-specific and account for >18% of the total protein-encoding genome.

Trans-sialidases are a heterogenous group of GPI-anchored proteins, a majority of which are expressed in the trypomastigote stage. Most TS family members contain a conserved sialidase super family motif (VTVxNVxLYNR) but are not enzymatically active. The enzymatically active TS variants consist of 12-amino-acids long shed acute phase antigen (SAPA) repeats, are expressed in the trypomastigote stage, and catalyze the sialylation of parasite mucins through transfer of sialic acid from the host cell surface (Schenkman et al., 1994). This step is necessary for *T. cruzi* attachment and invasion of host cells, survival in and escape from the parasitophorous vacuole, and differentiation into a replicative amastigote form (Hall, 1993; Schenkman et al., 1994; Tan and Andrews, 2002). TC85, another member of the TS super family, binds to laminin and cytokeratin in vitro, and is hypothesized to facilitate movement of *T. cruzi* through the extracellular matrix, allowing it to traverse the tissues to invade other organs (Magdesian et al., 2001).

The substantial diversity of the TS gene family has likely developed in response to host immune pressure. Accordingly, several of the TS family members are identified to be targets of humoral and cell-mediated immune responses in Chagasic patients and experimental animals. A trypomastigote surface antigen, TSA1 (85 kDa), was the first *T. cruzi* protein shown to be the target of $CD8^+$ T lymphocytes in infected mice (Wizel et al., 1997) and humans (Wizel et al., 1998b). TSA1 peptide-specific $CD8^+$ T cell lines were cytotoxic against peptide-sensitized or infected cells, secreted IFN-γ and TNF-α, and were able, upon adoptive transfer, to confer substantial protection against challenge infection in mice (Wizel et al., 1997). Antibodies to enzymatically active TS (120–200 kDa) have been detected in the sera of Chagasic patients and experimental animals infected with *T. cruzi* (Pereira-Chioccola et al., 1994). The TS catalytic domain was identified to contain epitopes recognized by IFN-γ-producing type 1 cells and antibodies in Chagasic patients (Ribeirao et al., 2000).

Amastigote stage-specific proteins of TS family, i.e., ASP1 (Santos et al., 1997), ASP2 (Low and Tarleton, 1997), and ASP9 (Boscardin et al., 2003) have been identified, although their precise role is presently

unknown. ASP1 (78 kDa) and ASP2 (83 kDa) were shown to be the targets of in vivo (mice)-generated CTLs that were parasite- and peptide-specific, MHC-restricted, and CD8-dependent (Low et al., 1998). Human circulating CTLs specific for ASP1- and ASP2-derived peptides were detected in HLA-A2$^+$ *T. cruzi*-infected patients (Wizel et al., 1998b).

Mucins contain a large proportion (85%) of *O*-glycosidic-linked carbohydrates. Mucins of 35–50 kDa are present in insect stage epimastigotes and metacyclic trypomastigotes, whereas larger (80–200 kDa) mucin proteins are expressed in bloodform trypomastigotes. The large heterogeneity of mucins is due to the presence of different core proteins along with the complexity and extent of oligosaccharide side chains (Schenkman et al., 1993). Mucins serve as acceptors of sialic acid in a trans-sialylation reaction catalyzed by TS and are essential for parasite protection and survival in a mammalian host (Schenkman et al., 1993; Almeida et al., 1999). *T. cruzi* mucins, such as GP35/50 and SSP3, expressed in metacyclic and trypomastigote stages, respectively, have been ascribed an analogous function in parasite ligand–host receptor binding (Schenkman et al., 1993). The GPI component of mucins is a powerful inducer of polyclonal B cells, inflammatory cytokines, and macrophages (Acosta-Serrano et al., 2001). The differences in the structure, composition, and abundance of the mucin proteins may contribute to infectivity, virulence, and tissue tropism of *T. cruzi* or constitute an immune-evasion mechanism, but this has not yet been experimentally proven.

MASP family members consist of chimeric domains, i.e., an N- or C-terminal conserved domain combined with the N- or C-terminal domain of mucin or the C-terminal domain from the TS super family (El-Sayed et al., 2005). The mechanism of generation of such chimeric MASPs, their functions in parasite life cycle or immunogenic potential are unknown.

GP63 family members were recently identified in *T. cruzi.* These are homologs of *Leishmania major* surface protease, GP63, and may serve analogous function as a surface protease (Cuevas et al., 2003). The immunologic potential of *T. cruzi* GP63s has not been examined to date.

Other Immunogenic Proteins

Complement regulatory protein (CRP), the 160 kDa surface antigen of trypomastigotes was named so because of its ability to protect *T. cruzi* from complement-mediated lysis (Norris et al., 1989). Antibodies to CRP have been detected in sera of human Chagasic patients (Norris et al., 1994).

