Other key virulence determinants of both *B. mallei* and *B. pseudomallei* are surface polysaccharides, two of which have been well characterized. Capsular polysaccharide and LPS are also known as type I *O*-PS and type II *O*-PS, respectively (Deshazer et al., 1998; Reckseidler et al., 2001; Perry et al., 1995). The capsular polysaccharide is an unbranched homopolymer of -3)-2-*O*-acetyl-6-deoxy-β-d-manno-heptopyranose-(1-. The loss of capsule expression results in marked attenuation of *B. pseudomallei* and *B. mallei* (Atkins et al., 2002; Deshazer et al., 2001; Reckseidler et al., 2001). The significance of this polysaccharide in virulence is also reflected by the absence of the encoding gene cluster in *Burkholderia thailandensis*, a nonpathogenic bacterium that is closely related to *B. pseudomallei* (Ong et al., 2004; Kespichayawattana et al., 2004; Brett et al., 1998; Yu et al., 2006). The function of the capsular polysaccharide is not fully understood, but it may provide resistance to phagocytosis by reducing levels of complement C3 deposition (Reckseidler-Zenteno et al., 2005).

LPS consists of an unbranched heteropolymer with repeating d-glucose and l-talose units, with the structure -3)-β-d-glucopyranose-(-3)-6-deoxy-α-l-talopyranose-(1-. Approximately one-third of the l-talose residues bear 2-*O*-methyl and 4-*O*-acetyl substituents, and the remainders have 2-*O*-acetyl modifications (Knirel et al., 1992; Perry et al., 1995). The *B. pseudomallei* *O*-antigen appears to have properties typical of other bacterial *O*-antigens, for example, by providing resistance to serum killing (Deshazer et al., 1998). However, the LPS also appears to be less toxic and pyrogenic, compared to other enterobacterial LPS and is less active in stimulating murine macrophages, although it is more mitogenic (Matsuura et al., 1996). Antigenic studies suggest that the LPS is present in the avirulent *B. thailandensis* strain as well as *B. pseudomallei* and *B. mallei*, questioning the contribution of the LPS to infection (Anuntagool et al., 1998). However, previous studies have shown that LPS mutants of *B. pseudomallei* are markedly attenuated in animal models of disease (Deshazer et al., 1998).

Immunological studies with mabs demonstrate the expression of an exopolysaccharide by strains of *B. pseudomallei* and *B. mallei*. There was no cross-reactivity of the mab with other species of *Burkholderia* or *Pseudomonas* (Steinmetz et al., 1995). Two

simultaneous, independent studies elucidated the structure of this polysaccharide to consist of a linear tetrasaccharide repeating unit comprising of three galactose residues, one bearing a 2-linked *O*-acetyl group, and a 3-deoxy-d-manno-2-octulosonic acid (KDO) residue (Masoud et al., 1997; Nimtz et al., 1997). The encoding gene cluster for the exopolysaccharide is yet to be determined. However, in addition to the gene clusters encoding capsular polysaccharide and LPS, two other gene clusters have been reported (Holden et al., 2004). The functions of these clusters are unknown, but mice challenged with *B. pseudomallei* strains with mutations in each of these clusters showed a delayed time to death, compared to wild-type strains (Sarkar-Tyson et al., 2007), suggesting that they play roles in virulence.

PROSPECTS FOR A VACCINE

There is no experimental or licensed vaccine against glanders or melioidosis, and the development of effective vaccines or alternative therapies is an essential requirement. Infection with both pathogens clearly involves the interaction of a number of virulence factors and is dependent on the host's susceptibility to infection. Because of the genetic and biochemical similarities between *B. pseudomallei* and *B. mallei* and the similar mechanisms of virulence, it is conceivable that one vaccine would provide protection against both glanders and melioidosis. Previous studies have shown that antibodies to the flagella, LPS, and capsular polysaccharides are protective against *B. pseudomallei* and *B. mallei* (Brett and Woods, 1996; Brett et al., 1994; Charuchaimontri et al., 1999; Ho et al., 1997; Jones et al., 2002; Nelson et al., 2004; Trevino et al., 2006). The possibility of an *O*-polysaccharide-antigen-flagellin protein conjugate was investigated and shown to elicit high titers of IgG, which was capable of protecting diabetic rats from *B. pseudomallei* challenge (Brett and Woods, 1996). However, this vaccine may not be effective against *B. mallei*, which does not express flagella. It has been reported that an acellular vaccine has been used successfully in captive marine mammals to protect against *B. pseudomallei* infection. The vaccine contains protein and polysaccharide (1:3) and induces high levels of specific antibodies to *B. pseudomallei* (Vedros et al., 1988). The use of this vaccine has significantly reduced mortality in marine mammals. Alternative vaccine strategies, such as DNA vaccine strategies, have been investigated using the flagellin-encoding gene of *B. pseudomallei*, *fliC*, and immunization resulted in both a humoral and cellular immune response (Chen et al., 2006b). Subsequent challenge with wild-type *B. pseudomallei* resulted in reduced bacteremia in the liver and spleens of vaccinated animals (Chen et al., 2006b). Introduction of CpG oligodeoxynucleotide to the DNA plasmid/*fliC* construct further improved the levels of resistance to *B. pseudomallei* infection, possibly by biasing a Th-1-type immune response (Chen et al., 2006a). There have been attempts to identify potential protective subunits, including immunoscreening of a lambda Zap II-expressed genomic library of *B. pseudomallei* genes and a proteomic-based method to specifically select for immunogenic, surface-located antigens (Harding et al., 2007; Jitsurong et al., 2003). Several immunogenic proteins have been identified and are currently being investigated for their protective efficacy against melioidosis and glanders (Harding et al., 2007).

Inactivated whole-cell vaccines also show potential as the basis for vaccines. Mice immunized with heat-inactivated *B. pseudomallei* were protected after lethal challenge (Razak et al., 1986). In our laboratory, we have shown that mice immunized with heat-inactivated *B. pseudomallei* are protected, compared to unvaccinated mice against a subsequent i.n. challenge with either *B. pseudomallei* or *B. mallei* (Sarkar-Tyson, unpublished data). These results indicate that a vaccine might be devised that protects against both diseases. The use of immunostimulatory CpG 1826 in conjunction with dendritic cells, pulsed with heat-killed *B. pseudomallei*, proved to be effective in providing protection against virulent wild-type strains in the BALB/c animal model of infection (Elvin et al., 2006). These studies demonstrate that inactivated strains may be effective as vaccines against melioidosis and glanders and merit further investigation.

Avirulent strains and auxotrophs of *B. pseudomallei* and *B. mallei* have been used to vaccinate animals prior to respiratory challenge with mixed results (Dannenberg and Scott, 1958; Levine and Maurer, 1958; Ulrich et al., 2005; Atkins et al., 2002). *B. pseudomallei* mutants with auxotrophies for purines, branched-chain amino acids, or aromatic amino acids have been shown to be attenuated and protective in murine models of disease. For example, immunization with a branched-chain amino acid auxotroph provided protection against at least 100 MLD doses of wild-type *B. pseudomallei* (Atkins et al., 2002). The abilities of these *B. pseudomallei* auxotrophs to induce protection against inhalation disease are not known. A *B. mallei* mutant with auxotrophy for branched-chain amino acids has also been constructed and tested as a vaccine (Ulrich et al., 2005). Aerogenic immunization with this mutant provided limited protection against a subsequent inhalation challenge with *B. mallei* (Ulrich et al., 2005). While live-attenuated strains of

B. pseudomallei and *B. mallei* show potential as vaccines, there are some significant concerns associated with their use. In the study reported by Ulrich et al. (2005), immunity was not sterile, and although "protected" animals did not develop acute diseases, abscesses were apparent in spleens and livers of immunized mice. Even if sterile immunity could be induced, it is not clear whether attenuated mutants would be licensable as vaccines because of the possibility of long-term persistence of the vaccine.

KEY ISSUES

- *B. mallei* and *B. pseudomallei* elicit humoral and cell-mediated immune responses to infection. Further research into these responses should provide essential information for vaccine development.
- Vaccination against disease caused by *B. mallei* or *B. pseudomallei* is possible. Both inactivated whole-cell and live-attenuated vaccines are effective, although it may be difficult to license live-attenuated vaccines.
- Subunit vaccines based on polysaccharides or proteins alone may not provide sufficient protection against melioidosis or glanders, and multicomponent or polysaccharide–protein conjugates may elicit more effective responses.

CHAPTER

44

Chlamydia

Roger G. Rank
Department of Microbiology and Immunology, University of Arkansas for Medical Sciences and Arkansas Children's Hospital Research Institute, Little Rock, AR, USA

OUTLINE

ABSTRACT

Chlamydiae are responsible for a variety of infections in humans including genital infections in men and women, ocular infections in the form of inclusion conjunctivitis and trachoma, community-acquired pneumonia, and atypical pneumonia. Chlamydial genital infections have a worldwide distribution and are the major bacterial cause of sexually transmitted disease that may ascend the genital tract causing salpingitis with potential sequelae of involuntary infertility and ectopic pregnancy in women. Trachoma is the most common cause of preventable blindness in the

world but is concentrated in underdeveloped countries. Both genital and ocular diseases are primarily caused by the acute inflammatory response elicited by the infection of the host cell and the T cell response to the organism. However, infections resolve through both antibody- and Th1-mediated mechanisms. Currently, there are no vaccines for either disease in humans although intensive efforts to develop a trachoma vaccine including human trials occurred in the 1960s. While the whole organism vaccines employed were successful in developing some immunity over the short term, no long-term protection could be produced and trials were halted because of some evidence of a higher conversion rate in individuals given the vaccine in contrast to control subjects. The trials also made clear that immunity was serovar specific. No clinical trials have since been performed. Since the cessation of those trials, there has been little effort on a vaccine for trachoma, and the emphasis has shifted to a vaccine against genital infections. Current vaccine efforts are concentrating on specific bacterial proteins rather than whole organisms because of the cross-reactivity between human and chlamydial hsp60. The major outer membrane protein of chlamydiae that is surface-exposed and highly immunogenic can elicit a protective response and has been the subject of much work related to vaccine. It has the disadvantage in that it is serovar specific and the protective epitopes are conformational, making production of a recombinant molecule problematic. Other molecules with genus specificity such as the chlamydial protease-like activity factor and polymorphic membrane protein D have been described but not as thoroughly explored as potential vaccine candidates. It is important that the vaccine does not exacerbate pathologic response or increase the incidence of clinical disease. A vaccine must be able to elicit long-term immunity, something which did not occur with the original trachoma trials and which does not occur with natural infection. A strategy of preventing ascending infection may in part facilitate longer term protection. Because there are multiple serovars that cause both genital and ocular infections, it is critical that a vaccine contain either multiple serovars and/or genus-specific antigens. Persistence of chlamydial infection, although still undefined and uncharacterized in humans and animals, is a major concern. A vaccine must be evaluated to determine whether it can prevent persistence or whether the organism is still present but prevented from causing disease. Before a vaccine can go to clinical trials, appropriate surrogates for infertility and ectopic pregnancy must be determined and evaluated in animal models.