Cruzipain, the major lysosomal cysteine proteinase (60 kDa) of *T. cruzi*, is encoded by multiple polymorphic tandemly organized genes located on different chromosomes (Campetella et al., 1992). Cruzipain consists of a catalytic moiety with high homology to cathepsins S and L, and a C-terminal domain, characteristic of type I cysteine proteinases of trypanosomatids (Cazzulo et al., 2001). The proteolytic function of cruzipain is essential for parasite differentiation and invasion of mammalian cells (Cazzulo et al., 2001). Irreversible inhibitors of cruzipain blocked parasite development, exhibited trypanocidal activity, and are currently examined for their therapeutic utility against *T. cruzi* (Santos et al., 2005). Cruzipain-derived epitopes were recognized by antibodies and IFN-γ-producing, CD8$^+$ immune cells in Chagasic patients, signifying its immunogenicity (Fonseca et al., 2005).

FCaBP, a 24 kDa flagellar calcium-binding protein, is expressed in all life cycle stages of *T. cruzi.* The N-terminal 24 amino acids, modified by palmitoylation and myristoylation, facilitate the flagellar localization of FCaBP (Godsel and Engman, 1999). Immune sera from *T. cruzi*-infected experimental animals and humans exhibit highly specific, sensitive reactivity with FCaBP (Godsel et al., 1995). FCaBP-specific CD8$^+$ T-cell are generated in mice infected with *T. cruzi* (Fralish and Tarleton, 2003).

GP90 (90 kDa) and GP82 (82 kDa), expressed on a plasma membrane of metacyclic trypomastigotes, interact with distinct host cell receptors. Attachment of the GP82-host cell receptor triggers a Ca^{2+} response in the target cell as well as in the parasite, an event that enables parasites to gain entry to the host cell (Yoshida et al., 2000). Binding of GP90 to its receptor failed to induce a Ca^{2+} response in parasites as well as host cells (Ruiz et al., 1998). Reduction in GP90 expression on the parasite surface resulted in increased infectivity, leading to a suggestion that GP90 may modulate parasite invasion by altering GP82-host receptor interactions (Malaga and Yoshida, 2001).

GP82-specific antibodies cross-reacted with heterologous antigens (GP90 and GP30/55), while antisera to GP90 reacted only with the homologous antigen (Yoshida et al., 1993). GP90 is specifically recognized by antisera from Chagasic, but not leishmaniasis, patients (Schechter et al., 1983), thus, suggesting its diagnostic importance. Immunization with GP82 or GP90 stimulated *T. cruzi*-specific CD4$^+$ T cell proliferation in lymph nodes of mice, signifying immunogenicity of the two glycoproteins (Yoshida et al., 1993).

A 11 kDa, cytoskeleton-associated, kinetoplastid membrane protein, KMP11, is highly conserved among trypanosomes (Thomas et al., 2000), though the biological role it plays remains unclear. The immunologic role

of KMP11 was evidenced by the detection of KMP11-specific antibodies in sera of chronically infected patients (Trujillo et al., 1999). Spleen cells from KMP11-immunized C57BL/$6^{A2/Kb}$ transgenic mice, when incubated with an immunodominant A2-specific peptide from KMP11, lysed antigen, or peptide-pulsed Jurkat$^{A2/Kb}$ cells, suggesting the presence of a human CTL epitope in KMP11 (Maranon et al., 2001).

LYT1 (61 kDa), a secreted antigen, is expressed in all parasite life cycle stages. Genetic deletion studies showed that LYT1 is not required for viability of epimastigotes, but is essential for parasite development in mammalian cells. *LYT1*-deficient mutants exhibited accelerated in vitro development, reduced infectivity, and diminished hemolytic activity that was restored upon complementation with episomally expressed LYT1 (Manning-Cela et al., 2001). LYT1-derived H-$2K^b$ peptides were presented in association with MHC I molecules. Antigen-specific CTLs generated in *T. cruzi*-infected mice showed high levels of lytic activity against peptide-pulsed target cells, thus signifying the immunogenicity of LYT1 (Fralish and Tarleton, 2003).

Paraflagellar rod proteins (PFR1-4, MW ~70 kDa; PFR5-6, 78–86 kDa) are highly conserved among different *T. cruzi* strains of clinical importance (Fouts et al., 1998; Clark et al., 2005). PFRs constitute a major structural component of flagellum and are critical for cell motility (Fouts et al., 1998; Clark et al., 2005). PFRs are highly immunogenic. PFR-specific $CD8^+$ T cells were elicited in infected mice and showed high levels of lytic activity against peptide-pulsed target cells and secreted IFN-γ in response to parasite-infected target cells (Wrightsman et al., 2002). PFRs are recognized by sera antibodies from indeterminate and chronic Chagasic patients (Michailowsky et al., 2003). Incubation of recombinant PFRs with PBMCs of Chagasic patients induced proliferation of antigen-specific, IFN-γ producing $CD4^+$ and $CD8^+$ lymphocytes (Michailowsky et al., 2003).

TC52, a 52 kDa trypanothione: glutathione disulfide thioltransferase enzyme, is essential for maintaining the intracellular thiol-disulphide redox balance in *T. cruzi* (Moutiez et al., 1997). *T. cruzi* heterozygous mutants deleted of one *TC52* allele exhibited low virulence and caused an attenuated form of Chagas disease in experimental animals. Deletion of both *TC52* alleles was lethal, indicating the importance of TC52 in parasite survival (Garzon et al., 2003). This enzyme is specific for the parasite (Moutiez et al., 1997) and targeted for therapeutics development. While TC52 was found to be immunologically silent in acutely infected animals, the immunomodulatory role of TC52 was suggested by the fact that recombinant TC52, in synergy with IFN-γ, stimulated gene expression for iNOS and IL-12, and NO production in ϕs (Fernandez-Gomez et al., 1998). A TC52-specific immune response appeared late in *T. cruzi* infection and may play a role in the modulation of its biological function(s) (Fernandez-Gomez et al., 1998).

The continuing progress in *T. cruzi* genomics, proteomics, and bioinformatics, followed by wet-lab testing of several genes in experimental models, is likely to further expand the pool of antigenic targets of *T. cruzi*.

Subunit Vaccines in Development (over the Last 10 Years)

A Brief Overview

Armed with data on protective immune mechanisms and their antigenic targets, researchers interested in vaccine development against *T. cruzi* were required to identify effective antigen delivery systems to elicit potent immune responses to the vaccine candidates. Initial studies utilized a protein immunization approach to test the vaccine potential of *T. cruzi* antigens. Most of these studies were designed such that the protective efficacy of putative vaccine candidates was determined based upon survival following a lethal challenge infection. Efforts were made to enhance the protective efficacy of protein vaccines by codelivery of adjuvants, use of alternative routes of antigen delivery, and by increasing the amount or the number of doses.

In subsequent studies, a DNA immunization approach was favored due to the ease of construction and production of the vectors, the stability of DNA, and the ability to enhance the immune response by the codelivery of genes encoding cytokines. Most importantly, this method of antigen delivery has proved to be efficient in eliciting antibodies, Th1 cytokines, and $CD8^+$ T cell immune responses to encoded antigens. Successful induction of humoral and/or cellular immune responses to the plasmid-encoded antigens using various routes of gene delivery has been shown to provide partial or complete protection against numerous infectious agents (reviewed in Donnelly et al. (2005)). *T. cruzi* proteins identified as targets of specific antibodies and CTLs in infected mice and humans (see section Efforts Toward Identification of *T. cruzi* Antigenic Targets) were tested as DNA vaccines in experimental models. Considering that complete genes were incorporated into the DNA vectors, epitopes capable of being presented by many MHC alleles were expected to be present. Accordingly, several of the genes were tested and afforded protective immunity in multiple mouse strains.

In parallel with the efforts toward identification of vaccine candidates, adjuvants were tested to enhance or skew the immune responses toward desirable Th1 type. Use of adjuvants to increase protective immunity against *T. cruzi* dates back to 1965 (Menezes, 1965) when saponin, a derivative from the bark of *Quillaja saponaria (Quil A*), was injected to enhance the protective efficacy of immunogens. Co-inoculation of saponin with freeze-thaw-inactivated parasites stimulated a Th1 type immune response, and slightly increased protection from challenge infection (Johnson et al., 1963). Recent studies have examined the utility of IL-12, GM-CSF, CD40, HSP70, and CpG oligodeoxynucleotides in enhancing the Th1 responses to defined antigen vaccines. GM-CSF was chosen as a genetic adjuvant because it is a potent cytokine capable of enhancing the antigen presentation capability of antigen-presenting cells, such as dendritic cells. In addition, it facilitates B- and T-cell-mediated immunity (Warren and Weiner, 2000). IL-12 is a key cytokine involved in $CD8^+$ T cell activation and proliferation, and in directing the immune responses to type 1 (Pan et al., 1999). Similarly, other adjuvants were chosen for their ability to skew the immune response to a protective Th1 type through different mechanisms. We discuss the efforts to date focused on testing and enhancing the protective efficacy of subunit vaccines against *T. cruzi* (Table 69.2).

Subunit Protein Vaccines

Initial studies examined the vaccine potential of GPI-proteins of *T. cruzi*, selected for their abundant expression and immunogenicity (see section Efforts Toward Identification of *T. cruzi* Antigenic Targets).