INTRODUCTION

Chlamydiae are highly adapted, primarily mucosal pathogens, infecting virtually all mucosal sites, depending on the species of *Chlamydia* and the species of the host. Chlamydial diseases have had and continue to have a profound impact on the health of individuals throughout the world. *Chlamydia trachomatis* is not only the leading cause of preventable blindness in the world through the production of scarring disease in the conjunctiva, but also the most common bacterial cause of sexually transmitted infections in the world, often leading to tubal obstruction and involuntary infertility in women. Moreover, *Chlamydia pneumoniae* infects 20–50% of the population in the United States producing community-acquired pneumonia and has been associated with potential exacerbation of coronary artery disease. Finally, *Chlamydia psittaci*, an avian chlamydia, can be zoonotic for humans, eliciting a respiratory infection with a high rate of mortality in untreated individuals. The latter, because of its high virulence and respiratory route of transmission, has been considered a possible bioterrorism agent. Thus, there are four different diseases caused by chlamydiae which either affect a significant number of people or have the potential, as in the case of *C. psittaci*, to affect a large number if employed as a bioterrorism agent.

For the purposes of this chapter, however, we will emphasize the pursuit of a vaccine(s) for genital tract infections and trachoma, because the widespread nature of these diseases and the vast impact they have on the human population worldwide make the development of a vaccine the most effective means of preventing the diseases and contributing significantly to the health of a large portion of the world's population. Because respiratory infections caused by *C. pneumoniae* are generally not severe and the effects of intervention on the development of coronary artery disease not clear (Grayston et al., 2005), there has been less enthusiasm for the pursuit of a vaccine against *C. pneumoniae* in recent years. Similarly, natural infections in humans caused by *C. psittaci* are uncommon and the employment of this agent in bioterrorism is less likely compared to other agents; hence, there is little interest in developing a human vaccine against *C. psittaci*. Nevertheless, since chlamydiae are remarkably similar, especially with regard to protective antigens, it is quite feasible that a vaccine developed for either genital tract infection or trachoma could employ comparable antigens and be utilized to prevent *C. pneumoniae* and *C. psittaci* infections as well.

SHORT HISTORY OF THE DISEASES

Trachoma is an ancient disease and one of the first diseases recognized as a distinct clinical entity with

the first references to treatment for it in China in the 27th century BC. The exudative aspects of the disease and treatment with copper salts were described in the Ebers Papyrus around 1500 BC in Egypt (Thygeson, 1962). It was widespread in ancient Greece and Rome, and several historical figures, including Paul of Tarsus, Cicero, Horace, and Pliny the Younger, were thought to have had trachoma. The term "trachoma" was first coined by a Sicilian physician, Pedanius Dioscorides, in 60 AD, and the four stages of the disease were later described by Galen. The disease was spread from the Middle East to Europe by the knights of the Crusades and later in the late 18th century by Napoleon's troops as a result of his campaign in Egypt.

The inclusion bodies associated with the organism were first described in 1907 by Halberstaedter and von Prowazek (1907) when they observed them in eye scrapings from experimental trachoma in nonhuman primates and then later in scrapings from humans. They named the organism "chlamydozoa" or "mantle bodies" because of their mantle-like structure on Giemsa stain. The similarity between the organism from trachoma and the etiologic agents of psittacosis and lymphogranuloma venereum was eventually recognized and Bedson (1953) accepted the agents of trachoma and inclusion conjunctivitis into the psittacosis-LGV group.

In contrast to trachoma, the history of genital infections caused by chlamydiae is more recent. It was observed at the end of the 19th century that conjunctivitis could be found in neonates who were not infected with gonorrhea (Kroner, 1884). Halberstaedter and von Prowazek (1909) found inclusions in infants with inclusion conjunctivitis and, later, Heymann (1910) observed inclusions in cervical smears and the urethra of parents of a child with inclusion conjunctivitis. The first actual recovery and isolation of chlamydiae from the cervix was demonstrated by Jones et al. (1959) in 1959. Shortly thereafter, organisms were isolated from the male urethra (Jones, 1964). While isolation of chlamydiae from the lower genital tract from males and females became quite common, it was not until 1977, that Mardh et al. (1977) documented the association of *C. trachomatis* with salpingitis and were able to isolate organisms from the fallopian tubes. With those findings and the wide distribution of chlamydial genital infections, the significance and necessity for a vaccine became apparent.

ETIOLOGIC AGENT(S)

Classification

Chlamydiae are obligate intracellular bacteria that are unique for their biphasic developmental cycle, the elementary body or the non-replicating infectious phase, and the reticulate body or the noninfectious replicating stage. While generally host species specific, chlamydiae can be found in nature infecting a wide range of mammals, including humans, mice, guinea pigs, sheep, cattle, cats, hamsters, swine, and koala bears, and birds including budgerigar, parakeets, parrots, cockatiel, pigeons, doves, and turkeys (Tanner et al., 1999).

Taxonomically, chlamydiae have their own order, Chlamydiales, which includes the family, Chlamydiaeceae (Moulder et al., 1984). Over the last several years, there has been dispute as to whether there are one or two genera; however, it has now been agreed upon by the research community, that there is a single genus, *Chlamydia*, with species related to the host species (Bavoil and Wyrick, 2006). Therefore, *C. trachomatis* is the primary human pathogen, which is the cause of trachoma and genital tract disease. *C. pneumoniae* is also a primary human pathogen and *C. psittaci* can be zoonotic for humans. The primary animal models for chlamydial infections include the mouse and guinea pig with their natural parasites, *Chlamydia muridarum* and *Chlamydia caviae*, respectively. *C. trachomatis* is subdivided into 18 serovars based on serovar-specific antigens in the major outer membrane protein (MOMP) (Wang and Grayston, 1971b). Serovars A, B, Ba, and C are primarily associated with trachoma while serovars D, Da, E, F, G, H, I, Ia, J, and K are associated with oculo-genital disease. Finally, L1, L2, L2a, and L3 are the causative agents of lymphogranuloma venereum.

Morphologically, the elementary body is approximately 0.3μm in diameter and somewhat spherical in shape while the reticulate body is larger at 1μm in diameter. A unique morphologic component of the elementary body is the presence of hexagonally arrayed projections on the surface which are now hypothesized to be the type III secretion apparatus originally described by Hsia and Bavoil (Hsia et al., 1997). Neither stage of the organism stains well with the gram stain, but they can be identified in their classic inclusion by aniline-based stains such as the Giemsa stain.

Chlamydiae have a small genome with only about 1×10^6 base pairs. One of the major stumbling blocks to chlamydial research, however, has been the total lack of the ability to manipulate the genome so that genes can be deleted or inserted, an important prerequisite to establish the function or role of many of the genes and open reading frames. Also, chlamydiae appear to lack de novo or salvage pathways for nucleotide biosynthesis and are, thus, forced into a life style of intracellular parasitism.

Antigens Encoded by Agent

Structurally, chlamydiae resemble gram-negative bacteria in that they have a trilaminar outer membrane. The main structural component of the outer membrane is the MOMP, a 38–42 kD protein with multiple cysteine residues providing disulfide cross-linking which gives the structural integrity to the outer membrane (Caldwell et al., 1981). In addition to being the major outer membrane structural protein, it also has porin activity and has been implicated in the attachment of chlamydiae to the host cell (Bavoil et al., 1984). MOMP is composed of essentially four loops, each having surface-exposed portions. There is greater amino acid diversity in the surface-exposed or variable domains, probably accounting for the antigenic variation among the *C. trachomatis* serovars. There are also genus- and species-specific epitopes associated with MOMP (Stephens et al., 1988). MOMP is an immunodominant, highly immunogenic protein in all chlamydial strains except for *C. pneumoniae* and, as such, has been identified as a major target antigen for the protective immune response. Other structural components of the outer membrane include a 60 kD cysteine-rich molecule, OmcB or Omp2, and a lipopolysaccharide (LPS) moiety. The LPS has mild endotoxic activity and resembles the "deep rough" (Re) mutant LPS of enteric bacteria (Nurminen et al., 1984). Another set of proteins, the polymorphic outer membrane proteins (PMPs) are associated with the outer membrane but appear to be variable in their surface exposure and immunogenicity.

PROTECTIVE IMMUNE RESPONSE

Genital Disease

It is clear that there is a substantial immune response to infection and that protective immunity to reinfection does indeed develop in humans following a chlamydial genital infection (Alani et al., 1977; Schachter et al., 1983; Jones and Batteiger, 1986), but that immunity is neither complete nor long-lasting, at least initially. Katz et al. (1987) observed that contacts of isolation-positive individuals were likely to be negative for chlamydiae if they had had a prior chlamydial infection less than 6 months previously, but if their prior chlamydial infection was greater than 6 months before, they were more likely to be positive. There is some evidence that solid immunity to reinfection can develop as older individuals appear more resistant to infection than adolescents, even when controlled for a number of exposures (Arno et al., 1994).