GP90 Though recognized as an antigenic target in infected mice and humans, GP90 proved to be poorly immunogenic as a vaccine. Specific antibody and cell-mediated immunity were potentiated when GP90 was codelivered with saponin adjuvant, and these immune responses were effective against a range of *T. cruzi* strains. Further, the levels of acute tissue damage, as measured by production of auto antitissue immunoglobulins, were significantly reduced in immunized mice and marmosets (Scott et al., 1985). All animals, immunized and nonimmunized, remained xenodiagnosis-positive (tested at 60 weeks postinfection), which suggested sterile immunity was not achieved.

GP82 Mice immunized with a C-terminal peptide of GP82 (224–516 amino acids) plus alum elicited specific antibodies that were not protective; these antibodies lacked agglutinating or complement-dependent cytotoxicity and failed to neutralize parasite infectivity. The substantial resistance exhibited by immunized mice to acute infection was correlated with intense proliferation in the spleen of IFN-γ-producing $CD4^+$ T cells (Santori et al., 1996).

GP56 Immunization of mice with purified GP56, followed by challenge infection, provided increased survival by only 4 days compared to those not immunized before infection. Considering an epimastigote stage protein that is not expressed by infective trypomastigote and intracellular stages, limited protection afforded by GP56 was not surprising (Harth et al., 1994).

Cruzipain Cruzipain-immunized mice exhibited delayed death upon lethal challenge infection (Laderach et al., 1996). Efforts to enhance the protective efficacy of cruzipain utilized codelivery of IL-12 (plus neutralizing anti-IL-4 antibody) (Schnapp et al., 2002) or CpGODN (Frank et al., 2003), selected for their capacity to drive immunity toward a Th1 bias. Immunization of mice by either of these vaccines elicited high specific antibody titers. Spleen cells from immunized mice, when stimulated in vitro with antigen or infected ϕs, strongly proliferated and produced high levels of IL-2 and/or IFN-γ cytokines. All immunized mice exhibited substantial resistance to *T. cruzi*, evidenced by low parasitemia and 80% survival to acute infection. While cruzipain-specific Th1 responses were associated with protective immunity to *T. cruzi* in vitro and in vivo, adoptively transferred cruzipain-specific T cells failed to confer protection against challenge infection in mice, indicating that additional immune mechanisms were important to cruzipain-specific immunity. Recombinant attenuated *Salmonella typhimurium* serovar expressing cruzipain served to elicit immunity to mucosal *T. cruzi* infection in mice.

PFR The protective efficacy of PFR proteins has been tested in detail. First, PFRs purified from *T. cruzi* were shown to protect mice against lethal challenge infection that was markedly governed by an antigen delivery route. The subcutaneous route of antigen delivery elicited protective immunity, while intraperitoneal injections elicited a strong, nonprotective antibody response (Wrightsman et al., 1995). Similar observations were made with recombinant PFRs. The subcutaneous, but not intraperitoneal, administration of PFR1 and PFR2 (individually or in combination) with Freund or alum adjuvant provided significant protection in 100% and 83% mice, respectively, against

[a] Experimental animals were observed for survival for *n* days postinfection.
[b] These antigens were shown to provide variable degree of protection in different mouse strains (data presented is from the animal model that exhibited best protection).
[c] Upon challenge infection, immunized animals exhibited very low (≤10%) parasitemia as detected in unimmunized/infected animals (data presented is from the animal model that exhibited best protection).
[d] Upon challenge infection, immunized animals exhibited moderate (~50%) parasitemia as detected in unimmunized/infected animals (data presented is from the animal model that exhibited best protection).
[e] Upon challenge infection, immunized animals exhibited similar parasitemia as detected in unimmunized/infected animals (data presented is from the animal model that exhibited best protection).
[f] Immunization with these antigens was effective in decreasing the severity of chronic disease, evaluated by histopathological analysis of cardiac tissue biopsies.

a lethal *T. cruzi* challenge. PFRs alone or delivered with other adjuvants (QS-21, Ribi-700, IL-12), irrespective of the route of antigen delivery, failed to control *T. cruzi* infection (Miller et al., 1996). Protection afforded by PFRs plus Freunds or alum adjuvants was associated with high levels of IFN-γ and IL-2 and low levels of IL-4 production in immunized mice. Using knockout mice depleted in specific immune functions, it was shown that PFR-induced protective immunity was MHC I- and $CD8^+$ T cell-dependent, and B cell responses were not necessary for resistance to *T. cruzi* infection (Miller et al., 1997). The function of $CD4^+$ T cells in PFR-immunized mice was associated with parasite clearance, as was also evidenced by the fact that these $CD4^+$ T cells released IFN-γ and stimulated NO production in infected ϕs, essential for killing of *T. cruzi* (Miller et al., 1997). Others showed that protection against *T. cruzi* in PFR-immunized mice was provided by induction of a highly polarized type 1 cytokine profile (Luhrs et al., 2003).

TC52 TC52 recombinant protein–elicited protection from infection in immunized mice was associated with TC52-mediated: (i) alleviation of immunosuppression otherwise presented by acute *T. cruzi* infection, and (ii) enhanced maturation of dendritic cells that play a central role in initiation of Th1 immunity (Ouaissi et al., 2002). The activation/maturation of dendritic cells from immunized mice was evidenced by increased CD83 and CD86 expression, inflammatory chemokines (IL-8, MCP-1, and MIP-1α) production, and presentation of potent co-stimulatory properties. Codelivery of alum or *Bordtella pertusis* adjuvants enhanced the protective efficacy of TC52 in immunized/infected mice.

CRP Immunization of mice with either the protein or DNA CRP vaccine elicited a Th1 type T cell response, comparable antibody titers, and similar immunoglobulin G isotype profiles. Only mice immunized with CRP-encoding plasmid produced antibodies that exhibited complement-dependent cytotoxicity to parasites and were protected against a lethal challenge infection with *T. cruzi*; thus suggesting the superiority of DNA immunization over protein immunization with recombinant CRP (Sepulveda et al., 2000).

ASP2 Protective efficacy of ASP2 was reported recently. Immunization of A/Sn mice with ASP2 recombinant protein alone or with *ASP2* DNA followed by ASP-2 recombinant protein resulted in 53% and 75 % survival, respectively (Araujo et al., 2005). Six ASP2-recombinant peptides, representing different segments of the ASP2 protein were tested for their efficacy as immunogen with alum and CPGODN 1826 adjuvants. ASP2 peptide consisting of the $CD8^+$ epitope provided 100% survival from challenge infection, indicating the importance of a $CD8^+$ T cell response in eliciting protection against *T. cruzi* infection (Araujo et al., 2005).

Subunit DNA Vaccines

Trans-Sialidase Genes The vaccine potential of several members of the TS gene family has been examined by the authors and others. *TSA1*, to our knowledge, was the first subunit DNA vaccine tested against *T. cruzi.* Intramuscular immunization of *TSA1* in C57BL/6 (H-2^b) and Balb/c (H-2^d) mice generated efficient antiparasite antibody responses and primed CTLs that lysed antigen-presenting cells in an antigen-specific, $CD8^+$ T cell-dependent manner. When challenged with *T. cruzi*, immunized mice (64% C57BL/6 and 89% Balb/c) survived lethal infection (Wizel et al., 1998a).

We have evaluated the protective efficacy of *ASP1* and *ASP2* DNA vaccines. C57BL/6 mice immunized with ASP1- or ASP2-encoding plasmids elicited protective levels of immune responses, evidenced by decreased parasitemia and 50% and 80% survival rates, respectively, from lethal infection (Garg and Tarleton, 2002). Codelivery of *IL-12*- and *GM-CSF*-encoding plasmids with *ASP1*- or *ASP2*-expression vectors resulted in splenomegaly, an indicator of the increase in lymphocyte activation and enhanced immune reactivity. In addition, an increase in the induction of immune responses, i.e., antigen-specific CTL activity, parasite-specific humoral immune responses, and secretion of type 1 cytokines (IFN-γ), correlated with improved resistance to challenge infection, was observed following co-administration of cytokines with *T. cruzi* antigen-encoding plasmids. Importantly, mice immunized with *ASP2* plus cytokine adjuvants exhibited better control of chronic inflammation and pathological lesions. This was the first observation to demonstrate that vaccination strategies capable of reducing the parasite burden below a threshold level will be successful in controlling the severity of chronic disease and provided a foundation for testing the vaccine potential of other *T. cruzi* antigenic targets as DNA vaccines.

Others have reported the protective efficacy of *ASP2* in A/Sn mice, which are highly susceptible to *T. cruzi*. Mice immunized with ASP2-encoding plasmid exhibited moderate parasitemia and minimal inflammatory foci in the heart and striated muscle. Subsequently, 63% of the immunized mice survived

as compared to controls that succumbed to challenge infection. Protective immunity was associated with increased secretion of IFN-γ by spleen cells and the presence of ASP-2-specific $CD8^+$ T cells (Vasconcelos et al., 2004).