The primary animal models for chlamydial genital infection, including the nonhuman primate, mouse, and guinea pig all support the above observations. When animals are challenged shortly after resolution of a primary infection, immunity is complete. However, if challenged at later times, reinfection occurs, albeit at lower levels and of shorter duration (Rank et al., 1988; Ramsey et al., 1989; Wolner-Hanssen et al., 1991). Generally, the shorter interval of time between challenge infections corresponds to a high degree of immunity with respect to length and peak level of infection. That reinfection can occur following a natural infection is of concern because it suggests that it may be difficult for a vaccine to elicit a sterile immunity.

Antibody

While there is a very strong antibody response both locally in the genital tract and systemically in humans and animal models, the protective role of antibody remains somewhat controversial. Brunham et al. (1983) observed in patients that the number of chlamydiae isolated from a cervical swab was inversely proportional to the level of IgA in cervical secretions. They also reported that women who developed postabortal salpingitis had significantly lower serum antibody titers than women who did not develop the disease (Brunham et al., 1987). Using guinea pigs infected intravaginally with *C. caviae*, Rank et al. (1979) reported that animals deficient in antibody were unable to resolve the infection. Similarly, animals deficient in antibody but cured of the infection with tetracycline were susceptible to challenge infection (Rank and Barron, 1983b). Thus, in the guinea pig model, antibody was essential for both resolution of a primary infection and resistance to reinfection. Of interest was their observation that passive administration of serum antibody from immune animals to naïve animals was able to reduce the level of infection, suggesting that serum IgG has transudated into the genital tract and was able to provide a level of protection (Rank and Batteiger, 1989). It should be noted that IgG is the dominant antibody in the female genital tract (Masson et al., 1969). Based on in vitro experiments, it is likely that the antibody inhibits chlamydial infection by neutralization (Caldwell and Perry, 1982), i.e., the prevention of the attachment of elementary bodies to the cell and/or the opsonization with subsequent phagocytosis of the organism (Wyrick et al., 1978).

In contrast to the guinea pig, antibody does not appear to be required for resolution of infection in the mouse model of genital tract infection. When B cell deficient mice are infected with *C. muridarum*, the course of the infection is the same as in control,

immunologically intact mice (Ramsey et al., 1988; Su et al., 1997). Recently, however, Morrison has shown some evidence that antibody may be involved to some extent in resistance to infection in the mouse, although the mechanism is not yet clear (Morrison and Morrison, 2005b).

Therefore, while one cannot state specifically that antibody is absolutely required for immunity to chlamydial genital infection in the human, the development of a strong antibody response in the genital tract should be the goal of a vaccine. Complete prevention of infection could only be accomplished by the presence of neutralizing or opsonizing antibodies in genital secretions.

Cell-Mediated Immunity

While the case for antibody remains to be confirmed, it is apparent that cell-mediated immunity (CMI) is an essential factor in the host protective response. Chlamydial genital infections in both guinea pigs and mice deficient in T cells fail to resolve (Rank and Barron, 1983a; Rank et al., 1985). When the relative contribution of both CD4 and CD8 was determined in mice, it was found that protection was dependent on the CD4 subpopulation. If CD4 cells were deficient, the mice failed to resolve their infections, while mice deficient in CD8 cells resolved their infections analogous to immunologically normal controls (Morrison et al., 1995). Moreover, the adoptive transfer of either CD4 cells or T cell lines enriched for CD4 cells into recipient mice were more efficient at resolving chlamydial genital infections in contrast to the adoptive transfer of CD8 cells or CD8-enriched T cell lines which had no effect on the course of the infection (Su and Caldwell, 1995; Ramsey and Rank, 1990; Morrison et al., 2000). Similarly, the adoptive transfer of a CD4 clone into nude mice resolved the infections in 80% of the mice (Igietseme et al., 1993). Of two CD8 clones tested, only one was able to resolve infections in nude mice and then in less than half of the recipients (Igietseme et al., 1994). A role for CD4 cells has also been implicated in humans. Kimani et al. (1996) reported that sex workers who were HIV positive had a higher incidence of chlamydial genital infections than did individuals who were HIV negative, suggesting that CD4 cells had a protective role.

It was further determined that Th1 cells were responsible for the protective response. When T cells from either the genital tract or draining lymph nodes of infected mice were assessed for IFN-γ or IL-4 by ELISPOT, the dominant cytokine was IFN-γ (Cain and Rank, 1995). Moreover, the adoptive transfer of a Th1 clone was able to resolve genital infections in nude mice while a Th2 clone was totally ineffective (Igietseme et al., 1993; Hawkins et al., 2002). The data would also suggest that the primary effector mechanism is an IFN-γ-mediated killing of intracellular chlamydiae (Cotter et al., 1997; Perry et al., 1997), although a recent study by Nelson et al. (2005) implicates a mechanism employing GTPases. Thus, not surprisingly, with respect to other bacterial infections, it is apparent that a Th1 CD4 T cell response is essential for the resolution of chlamydial genital infection and resistance to reinfection.

Trachoma

Just as with chlamydial genital infections, immunity to conjunctival infection also develops. With repeated infections, it becomes increasingly more difficult to isolate the organism. Ultimately, in the majority of the subjects, the infection resolves and the individual is resistant to reinfection (Taylor, 1985). Using a nonhuman primate model of trachoma, Taylor et al. (1981, 1982) demonstrated that ocular challenge of previously infected animals resulted in much abbreviated infections which were also substantially lower in the number of organisms isolated. With repeated infections, it became more difficult to isolate the organism, just as in human disease. Using the *C. caviae* guinea pig model of conjunctival infection, Monnickendam found similar results. Repeated infections demonstrated a marked degree of immunity with regard to the ability to isolate chlamydiae from the conjunctiva (Monnickendam et al., 1980a, 1980b). However, just as in genital infections, both nonhuman primates and guinea pigs could be reinfected and the ability to reinfect was related to the time interval between the prior and current challenge. For example, when guinea pigs were inoculated 35 days after a primary infection, there were few organisms isolated in contrast to a challenge 60 days after the primary infection when there were significantly more organisms detected for a longer period of time (Monnickendam et al., 1980a). It should be noted that, in general, specific immune mechanisms in trachoma are less well known than genital infections because of the lack of a mouse model in which one has a multitude of reagents and transgenic mice. Also, the major research emphasis with respect to chlamydial infections in the last 20 years has been on genital infections.

Antibody

In humans and animal models of trachoma, there is a strong local antibody response with the production of IgA and IgG as well as a strong systemic response. However, while there are ample studies to

demonstrate that incubation of antibody with chlamydiae can prevent or diminish infection both in vivo and in vitro (Nichols et al., 1973; Barenfanger and MacDonald, 1974), there is little evidence in vivo that antibody is essential for the resolution of ocular infection or resistance to reinfection. The only study that suggests a role for antibody in resolution of the infection was performed by Modabber et al. (1976) in which they depressed the B cell response by treatment with cyclophosphamide and observed that the ocular infection with *C. caviae* was prolonged. There are several studies that show a correlation with the presence of both IgG and particularly sIgA antibodies and resistance to reinfection, but none are definitive in demonstrating a protective role for antibody (Pearce et al., 1981; Malaty et al., 1981).

Cell-Mediated Immunity

The lack of a mouse model and a significant amount of basic immunologic research done in animal models of trachoma has resulted in only minimal information on the role of CMI in protective immunity in the conjunctiva. Just as with the antibody response, there is a strong local and systemic CMI response to chlamydial conjunctival infection, and there are numerous studies indicating a prime role for CMI in the pathologic response (see below). Both CD4 and CD8 T cells have been found in conjunctival tissue in the monkey model (Whittum-Hudson et al., 1986) as well as Th1 cytokine expression (Holland et al., 1996); however, neither depletion nor adoptive transfer studies have been performed to confirm a protective role for CMI. Nevertheless, because Th1 T cells are required for immunity in genital tract infections, it would be highly surprising if a similar response were not required for the resolution of ocular infection as well.

EPIDEMIOLOGY

Genital Disease

Chlamydia genital infection in the United States is clearly of epidemic proportion, and is the most commonly reported disease in the country. The CDC estimates that 2.8 million people are infected each year in the United States alone, and from 1986 through 2005, the rates of reported infection have risen from 35.2 to 332.6 cases per 100,000 population. This increase may be the result in part of increased screening and more sensitive diagnostic techniques. It is virtually impossible to know the total infection rate worldwide but it clearly is distributed throughout the world and probably at similar rates in the United States.

The rates of chlamydial infection are highest in adolescents and particularly in adolescent women. In one prospective study of a cohort of individuals between the ages of 18 and 26 years in the United States, 4.2% of the individuals were infected with *C. trachomatis* (Miller et al., 2004). In addition to the infection being most frequent in adolescents and young adults, other risk factors for acquisition of chlamydial disease include the following: (1) multiple sex partners or a partner with other partners during the last 3 months or a recent new sex partner; (2) inconsistent use of barrier contraceptives; (3) unmarried status; (4) history of prior sexually transmitted disease; and (5) lower socioeconomic class or education not beyond high school.

From a public health perspective, there is a tremendous cost to the health care system in the treatment of chlamydial genital infections. Of even greater significance is the incalculable psychological cost to couples who are unable to have children as a result of tubal obstruction in women as well as the financial costs of in vitro fertilization for those couples.

Trachoma

Trachoma is caused by specific serovars of *C. trachomatis* and is the leading cause of preventable blindness in the world with roughly 10% of the world's population infected. The disease is concentrated in tropical to subtropical areas of the world in underdeveloped countries (Figure 44.1). The disease is associated with poor public health conditions where the organism can be easily spread by mechanical means via flies and personal contact. In some areas, over 90% of children are infected. Women are three times more likely to be infected because of their close contact with children.