The immunogenic potential of a *TS* gene encoding the enzymatically active trans-sialidase was demonstrated by Costa et al. (1998). Mice immunized with *TS*-expressing plasmid were protected from challenge infection. The protective efficacy achieved by a DNA–DNA *TS* vaccine was not increased by DNA-recombinant protein vaccination approach (Vasconcelos et al., 2003). Along with the protection afforded by T-cell-mediated immune responses, a strong antibody response that was elicited in immunized mice contributed to protection from infection through inhibition of the enzymatic activity of the native enzyme. It was proposed that inhibition of TS activity prevented the sialylation of parasite surface mucins, a step essential for attachment, invasion, and survival of *T. cruzi* (details in section Abundantly Expressed Surface Antigens).

TSSA, another TS surface antigen, when delivered as a DNA vaccine in mice, elicited $CD4^+$ and $CD8^+$ T cell-dependent protective immunity against *T. cruzi*. Codelivery of IL-12 DNA improved the antigen-specific CD8+ T cell activity and vaccine efficacy of *TSSA*, as evidenced by the efficient control of parasitemia and tissue inflammation, and increased survival from infection in immunized mice (Katae et al., 2002). RANK-L, the ligand to receptor activator of NFκB, is implicated in CD40-CD40L-independent T cell priming by dendritic cells. Similar to IL-12, the co-administration of RANK-L-encoding gene enhanced the $CD8^+$ T cell-dependent vaccine efficacy of TSSA in mice (Miyahira et al., 2003).

KMP11, nonimmunogenic itself, was expressed in fusion with heat shock protein 70 (HSP70) that has adjuvant properties (Qazi et al., 2005). Murine immunization with *KMP11-HSP70* elicited antigen-specific, long-lasting IgG2a antibody response and $CD8^+$ CTL lytic activity, and subsequently, better control of parasitemia and 50% survival from lethal infection (Planelles et al., 2001).

A LYT1-encoding gene delivered with IL-12 and GM-CSF elicited antigen-specific $CD8^+$ CTLs and resulted in an 80% survival rate following lethal challenge infection (Fralish and Tarleton, 2003).

PFR2 and PFR3 were expressed in fusion with HSP70 for its adjuvant properties, and delivered to chronically infected mice. Immunization with PFR2-HSP70 and PFR3-HSP70 induced high levels of PFR-specific IgG2a antibodies. However, only PFR2-HSP70 elicited a statistically significant CTL response that was sufficient to provide protection against *T. cruzi* infection (Morell et al., 2006).

Not all of the antigenic targets were found to be useful as DNA vaccine candidates. For example, genes encoding FCaBP, TCβ3, mucins, and CCL4/MIP-1β failed to provide any protection from *T. cruzi* infection (Katae et al., 2002; Fralish and Tarleton, 2003; Roffe et al., 2006). It is interesting that FCaBP and TCβ3 were recognized by CTLs in infected mice and elicited a cell-mediated immune response in mice when delivered as a DNA vaccine, implying that mere elicitation of $CD8^+$ T cell responses by an antigen is not indicative of its vaccine potential. Similarly, all of the genes that provided protection in one mouse strain were not protective in other inbred strains of mice. Examples include *ASP1*, *ASP2*, *TSA1* that were tested individually or in combination (Garg and Tarleton, 1998), and *TSSA* (Katae et al., 2002). All of these genes failed to alter susceptibility of C3H mice to *T. cruzi* infection, suggesting host genetic restriction may also contribute to inefficacy of vaccine candidates.

Multicomponent Subunit Vaccines

Considering that an increase in the level and diversity of *T. cruzi*-specific immune responses could enhance the protective capacity of DNA vaccines, some investigators tested immunization with multiple genes encoding members of the TS or mucin families. The ability of the mixed genes to elicit protective immune responses depended upon: (i) the amount of a given plasmid sufficient to elicit protective responses, and (ii) the total amount of DNA that can be injected without toxicity. Various dilutions of TS family members (*ASP1*, *ASP2*, and *TSA1*) (0.001–33μg/mouse) were tested and showed that codelivery of as little as 1ng of each gene (plus IL-12 and GM-CSF adjuvants) resulted in the activation of a substantial, antigen-specific CTL response, while 10ng of each DNA was needed to induce moderate levels of a parasite-specific antibody response (Garg and Tarleton, 1998). The level of resistance to *T. cruzi* infection correlated with the amount of DNA delivered, the maximal protection being obtained with 1μg of each vaccine DNA plus cytokines. An inhibitory effect on the elicitation of antigen-specific immune responses was not observed when mice were immunized with the mixture of plasmids, indicating that multiple genes with or without cytokine adjuvants can be used in developing immunization strategies for control of *T. cruzi* infection. The level of protection from *T. cruzi* infection induced in mice immunized with mixture of TS family members (Garg and Tarleton, 2002; Fralish and Tarleton, 2003) was, however, not significantly better than that induced in mice immunized with individual

family members (Table 69.2). Attempts to enhance the protective efficacy of TS family members by a DNA prime-protein boost approach were also not successful (Vasconcelos et al., 2003). No protection was observed in mice immunized with a pool of genes encoding mucin family members (Fralish and Tarleton, 2003). The findings of either no or little induction of protective immunity with a cocktail of antigen-encoding vectors was attributed to the fact that genes of large families may express shared epitopes that do not present any protective benefits in inbred mice. It was anticipated that the potential synergistic immunologic benefit of a combination of epitopes from multiple genes would induce a higher frequency of immune effectors in heterogeneous host populations and provide effective immunity against diverse parasite strains, both of which would likely be verified in future studies.