Unfortunately, trachoma is a disease of underdeveloped countries that have no economic means to deal with the disease. Moreover, because blindness strikes adults in their prime working years, it can remove them from the workforce and hinder their ability to care for themselves and their families. When blindness strikes women, they can no longer perform their duties as caretakers of the home and often an older daughter must leave school and take over her mother's role, taking her away from a formal education. Thus, the disease can prevent families and societies from rising above poverty. It is estimated that the disease results in $2.9 billion of lost productivity each year for the affected countries.

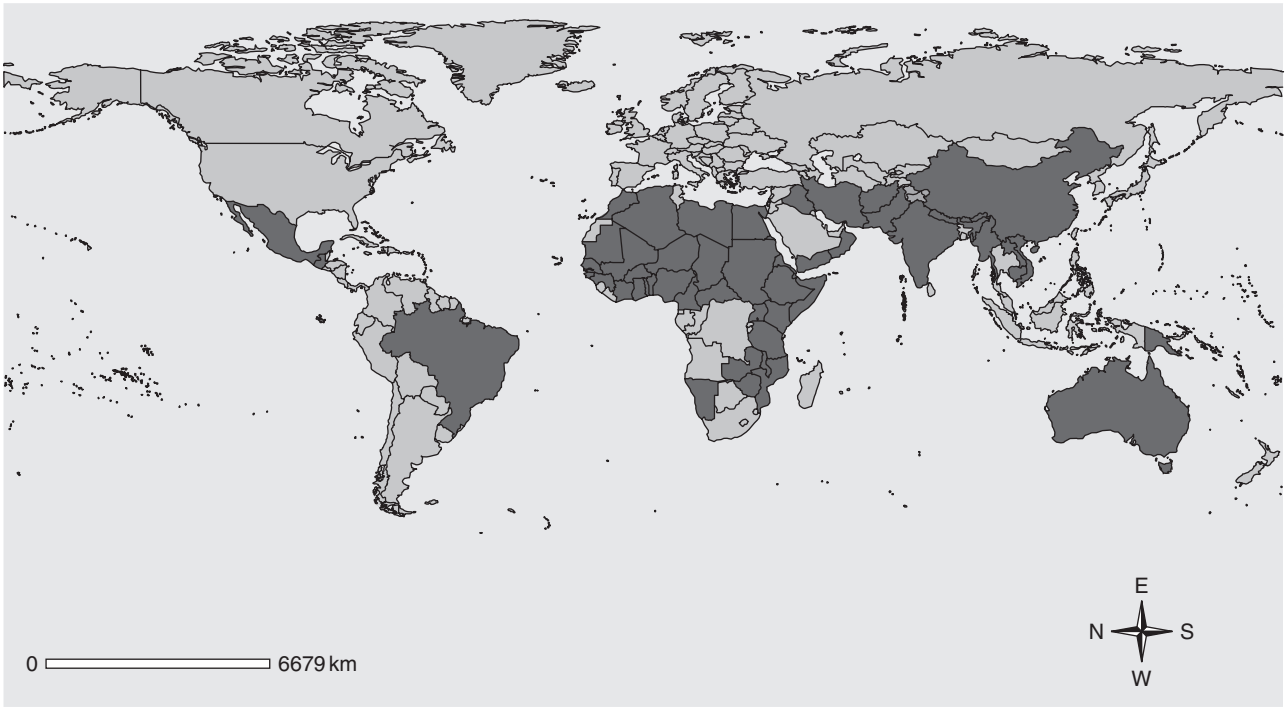

FIGURE 44.1

Potential as Biothreat Agent

C. psittaci was originally included on the United States Select Agent list but is no longer on the list. While the organism can be transmitted by the respiratory route and has a high mortality rate in untreated individuals, it is a relatively labile organism and would not lend itself readily to use in biological warfare.

CLINICAL DISEASE

Genital Disease

C. trachomatis targets the endocervix in women, producing a range of symptomatology, from a mild to severe cervicitis, although about 70% of the infections in women are asymptomatic. Symptoms, if present, are generally nonspecific, but may include purulent or mucopurulent discharge from the endocervix, intermenstrual or postcoital bleeding, dysuria, urinary frequency, dyspareunia, and vulvovaginal irritation. Upon physical examination, again, a range of findings are observed, with purulent or mucopurulent discharge on the surface and/or exuding from the canal being a key finding. Cervical friability and cervical edema may also be present.

About 20–40% of women positive for chlamydiae in the lower genital tract will develop pelvic inflammatory disease (PID) that can lead to fibrosis and tubal obstruction of the fallopian tube and potentially involuntary infertility. Ectopic pregnancy has also been associated with PID caused by *C. trachomatis*. The primary indicator of PID is an onset of lower abdominal pain with diffuse tenderness in the lower quadrants which may be unilateral or bilateral. Rebound tenderness and decreased bowel sounds are common. About 50% of the patients may have fever. Pelvic exam may reveal purulent endocervical discharge and cervical motion tenderness or uterine/adnexal tenderness. It is also possible that PID may be subclinical. Among women who are confirmed with PID, there is a 20% chance that scarring and infertility will develop. Because of the high incidence of subclinical disease, women do not seek medical care, thereby increasing the risk of infertility and ectopic pregnancy.

In males, presentation is typically in the form of urethritis with a mucoid or watery discharge along with dysuria. However, about 40–50% of individuals may have asymptomatic infections. The incubation period is variable but is typically 5–10 days after exposure. Epididymitis may develop but is uncommon. It should be noted that it is not uncommon in men or women to have infections with more than one sexually transmitted agent. Moreover, it is possible for both men and women to develop inclusion conjunctivitis

as a result of contaminating organisms from the genital tract.

Newborns may also acquire the infection at birth by passage through the birth canal. The most common clinical manifestation in the newborn is inclusion conjunctivitis within 5–14 days of delivery (Weinstock et al., 1994). Clinical findings range from mild swelling with a watery eye discharge, which becomes mucopurulent, to marked swelling of the eyelids with red and thickened conjunctivae. A pseudomembrane from adherence of the exudate to the conjunctiva may be present. The infection is easily treated with no residual sequeleae. In 5–30% of the infants born to infected mothers, a pneumonia will develop, but not until 4–12 weeks after birth. Cough and nasal congestion without significant discharge are common, and the infant is usually afebrile or has only a slight fever. Rales are often present on auscultation of the lungs.

Trachoma

Trachoma is a chronic disease process which can extend over many years and even decades and is the result of continual exposure to the infectious agent. The initial infection results in an inclusion conjunctivitis, involving both the bulbar and palpebral conjunctiva and consisting of congestion and edema. This gives way to the development of organized lymphoid follicles. Corneal involvement also occurs with the production of punctuate erosions of the epithelium and cellular infiltrates of the central corneal epithelium. The characteristic sign of trachoma is a neovascularization (pannus) of the superior limbus. Ultimately, the most significant damage occurs when the follicles of the palpebral conjunctiva scar and produce distortion of the eyelids so that the eyelashes continually scrape the cornea (trichiasis), causing further damage and scarring that results in blindness.

TREATMENT

Genital Disease

Fortunately, *C. trachomatis* is sensitive to several antibiotics and no resistance to any of the antibiotics has been confirmed. For treatment of urethritis, cervicitis, and conjunctivitis, azithromycin (1 g PO as a single dose) and doxycycline (100 mg PO BID for 7 days) are the two recommended regimens with both being equally efficacious (97% versus 98% cure rates) (Lau and Qureshi, 2002; Workowski and Berman, 2006). Alternative regimens include 7 days of erythromycin base (500 mg PO QID), erythromycin ethylsuccinate (800 mg PO), ofloxacin (300 mg PO BID), or levofloxacin (500 mg PO QD). In addition to antimicrobial treatment, it is important that partners be treated as well and that the patient and partner be evaluated for other sexually transmitted infections and safer-sex counseling be provided along with provision of condoms and contraception.

In the case of PID, either of the following parenteral regimens has been recommended: (1) Cefoxitin (2 g intravenously every 6 h) plus doxycycline (100 mg intravenously or orally every 12 h); (2) Clindamycin (900 mg intravenously every 8 h) plus gentamicin loading dose (2 mg/kg of body weight) followed by a maintenance dose (1.5 mg/kg) every 8 h (Workowski and Berman, 2006).

Conjunctivitis and pneumonia in the newborn caused by chlamydiae are treated with oral erythromycin (50 mg/kg/day PO in four divided doses) for 14 days for either chlamydial conjunctivitis or pneumonia (Workowski and Berman, 2006).

Trachoma

Trachoma can be readily treated with antibiotics but people are continually exposed to the infection; therefore, treatment becomes problematic, particularly in the parts of the world where trachoma occurs. Trichiasis can also be surgically treated, but, again, the logistics and lack of resources make this difficult. Currently, the International Trachoma Initiative has employed the SAFE strategy to eliminate trachoma. In this strategy, efforts are being made to correct advanced stages of trachoma with *surgery* while entire villages are being treated with *antibiotics* (Zithromax donated by Pfizer). People are being educated to do *face-washing* to reduce the chance for acquisition of trachoma. Finally, work is being done to change the *environment* by improving access to water and improving public hygiene.

PATHOGENESIS

The pathogenesis of chlamydial disease is directly associated with both the innate and adaptive host response to infection and is likely similar regardless of the site of infection. Since most chlamydiae enter the body via a mucosal tissue, the first target cell is an epithelial cell. In the process of infecting the cell, chlamydiae come into contact with toll-like receptors (TLR) and perhaps other yet-undefined receptors which initiate a signal transduction pathway resulting in the

production of proinflammatory chemokines and cytokines, particularly IL-8, IL-1β, and TNF-α. Rasmussen et al. (1997) reported that infection of cervical and colonic epithelial cells with either *C. trachomatis* or *C. psittaci* up-regulated mRNA expression and secretion of the proinflammatory cytokines, IL-8, GROα, GM-CSF, and IL-6. IL-8 expression was seen as early as 2 h after infection and NFκB translocation was detected as early as 30 min after infection (Rasmussen et al., 1998). That these responses only occurred after infection with viable organisms and not by incubation of cells with inactivated organisms indicated that the process was initiated by a specific host/organism interaction.