Genome-Based Vaccines

By using the sequence database of *T. cruzi* (El-Sayed et al., 2005), there is the potential to conduct a large-scale, unbiased screening of the *T. cruzi* genome for the identification of genes of interest. Sophisticated bioinformatics programs are designed to evaluate gene functions on the basis of homologies to genes characterized in other organisms and the presence of motifs predictive of targeting, cellular localization, surface expression, and functional characteristics of the gene product. Such programs have the ability to circumvent the time-consuming, laborious experimental techniques and allow us to directly proceed from sequence information to antigenic target identification and vaccine design. Web-based bioinformatics tools coupled with an experimental strategy have been employed for the identification of putative genes encoding GPI-anchored or secreted proteins in a *T. cruzi*-expressed sequence tag (EST) database. Molecular and biochemical characterization of eight of the sequences selected by this approach demonstrated that the encoded proteins were conserved in the genome of *T. cruzi* strains of clinical importance and expressed as surface proteins during different developmental stages of the parasite. When delivered as a DNA vaccine in mice, the selected antigens elicited a trypanolytic antibody response that was in agreement with the intensity of the surface expression of these proteins in infective and intracellular stages of the parasite (Bhatia et al., 2004). This study validated the hypothesis that a *T. cruzi* sequence database committed to appropriate screening strategies would be an efficient resource for the identification of potential vaccine candidates.

Therapeutic Vaccines

No approved postexposure immunoprophylactic or therapeutic treatment exists for *T. cruzi*. Several studies have shown improved survival and preservation of cardiac structure in acutely or chronically infected mice treated with TSA1-, Tc52-, and TC24-encoding genes (Dumonteil et al., 2004; Sanchez-Burgos et al., 2007) that was associated with vaccine-induced rapid increase in the number of $CD4^+$ and $CD8^+$ T cells (Zapata-Estrella et al., 2006). Conversely, treatment of acutely infected mice with ASP2-, and TS-encoding plasmids was not effective in controlling parasetimia or prolonging survival (Sanchez-Burgos et al., 2007; Dumonteil, 2007).

Recombinant Virus Vaccines

Replication-deficient recombinant human viruses have an unprecedented ability to induce strong Th1 type immune response (Rocha et al., 2004). Several studies have been performed to evaluate the ability of the recombinant viruses encoding *T. cruzi* genes in inducing a long-lasting and protective immunity against *T. cruzi* infection in experimental models. Priming of immune response in mice with adenovirus encoding a single $CD8^+$-T-cell epitope derived from *TSSA* antigen, followed by boosting with vaccinia virus encoding the same $CD8^+$-T-cell epitope along with vaccinia virus encoding RANK-L as adjuvant provided significant protection against lethal *T. cruzi* infection (Miyahira et al., 2005) (Table 69.2). Further, recombinant adenoviruses encoding *ASP2* and *TS* antigens, alone or in combination, elicited strong antibody and T-cell responses and provided high level of protection against lethal *T. cruzi* challenge in mice (Machado et al., 2006). These studies have opened another arena for developing and testing the potential of *T. cruzi* vaccines.

Summary

Taken together, the above studies established the immunogenic potential of several of the parasite surface antigens and provided evidence for the usefulness of a DNA immunization approach in eliciting protective immune responses against *T. cruzi*. Unfortunately, all of the tested antigen(s) that conferred protection for a short term (2–4 weeks after vaccination) failed to confer long-term immunity. Further, all of the defined antigens tested so far, individually or in combination, with or without adjuvants, failed to produce sterile immunity and/or prevent death from infection in 100% of the vaccinated animals. It is surmised that

the immune responses elicited by the tested vaccine candidates were either below the threshold required for generation of sterile immunity or were not rapid enough in their kinetics to control *T. cruzi* efficiently during the acute phase of infection. The ability of parasites to utilize multiple immune-evasion mechanisms may also contribute to *T. cruzi* survival in the immunized host.