In vivo in the mouse genital track model, TNF-α production can be observed as early as 6 h after infection, suggesting the bacterial components or early steps in the cell infection process already elicit the response (Tseng and Rank, 1998). As a result the production of proinflammatory chemokines and cytokines, an acute inflammatory response is initiated. There may be other bacterial products that participate in the induction of the inflammatory response, such as via the type III secretion system but these are yet to be determined. Darville et al. (2003) reported that the toll pathway, especially via stimulation of TLR 2, was important in the pathologic response. They observed that TLR 2 knockout mice did not have upper tract pathology following genital infection with *C. muridarum* even though the infection course was not changed. Interestingly, mice lacking TLR 4 developed typical upper tract pathology. This is of particular interest since LPS and hsp60 activate TLR 4 and had been thought to be involved in eliciting the pathologic response.

We have noted that neutrophils can be observed entering the conjunctival epithelium 6 h after *C. caviae* infection of the guinea pig conjunctiva with heavy inflammation by 24 h, before a single developmental cycle has been completed (Rank, R.G., unpublished data). In all animal models, in the initial days of the infection, the histopathologic response is characterized by the acute inflammatory response, and it is generally accepted that the products of the neutrophil response cause tissue damage. In fact, Ramsey et al. (2005) have demonstrated a key role for matrix metalloprotease 9 in the induction of fibrosis in the mouse oviduct.

As the infection progresses, the adaptive immune response becomes activated and one finds an influx of mononuclear cells, particularly T cells, B cells, and macrophages, to the local site. In the MoPn infection of the mouse, this is mainly CD4 cells but in the guinea pig and subhuman primate, there are equal numbers of CD4 and CD8 cells (Van Voorhis et al., 1996; Whittum-Hudson et al., 1986; Kelly et al., 1996; Rank et al., 2003). However, the T cell response is clearly a Th1 response. These cells and the cytokines they secrete are critical for the resolution of infection, but it cannot be ruled out that they also contribute to the induction of pathology. It is apparent that upon reinfection, the mononuclear response is more intense, producing disease of increased severity (Wolner-Hanssen et al., 1986; Tuffrey et al., 1990; Rank et al., 1995).

It is likely that the severity of the pathologic outcome is dependent on two major factors: the infection dose and the number of infection episodes. Because the organism itself is responsible for eliciting proinflammatory cytokines from the host cells, it stands to reason that the more organisms that are introduced, the greater is the level of resultant chemokines and cytokines and, consequently, inflammatory infiltrate. The incubation period and level of peak infection are clearly associated with the number of chlamydiae inoculated (Rank et al., 2003), and the severity of disease is related to the number of organisms as well (Rank et al., 1979).

Upon repeated infections, the organisms will once again induce an inflammatory response, but in this case, there will be an anamnestic cell-mediated immune response, and it is quite likely that the mediators produced by CD4 and CD8 cells may also elicit tissue damage. Trachoma is clearly associated with the specific host adaptive response as it is difficult to isolate chlamydiae from individuals with chronic trachoma. Thus, the pathologic response is most likely a summation of the effects of both the innate inflammatory response and the T cell response.

VACCINES

History

When it became clear that the causative agent of trachoma was a bacterium and that it could be easily propagated in embryonated eggs (T'ang et al., 1957), a major effort was made in the 1960s and 1970s to develop a vaccine. During this time, four groups were working simultaneously in four separate areas of the world to evaluate their own versions of a trachoma vaccine. The investigative teams were optimistic about chances for success because many infected individuals did eventually resolve their infections and developed immunity to reinfection. As with most vaccines in this time period, either live or formalin-inactivated purified elementary bodies were used in all of the trials, with or without adjuvants, using a variety of regimens.

However, despite a massive effort by the four different groups, no universally effective vaccine was forthcoming. Nevertheless, a tremendous amount of information about the disease and immune mechanisms was accrued that can be used today in vaccine research. The work of these teams evaluating potential vaccines in actual human trials as well as in nonhuman primates is reviewed in great detail in two books (Bietti and Werner, 1967; Schachter and Dawson, 1978) but will be revisited in this chapter to give the reader a sense of the information gained from these trials. It should be noted that all of these trials were designed to develop a vaccine for trachoma. There have been no human trials of a vaccine for chlamydial genital infections.

By far the most extensive and detailed studies in both nonhuman primates and in clinical field trials were performed by the University of Washington group led by Thomas Grayston in collaboration with the United States Naval Medical Research Unit No. 2 (NAMRU-2) in Taiwan. In the first field trial of a potential vaccine from 1959 to 1960, they immunized uninfected younger siblings of first-grade children with active disease with two different formalized vaccines suspended in aluminum hydroxide (Grayston et al., 1963). One vaccine consisted of a locally (Taiwan) isolated serovar C and the second was a mixture of serovars B and C. Over a period of 2½ years, 405 children where included in the study and given 4 doses of the vaccine. Overall, 18% of the placebo group converted to active trachoma while only 8% of the vaccine group converted, demonstrating that the vaccine was effective. In 1965, a long-term follow-up was performed on these initial subjects (Woolridge et al., 1967b). It was observed that 1 year after the administration of the full immunization regimen, which was 2 ½ years after the initial injection, the protective effect began to break down, and by 6 years, there was no difference between the immunized and placebo groups. Thus, it was apparent that the immunity was limited in the length of its effectiveness.

Extensive studies were also performed in nonhuman primates to refine the immunization regimen and evaluate adjuvants (Wang et al., 1967). In these studies, they utilized yolk sac–grown organisms either in crude suspensions or purified by different methods. Serovars B and C were tested as well as the aggressive Bour strain (serovar E) alone or mixed with Freund's complete or incomplete adjuvant. Several observations were derived from these experiments. Protection was clearly related to the number of chlamydial particles included in the vaccine, and both Freund's complete and incomplete adjuvants appear to have comparable results. Of importance was the observation that immunity was serovar specific. Challenge of immunized monkeys with heterologous serovars did not result in a protective response.

Based on the results employing mineral oil (incomplete Freund's adjuvant) in monkeys, field trials were initiated in Taiwan in which either monovalent or bivalent vaccines of trachoma strains isolated from Taiwan (serovars B and C) were produced from yolk sac–grown material, formalin-inactivated and emulsified with mineral oil (Woolridge et al., 1967a). Second- and third-grade children were inoculated intramuscularly followed, 6 months later, by a booster inoculation. The bivalent vaccine demonstrated a protective response with only 5.1% of the children converting to trachoma over a period of 3 years versus 8.8% for the placebo group. Interestingly, the opposite response was seen in children immunized with the monovalent vaccine, 8% converting to trachoma in the vaccinated group in comparison to 3.3% with the placebo. The conversion rate in the placebo group was unusually low; hence, this may have affected the overall results. There was concern expressed that the majority of the conversions to positivity occurred prior to the booster immunization, similar to what was seen in monkeys challenged with a strain of chlamydiae heterologous to the vaccine type, possibly suggesting a hypersensitivity response (Wang et al., 1967).

Not only because trachoma rates were relatively low in Taiwan as a result of the improving public health conditions but also because of the encouraging results, the Seattle group initiated field trials with collaborators in India in an area where the trachoma incidence was 85% (Dhir et al., 1967). In these trials, two vaccines were prepared by either gradient purification or ether extraction from elementary bodies grown in yolk sacs and were then formalin-inactivated. Each vaccine contained serovars B and C at concentrations of particles 10^9/ml as it was previously found that a successful vaccine was dependent on having large numbers of elementary bodies. Four hundred fifty-one children with no evidence of trachoma between 3 months and 5 years of age were vaccinated and given a follow-up booster 3 months later. When examined 1 year after immunization, 36.8% of the placebo-inoculated subjects had converted to trachoma while only 10 and 18.5% of the two vaccine groups converted, suggesting a definite protective effect. The strongest protective effect was in the first 3 months following immunization and gradually declined thereafter, supporting previous observations that immunity induced by the vaccine was short lived. It is important to note that in this study, no difference in severity of disease was noted between immunized and control groups.

Follow-up studies with these vaccines were performed in monkeys (Grayston et al., 1971). Similar

results were seen in that immunity did develop when high doses of organisms were contained in the vaccine; but, as in the human trials, immunity was short lived and serovar specific. They also noted that immunization with lower doses of organisms in the oil-based vaccine-containing serovars A, B, and C resulted in more severe disease upon challenge with each of the serovars.

Early human trials of a chlamydial vaccine were performed in Ethiopia by a group from Italy. For these trials, a formalized vaccine prepared from yolk sac–grown elementary bodies of a *C. trachomatis* isolate from Ethiopia was used. The vaccine was administered intramuscularly with either an aluminum hydroxide or water-in-oil adjuvant followed with an aqueous booster at 40 days and sometimes another aqueous booster at 6 months. The vaccines were standardized by the counting of chlamydial particles, the determination of DNA and nitrogen content, and the antigenic concentration of the batch with a standard rabbit antibody by the complement fixation assay. As in the majority of vaccine trials in this period, success was judged by the absence or lessening of clinical disease and sometimes in the reduction in the number of organisms detected on Giemsa-stained conjunctival smears. Initial trials in nonhuman primates and then in human volunteers demonstrated a high degree of protection against conjunctivitis upon challenge with lower doses of organisms although the intensity of the disease in volunteers becoming infected was not diminished. Nevertheless, these results suggested that a protective response could be elicited.

This group conducted field trials in Ethiopia from 1960 through 1962, immunizing children from 2 to 4 years of age who were either free of trachoma or had evidence of disease (Bietti and Werner, 1967). Thus, they were able to evaluate both the therapeutic and prophylactic effects of the vaccine. A summary of the trials over this period showed that 40% of the healthy patients developed disease versus 72% of healthy patients receiving no vaccine. Similarly, of those patients with severe follicular trachoma, vaccination reduced the level of disease in 63% of the cases versus only 23% of controls. If two booster doses were given, 83% of the immunized subjects had a positive outcome. If the disease was more advanced, disease reduction was 79% in vaccinated individuals versus 59% for controls. Therefore, it appeared that immunization was able to both prevent disease and to reduce disease in those already confirmed with trachoma.

Based on the success of these field trials, more expansive trials were conducted in the 1964–1965 with 10,000 subjects included. In two separate trials, 2500 subjects were given the vaccine and 2500 a placebo. In the trial for which data were published (Bietti and Werner, 1967), 17% of vaccinated individuals without previous disease developed clinical trachoma in contrast to 33% of subjects given placebo. For those with existing trachoma, 59% of the vaccinated people improved as compared to only 43% of the placebo-inoculated people. The data in this larger trial suggested that the vaccine still had positive prophylactic and therapeutic effects, although they were not as strong as in the initial field trials. This may have been the result of the trial being conducted in different region which had a higher standard of living.

The group from the Medical Research Council in London, headed by Collier and Blyth (1966a) initiated trials first in baboons. For immunogens, they used several different isolates, two of which were clearly genital isolates. The primary strain they used was the so-called "fast" strain which was later found to be LGV (L2) (Wang and Grayston, 1971a); therefore, for many of the studies, they were not using a typical trachoma strain, but live, potentially invasive LGV. The vaccines were grown predominantly in yolk sacs and were administered parenterally as live vaccines. The "fast" strain was also grown in HeLa cells because it was easy to grow in cell culture and was also administered as a live vaccine. In the course of their studies, they observed that they had good protection against challenge with the homologous strain but less effective protection using challenge with a heterologous strain. They also experimented with different methods of inactivation, including inactivation by heat, formalin, or exposure to UV light and reported that all reduced the immunogenicity of the vaccine (Collier and Blyth, 1967). Overall, their studies in baboons showed that the lack of cross-reactivity among strains was a problem, the immunity to reinfection was relatively short lived, and live vaccines were more effective. Moreover, the use of adjuvants may have led to increased disease via a hypersensitivity mechanism (Collier and Blyth, 1966b), but again, it should be noted that they were using a live strain of an aggressive chlamydiae, not at all typical of the human trachoma strains.

Based on their results in the baboon trials, the group moved on to field trials in The Gambia using live vaccines administered either subcutaneously or intramuscularly (Sowa et al., 1969). Results were mixed, with an initial trial producing short-term improvement in clinical disease; however, subsequent trials were inconsequential with either no evidence of protection or, in the case of the third trial in which the LGV-like "fast" strain was used, a possibility of exacerbated disease, although this may have been an artifact of the clinical scoring system used. The trials were halted when they subsequently found that the

chlamydial strain they were using in the vaccine could become systemic in baboons (Collier and Smith, 1967; Collier and Mogg, 1969). This strain was later found to be an LGV contaminant, hence its "fast" or aggressive growth and systemic distribution in baboons.

Concomitant with the ongoing trials by the above groups, the group led by Nichols et al. (1966, 1969) from the Harvard School of Public Health was conducting field trials in Saudi Arabia followed later by experiments in New World monkeys. In these trials, children 3 years of age or younger, were grouped according to whether they had active trachoma, nontrachomatous conjunctivitis, or no disease, so that they could determine the effectiveness of the vaccine in both prophylactic and therapeutic modalities. They were immunized with vaccines containing equal portions of serovars B and C derived from yolk sacs and inactivated with formalin. Two preparations were in aqueous form at two different concentrations while the remaining vaccine was administered along with thimersol as adjuvant. A booster dose was administered in all three groups 6 months after the primary immunization.

In contrast to other groups, in addition to the clinical evaluation of the subjects, they also quantified the number of chlamydiae on conjunctival swabs. Both aqueous vaccines delayed the conversion of subjects to active trachoma while there was no such effect with the adjuvant vaccine; however, the overall microbiological conversion rate was not significantly affected by any of the vaccine regimens. Nevertheless, there was a reduction in numbers of inclusions detected in immunized subjects converting from negative to positive within 6 months after the primary immunization with either the low dose aqueous or adjuvant vaccines. In children who were positive at the outset, there was only evidence of reduction in inclusion number in those receiving the higher vaccine dose. Of interest was the observation that of the children who were clinically normal at the beginning of the study, those that received the higher dose aqueous vaccine developed disease three times more readily than control subjects, although their clinical disease was no worse than controls and there may have been a reduction in the number of organisms. Just as in other field trials, the effectiveness, even if marginal, was only apparent for a short period of time following immunization.

After approximately a decade of human vaccine testing, all studies were halted and to the current day, there have been no further trials in humans with potential vaccines against either trachoma or genital tract infections. So after all of these trials, what have we learned and what is the significance with regard to the current pursuit of a vaccine? In many of the studies, there was clear evidence for immunity. Generally, immunity was associated with the administration of high doses of formalin-treated organisms and was preventive if administered to previously uninfected individuals. The vaccine was also able to either prevent infection or reduce the infection so that if acquired, it was likely subclinical or otherwise undetectable. In support of this, the Harvard group was able to demonstrate a reduction in the number of organisms (Nichols et al., 1969). Evidence for a therapeutic effect in individuals who were already infected was also observed. Nevertheless, the consistent finding in all of the studies was that the immunity induced by the vaccine was very short lived, even with booster inoculations and natural exposure to the organism. That immunity lasted on the average only less than 1 year is clearly problematic when considering immunization of large populations, particularly in underdeveloped countries.

Another key observation that was supported by studies in animal models and in vitro was that the protective effect when seen was serovar specific. Especially in non human primate experiments, it was observed that immunization with one serovar did not protect against other serovars. In the case of trachoma or genital tract infections, this certainly indicates that a vaccine will have to be composed of either a single genus- or species-specific epitope or multiple serovar-specific epitopes.

Perhaps the most significant consequence of the human trials and from concurrent studies in monkeys which continues to impact on the development of a vaccine today was derived from the observations that in certain situations, there actually seemed to be either exacerbated disease or an increased rate of conversion to active trachoma in subjects receiving the vaccine (Grayston and Wang, 1975). In one of the early volunteer experiments, medical students in Taiwan were immunized with trachoma strains and then challenged in the eye (Grayston et al., 1961). Interestingly, the immunized students had an earlier onset of disease, and there was a correlation between the complement fixation antibody titer and the severity of the disease, suggesting some form of a hypersensitivity response. There is still much debate about how significant and representative the findings suggesting a hypersensitivity response were and whether the potential for a hypersensitivity response is a realistic concern.

In general, it appeared that the adverse responses were observed in situations where there was an inadequate amount of antigen in the vaccine or where there was a single serovar. Woolridge et al. (1967a) saw a slightly increased incidence of conversion in

individuals vaccinated with a monovalent vaccine while Nichols et al. (1966) reported increased incidence of conversion to active trachoma in subjects administered a vaccine with a lower number of organisms. While the authors cautiously suggested that these results may have been associated with sensitization by the vaccine followed by a "hypersensitivity" response, the data are not all clear that there was a true hypersensitivity response. Exacerbated disease was not observed even in those vaccinated subjects who converted to active disease, although one can argue that sensitization by a vaccine would create a more rapid follicular response upon contact with the infectious agent in contrast to naïve individuals.

While the human trials only showed marginal data with regard to a hypersensitivity response, immunization of monkeys produced more definitive results. In early monkey experiments, Wang and Grayston (1967) observed that pannus occurred more frequently in vaccinated monkeys than in control monkeys and that pannus was also more frequent in monkeys immunized with the Bour strain. The Bour strain was actually a serovar E organism, albeit it was isolated from a trachoma case in the San Francisco area, and was considered to be an aggressive strain. This strain was originally used in the monkey model because it was able to produce a more characteristic disease than the serovar B and C strains. These data were similar to those published by Collier and Blyth (1966b) in which they reported more severe disease in challenge of animals immunized with the 'fast' (likely LGV) strain and challenged with a non-trachoma isolate. Since these studies were done with exceptionally aggressive strains and in some cases, had heterologous challenges, one must question whether they are truly predictive for human vaccination. However, additional studies in monkeys using the same trivalent vaccine (serovars A, B, and C) as used in human trials did indeed show enhanced disease in monkeys immunized with a low-dose vaccine when challenged with a homologous strain of each serovar (Grayston et al., 1971).

Because the pathogenesis of trachoma is clearly associated with the cell-mediated immune response, the adverse reactions observed in humans and monkeys in these studies have raised major concerns among pharmaceutical companies that a vaccine, particularly a whole organism vaccine, might have potential deleterious effects. This concern was heightened several years ago in studies that suggested that hsp60 was an antigen which was responsible for eliciting the pathologic cell-mediated response (Morrison, 1991). Further studies showed that although hsp60 was highly immunogenic and an antibody response to it correlated with severe disease, it was not responsible for the hypersensitivity response (Rank and Sanders, 1992; Rank et al., 1995; Stephens, 2003). However, during the study of this antigen, it was noted that there was significant sequence homology between chlamydial and human hsp60 (Morrison et al., 1989). While there has been absolutely no evidence for an autoimmune response resulting from chlamydial infection, there is still major concern in the development of a vaccine that no component with cross-reaction to human antigens should be incorporated into a vaccine. Thus, it is highly unlikely that any future vaccine trials will utilize whole organisms, even if attenuated or killed, as was done in the original trachoma trials. The risk of litigation for vaccine companies is just too great.

Current Licensed Vaccines

There are currently no licensed vaccines for use in humans for either chlamydial genital infections or trachoma. Nevertheless, it should be mentioned that there are currently two licensed vaccines used in veterinary practice. Fevaxyn Pentofel™ from Fort Dodge, a division of Wyeth, is an inactivated veterinary vaccine for several diseases in cats, including chlamydial conjunctivitis caused by *Chlamydophila felis*. However, its protective value against conjunctivitis appears limited, reducing the length of clinical disease by only a few days. Moreover, it is not able to prevent the establishment of chronic infection, characteristic of the feline disease. Live vaccines have been used that also provide marginal protection but may result in actual conjunctival infection if they get inadvertently in contact with the eye.