PROSPECTS FOR THE FUTURE

Studies in experimental models have delineated the effector mechanisms that are essential to provide resistance to *T. cruzi* infection. Several defined vaccine candidates are known to elicit partially protective immunity against *T. cruzi*. A systemic approach to vaccine development against *T. cruzi* in future studies would require further characterization of protective immune responses, identification of new antigenic targets of these protective responses, development of efficient antigen delivery systems, and use of adjuvants and vaccination regimens to enhance the protective responses to known vaccine candidates. Given the complexity of the *T. cruzi* genome, multiple life cycle stages in the mammalian host, and strain variations, it is essential that substantial efforts are employed in selecting the appropriate vaccine candidates. Microarray analysis has emerged as a powerful technology to assess differential gene expression in various stages or strains of pathogens, and identification of stage-specific virulence genes that could be potent drug or vaccine targets (Rathod et al., 2002; Grifantini et al., 2002). The development and free availability of complete genome arrays will facilitate the efforts of the research community in identifying stage-specific novel genes that may also be conserved across various lineages of *T. cruzi* and serve as potential vaccine candidates. Development of computational strategies for efficient screening of the *T. cruzi* EST database has proven to be useful in identifying novel vaccine candidates (Bhatia et al., 2004) and we anticipate that complete sequencing and annotation of *T. cruzi* genome (El-Sayed et al., 2005) would facilitate the unbiased identification and testing of additional vaccine candidates in the next 5 years. Once the selected antigens are shown to be effective in eliciting protective immunity in mice, testing and optimization of the gene-mixes consisting of protective candidates that synergize in their antigenic activity would facilitate formulation of the multivalent vaccines capable of providing maximally protective immunity against *T. cruzi*. Further development of small (mice) and large animal models (dogs) would be essential to conduct the field studies and adequately assess the protective efficacy of vaccines in providing short- and long-term immunity before a clinical trial in humans can be envisioned.

Given the parasites' ability to evade immune detection and survive long-term in an immuno-competent host, it is unlikely that anti-*T. cruzi* vaccines would be effective in preventing infection or in providing sterile immunity. It is, however, likely that vaccines capable of eliciting immune responses that are sufficient to keep the parasite burden below a threshold level would be effective in eliminating the parasite-mediated pathology and tissue injury and thus arrest the progression of Chagas disease severity.

KEY ISSUES

- Several studies have shown that control of acute parasitemia and tissue parasite burden is an effective approach in arresting the development and progression of disease.
- Some success with the first-generation vaccines, including fractionated or inactivated parasites, led the identification of effector immune mechanisms against *T. cruzi*.
- The use of new technologies and experimental systems has allowed a better understanding of the mechanisms underlying the protective immune response against *T. cruzi*.
- Secreted and GPI-anchored proteins of *T. cruzi* are recognized as the best choice for the development of subunit vaccines.
- The DNA vaccination approach has proved to be promising in eliciting both humoral and cellular immune responses and testing and identification of vaccine candidates against *T. cruzi*.
- Completion of *T. cruzi* genome sequencing and development of a variety of bioinformatics and computational tools would allow the global screening of the genome for the identification of novel vaccine candidates.
- The complexity of the parasite life cycle, expression of developmentally regulated proteins in different morphological stages, and multifaceted manifestations of Chagas disease caused by different *T. cruzi* strains necessitates the identification of multiple antigenic targets.
- The complexity of the protective immune responses constituted by lytic antibodies, CTLs, and type 1 cytokines complicates the selection of protective vaccine candidates.

- The expression of immune-suppressive membrane antigens (SAPA (Gorelik et al., 1998), AGC10 (Kierszenbaum et al., 1999)) and the parasite's ability to utilize multiple immune-evasion mechanisms (Sztein and Kierszenbaum, 1993; Ouaissi et al., 1995, 2001) may limit the immunoprotective capacity of anti-*T. cruzi* vaccines.
- The lack of interest of large pharmaceutical companies in developing vaccines against tropical diseases requires a major commitment from the health care agencies of developed and endemic countries.
- Concerted efforts are needed in testing the vaccine potential of known and novel antigenic targets, followed by the design of a multicomponent vaccine cocktail that is effective in eliciting protective immunity in multiple hosts against different parasite strains.
- Evaluation of route and mode of delivery, immunization dose and regimens, and the role of adjuvants in eliciting maximal protective immunity in experimental hosts would provide an impetus for future developments.

ACKNOWLEDGMENTS

The work in N. J. Garg's laboratory has been supported in part by grants from the American Heart Association, John Sealy Memorial Endowment Fund for Biomedical Research, American Health Assistance Foundation, and National Institutes of Health. V. Bhatia was an awardee of a Postdoctoral Fellowship from the Sealy Center of Vaccine Development. M. A. Zacks was awarded the James W. McLaughlin Predoctoral Fellowship and a Postdoctoral Fellowship in the Emerging Infectious Disease Program at the US Centers for Disease Control and Prevention. Our thanks are due to Ms. Mardelle Susman for proofreading and editing of the manuscript.