A vaccine is also commercially available in Europe for the prevention of abortion in sheep caused by *Chlamydophila abortis*. Enzovax is a freeze-dried vaccine containing $10^{5.0}$–$10^{6.9}$ IFU of live, attenuated strain of *Chlamydophila abortus* per dose and is produced by Intervet in the United Kingdom. The attenuated strain is a temperature-sensitive mutant originally derived by Rodolakis which is infectious for sheep but produces a mild infection (Rodolakis and Souriau, 1983; Rodolakis and Bernard, 1984). As in the vaccine for *C. felis*, it is difficult to measure the outcome, but the vaccine itself does not exacerbate the disease and may have some mild protective effects. Not surprisingly, frequent boosters are required.

These vaccines are mentioned here because it is interesting that both of the vaccines are whole organism vaccines with the ovine vaccine being live attenuated; but they do not appear to elicit any untoward effects analogous to what was seen in the monkey experiments

with *C. trachomatis.* Of course, clinical trials in the veterinary world are not as rigorously controlled and monitored as in human studies. Also, as has been seen over and over again in human and monkey trials, as well as in other animal models, immunity is not long-lasting and booster inoculations are essential.

VACCINES IN DEVELOPMENT

Despite the limited success and lengthy interval since the trachoma clinical trials 40 years ago, there has been a continued emphasis on research directed to the development of a vaccine. However, the target of vaccine efforts has changed from trachoma to genital tract infections caused by chlamydiae, with specific emphasis on the prevention of upper genital tract disease and involuntary infertility in women. Trachoma is no less important, but genital tract infections are epidemic in the developed countries, and there is a distinct economic advantage for vaccine companies to pursue a vaccine for chlamydial genital infections. The vast majority of research in the intervening years since the trachoma trials has addressed the immune mechanisms operative in natural immunity to chlamydial genital infection and the mechanisms of pathogenesis. Moreover, since the use of a whole organism is not feasible, there has also been continued interest in determining the potential protective antigens that could be incorporated into a vaccine. At this point, virtually all of the vaccine development is still in the discovery and preclinical development stages.

Discovery/Basic Science

The basic science work has centered on several important questions such as the following: (1) what arm(s) of the immune response is/are critical for protection; (2) can a long-lasting protective response be produced; (3) should a strategy of preventing infection or preventing disease be adopted; (4) what is/are the protective antigen(s); (5) will the candidate vaccine prime the individual for, actually elicit, or exacerbate a pathologic response? Each one of these questions is critical in the ultimate development of an effective vaccine.

It is evident from the review of the adaptive immune response that both antibody and cell-mediated immune responses are elicited during a natural infection. There is virtually universal agreement among researchers that a cell-mediated response is essential for a protective response, especially in a natural infection. Studies in mouse and guinea pig models of genital infection have definitely demonstrated that a CD4 Th1 cell-mediated immune response is essential for a protective immune response (Rank and Barron, 1983a; Rank et al., 1989; Morrison et al., 2000). Studies in humans have also supported the protective role of the CD4 cell (Kimani et al., 1996).

While it is the consensus that any vaccine will need to induce CD4 Th1 response, there are caveats associated with this response. Firstly, it is highly unlikely that a Th1 response will be able to prevent infection, especially over the long term. Since there is minimal resident lymphoid tissue in the genital tract, T cells must be recruited to the local site upon infection. The production of the appropriate chemokines will only be initiated upon infection and will occur only during the first developmental cycle through the stimulation of toll receptors and perhaps other yet-undefined mechanisms. Thus, it is unlikely that T cells will gain access to the site prior to the end of the first developmental cycle of the organism. During that time, the acute inflammatory response will already be under way. In the guinea pig conjunctival model, we have observed PMNs in the local tissue as early as 6 h after infection (Rank, R.G. and Wyrick, P.M., unpublished data). Even in an anamnestic response, it is unlikely that T cells will enter the site within the first 24–48 h of infection. Kelly and Rank (1997) observed a large influx of CD4 cells by 7 days after a challenge infection in the mouse, and although they did not look earlier, the high number suggested that the CD4 cells were present before 7 days.

The lack of resident lymphoid tissue in the genital tract may also explain why immunity to reinfection is short lived as seen in humans and all of the animal models. One can hypothesize that T cells are recruited to the local site and then bring about resolution of infection; however, when the organisms have been eliminated, there is no longer any stimulus to recruit and retain cells at the site. Upon a challenge infection, the cells must once again be recruited to the local site, a process which can take some time. Evidence for this mechanism was reported by Igietseme and Rank (1991) who observed that resolution of genital infection in the guinea pig was concomitant with an increase in the number of chlamydia-specific T cells in the genital tract. The animals were immune to reinfection as long as the T cells were still present, but they became susceptible to reinfection when T cells were absent. This is a difficult phenomenon to overcome with a vaccine, since it would obviously neither be practical nor desirable to maintain a constant T cell response in the genital tract. This may not be as critical an issue in the eye which has resident lymphoid tissue and after infection, follicles, which contain both B cells

and T cells (Whittum-Hudson et al., 1986) and might explain in part why in trachoma, one has difficulty isolating organisms in the latter stages of the disease.

A vaccine must also be able to elicit a T cell response which can home to the genital tract. Because the genital tract is a mucosal site, T cells induced by a systemic inoculation may not necessarily have the appropriate homing receptors to allow them to readily move to the local genital tissue. The homing receptor $\alpha 4\beta 7$ has been found to be an important receptor for the homing of T cell clones to the genital tract in mice (Kelly and Rank, 1997).

While the role for CMI is clear, there has been substantial debate about the requirement for an antibody response. The data in the guinea pig model strongly indicate a role for antibody in resolution of a primary infection and resistance to reinfection (Rank et al., 1979; Rank and Barron, 1983b), but the role in the mouse model is not as clear; although recently Morrison and Morrison (2005a) have presented evidence for a role of antibody in resistance to reinfection in the mouse. There have been many reports in vivo and in vitro demonstrating that antibody can neutralize chlamydial infection (Rank, 1999), but it has been difficult to prove a correlation between the neutralizing antibody titer and a protective response (Jones and Van der Pol, 1994). Antibody would be the most obvious effector arm to either prevent infection or limit the course of infection in a time-sensitive manner. Moreover, especially with respect to infection in the female genital tract, IgG can be transudated into the genital tract from serum and is actually the dominant antibody in the female genital tract (Masson et al., 1969; Rank and Batteiger, 1989). Immunization by intramuscular or subcutaneous routes can induce a strong systemic antibody response that has the potential to be long-lasting. The continual presence of IgG in the genital tract of female guinea pigs was observed up to 825 days after a primary infection, long after IgA levels in secretions had diminished about day 50 (Rank et al., 1988). Thus, an ideal vaccine would elicit both an antibody- and cell-mediated immune response with the former neutralizing and decreasing the number of organisms while the latter would be necessary to clear the infection.

Since it will be very difficult to develop a vaccine that universally prevents infection, a vaccine for chlamydial genital infection could be considered to be successful if it is able to prevent ascending infection in women, so that salpingitis with its sequelae do not occur. It would be hoped that the antibody response could reduce the number of organisms present and delay or block the organisms from moving up the genital tract until antigen-specific T cells are recruited to the site to eliminate the infection. It has been demonstrated in the guinea pig that the incubation period, i.e., the time until organisms can be isolated from the lower genital tract following inoculation, increases as fewer organisms are used in the inoculum (Rank et al., 2003). Thus, the more effective the antibody response in the lower genital tract, the more likely is the possibility that the number of organisms will be diminished and ascending infection prevented. In addition, while adolescent females will be the target population for a vaccine, it would also be practical to immunize males. Ideally, this would not only diminish disease in males, but if there were a low level of infection and/or abbreviated infection in males, the inoculating dose for females would be lower and perhaps more readily controlled by the host response in an immunized female.

Vaccine Candidates

As one might expect, there has been a great deal of effort made in defining the protective antigens, and therefore, potential vaccine candidates. As described above, whole organism vaccines have been evaluated in trachoma clinical trials and two whole organism vaccines are in use in veterinary practice. However, even though all antigens are present, protection against challenge was variable and clearly short lived. Moreover, because of hypersensitivity and cross-reactive antigen issues, the use of whole organisms, even if attenuated, is not practical or safe for human use. Thus, researchers have been targeting individual proteins as candidates. To be a successful vaccine candidate, the protein should ideally have epitopes that bridge several serovars of *C. trachomatis*, have a structure such that one can construct a recombinant protein analogous to the native protein, and not elicit an exacerbated response upon subsequent challenge.

The vast majority of the research investigating potential vaccine candidates has centered on the MOMP, also referred to as the outer membrane protein A (ompA) (Table 44.1). The literature on MOMP and immunization studies with MOMP have been reviewed in detail previously (Rank, 1999). Caldwell first reported that antibodies to MOMP could neutralize infectivity of elementary bodies in cell culture (Caldwell and Perry, 1982), and Williams et al. (1984) later observed that incubation of *C. muridarum* elementary bodies with antibody to MOMP could neutralize infectivity in vivo in the mouse lung model. In studies on human sera as well as in infection studies in animals, MOMP was found to be highly immunogenic, appearing as a major band in immunoblot analyses, and correlations were observed with the resolution of infection. However, initial immunization

TABLE 44.1 Current vaccine candidates

Vaccine candidate	Location/function	In vivo protection
MOMP (ompA)	Outer membrane; porin	Yes
CPAF	Cytosol; protease	Yes
PmpD	Outer membrane	Not tested
PorB	Outer membrane; porin	Not tested

studies with MOMP or epitopes of MOMP were not highly successful even though antibodies generated to the protein and/or epitopes could neutralize infection in vivo. Subsequently, Zhang et al. (1989) observed that only those monoclonal antibodies which were able to recognize surface determinants were successful in neutralizing infectivity. It became apparent that conformational epitopes on MOMP were critical for the induction of protective immunity when *C. caviae* genital infection in guinea pigs could be significantly reduced in intensity by immunization with MOMP purified from whole elementary bodies with nonreducing methods but not by MOMP purified with sodium dodecyl sulfate which breaks disulfide bonds (Batteiger et al., 1993).

There is no doubt that MOMP is immunogenic and in immunization protocols with adjuvants approved for human use can markedly reduce the level of subsequent challenge infection and even prevent the development of infertility in mice (Pal et al., 2005); however, the major problem that needs to be surmounted is that a recombinant protein with the intact conformational epitopes must be produced. Without a recombinant protein, it will be logistically and economically not feasible to derive sufficient MOMP from chlamydiae for vaccine production. Moreover, MOMP clearly is serovar-specific although a vaccine could conceivably contain multiple MOMP molecules representing the dominant genital or ocular serovars. That a recombinant MOMP can be produced with the ability to elicit a protective response was reported by Eko et al. (2004). They transformed *Vibrio cholerae 01 strain H1* with recombinant MOMP and omp2 from serovar D and then produced outer membrane ghosts which they used for immunization of mice. The multivalent vaccine elicited a strong Th1 response as well as IgG2a and IgA antibody responses in genital secretions. That the antibodies were detected against whole elementary bodies in an ELISA assay suggested that they were recognizing surface determinants. When T cells from mice immunized with the multivalent vaccine were adoptively transferred into naïve mice and those mice challenged, a protective response was seen. Whether the recombinant MOMP and recombinant omp2 alone were able to induce a similar response was not assessed.

Another outer membrane protein of interest is PorB, an outer membrane protein with porin function which is conserved across *C. trachomatis* serovars (Kawa and Stephens, 2002). While natural infection in humans and intraperitoneal infection of mice with *C. trachomatis* results in minimal antibody responses to this protein, immunization of mice with PorB produces a substantial serum antibody response (Kawa et al., 2004). Moreover, antibodies to PorB neutralize in vitro, making it a possible vaccine candidate, although animal protection studies have not yet been performed.

Recently, Caldwell et al. (1975) have described and characterized the polymorphic membrane protein D (pmpD) (Crane et al., 2006). This is a high molecular weight molecule (~155 kD) which is recognized by convalescent sera from individuals with cervicitis, urethritis, LGV, and trachoma. The exciting aspect of this antigen is that it is a surface-exposed epitope that is conserved among *C. trachomatis* serotypes and that antibodies to pmpD can neutralize infectivity in cell culture. Thus, in addition to MOMP, it is the only other molecule that has been found to elicit neutralizing antibodies. A potential problem is that antibodies to both MOMP and LPS are able to block the neutralizing effect of the anti-pmpD antibodies, which could be a problem for individuals who have already been exposed to *C. trachomatis* prior to receiving a vaccine. Furthermore, if the protection generated by a pmpD vaccine was not sufficient to prevent infection, antibodies generated to MOMP and LPS in a low-level infection may abrogate the effects of the vaccine. Nevertheless, these findings are exciting, and pmpD holds promise as a possible vaccine candidate.

Recently, data have been published by Zhong et al. (2001) that an intracellular molecule secreted into the cytosol, chlamydial protease-like activity factor (CPAF) is highly immunogenic in humans. At least in vitro, CPAF degrades major histocompatibility complex transcription factors RFX-5 and USF-1 as well as keratin-8; however, its exact role in chlamydial infection of the host cell is not clear. Of interest is the observation that it is functionally conserved among several chlamydial species (Dong et al., 2005). Intranasal immunization of mice with recombinant CPAF, derived from the sequence of serovar L2, plus IL-12, was able to reduce the length of genital infection as well as significantly reduce the pathologic response in the oviduct (Murthy et al., 2007). These data suggest that this may be a viable vaccine candidate, especially

if there is the potential for cross-serovar protection, although this needs to be evaluated further.

While the above molecules have been described in the literature as possible vaccine candidates, they are by no means the only candidates. With the small size of the chlamydial genome, it has not been difficult for those companies interested in vaccines to express virtually every open reading frame as either a protein or DNA vaccine and screen each for a possible protective role in relevant animal models. Most likely, some promising candidates are under evaluation behind closed doors and none have yet come to clinical trials.

Vaccine Candidates and Pathologic Response

Because of the experiences in the trachoma vaccine trials and subsequent studies on hsp60, there is obviously a great deal of concern that a vaccine may prime the host response so that upon infection, the individual may have more severe disease. It is important to point out that the trachoma vaccines for the most part were able to elicit a protective response, albeit short lived. Even in monkeys, there was a high degree of success in inducing a protective immune response. The reasons that some individuals had a higher rate of conversion to disease are not clear but could reasonably be associated with prior sensitization by the vaccine, since the pathologic response in chlamydial infections is indeed host mediated. Nevertheless, it is also important to note that in trachoma, the organism is inoculated in nature directly into the target tissue site that is also a site with resident lymphoid tissue. Any host cellular response will have the potential to have immediate pathologic consequences.

In contrast, the site of infection in the genital tract that results in morbidity is the upper genital tract of women. Based on animal model studies, it appears that the organism requires several days to reach the upper genital tract (Rank and Sanders, 1992). Therefore, it is quite conceivable that even if there is a substantial host response to the organism, analogous to the trachoma studies, the pathology may be restricted to the lower genital tract which is capable of repair and where any residual fibrosis would be of less long-term consequence. The infection could easily be resolved prior to the organism reaching the fallopian tubes. In fact, none of the immunization studies in animal models of genital tract infection have reported any evidence for enhanced upper tract disease upon challenge (Pal et al., 1997; Su et al., 1998; O'Connell et al., 2007; Murthy et al., 2007). Thus, a vaccine designed to protect against genital infection has an anatomical advantage on its side.

Clinical Trials

At the time of this writing, no vaccine candidates have advanced to clinical trials. Even if a vaccine candidate were ready today for testing, there are several important issues which must be determined for the proper evaluation of a vaccine in clinical trials. The most important issue is what population will be immunized. The obvious population to be immunized is the adolescent female population since the infection is epidemic in this population and the prevention of infertility in women is the major reason for producing a vaccine. Ideally, one should immunize adolescent females prior to the onset of sexual activity. Currently, with the HPV, meningococcal and acellular pertussis vaccines being used in the adolescent population, there is clear precedent for an adolescent panel that has not been present before. Whether a vaccine will be effective if the subject has already had a chlamydial infection is also an important question. If the vaccine is successful in adolescent females, should the population be expanded to include adolescent males? Obviously, chlamydial infections are also epidemic in males but infertility in males following chlamydial infection is a rare event; so is it justifiable to immunize males in order to decrease the incidence of infection in females?

When the HPV vaccine was tested, investigators could not wait the length of time necessary to determine whether the vaccine would prevent cancer, so a surrogate endpoint was adopted. There is a similar issue in immunizing against chlamydial genital infections. It is quite apparent that it will not be practical to follow women to determine if infertility develops because of the long time interval that may occur before the onset or clinical detection; so an alternative endpoint must be determined. For the reasons given in earlier sections, it may be difficult to actually prevent infection with a vaccine, and given the already high incidence of subclinical infections, it may be problematic to determine whether the vaccine is reducing the infection to a subclinical state or whether the vaccine has had no effect, and the infection is naturally subclinical. Thus, clinical outcome in the short term may not be practical. One can potentially make use of the observation that the titer of antibody to hsp60 has been correlated with the presence of upper tract disease (Brunham et al., 1985; Wagar et al., 1990). While it does not appear that hsp60 itself is involved in inducing the pathologic response, it may well be a marker of either intensity and/or frequency of infection. In support of this, when antibody titers to hsp60 were measured in guinea pigs following one or more intravaginal infections with *C. caviae*,

a strong correlation was observed between the titer and the number of times the animals were infected (Rank and Sanders, 1992). It was also found that upper genital tract pathology was more likely to develop with repeated infections, just as seen in humans (Rank et al., 1995). Thus, if immunized individuals have either a lower incidence of hsp60 antibody conversion or lower titers than unimmunized individuals, this may be considered predictive for the prevention of upper tract disease.

The longevity of a protective effect will also be an important factor to evaluate, since all of the human trials and animal studies showed that solid immunity is short lived. In the trachoma trials, protective immunity began to break down with 1–2 years of immunization; this may be a reasonable time over which to monitor the subjects in a clinical trial.

There is also the issue of persistence. While a great deal of effort has been expended on understanding persistence mechanisms in vitro, the in vitro models of persistence have no proven parallel in humans and are likely not predictive at all of the persistence in the human host. While there is no question that chlamydiae can persist in animals, no one has yet detected or demonstrated a uniquely "persistent" form in any animal model of chlamydial infection. It is more likely, based on precedents with other organisms such as in carrier states of various bacteria and long-term low-level infections of organisms such as *Plasmodia*, that persistent infection is simply a low-level chronic infection, in which the organism undergoes normal replication but is maintained at a low level by the host response. Nevertheless, clinical trials will have to address the potential for such an infection, even in the presence of a protective host response generated by the vaccine.

PROSPECTS FOR THE FUTURE

The prospects for a vaccine against chlamydial genital infection at this time are still somewhat daunting. There are several chlamydial antigens that have been identified as potential vaccine candidates—the most well-described is the MOMP that is surface exposed and highly immunogenic. However, it is clear that conformational epitopes are the key protective targets, and it has been difficult to produce recombinants that maintain the native conformation. Moreover, the protective epitopes of MOMP are serovar specific, although a vaccine could combine MOMPs from several of the most prevalent serotypes. There are other immunogens that have genus-specific epitopes, but these are still in the early stages of experimental evaluation in animal models. It is quite likely that a vaccine will need to contain multiple antigens to be most effective and to be effective against multiple serovars. A successful vaccine against a local genital tract infection, especially with the goal of eliciting an effective Th1 response may require specific adjuvants to produce that response locally.

Importantly, the trachoma vaccine trials revealed that a vaccine can indeed provide a certain level of protection, but there are clearly important issues that must be resolved. Among these, there must be certainty that a vaccine will not elicit more pathology or increase the risk of disease as seen in some of the trachoma vaccine trials. This issue alone and the observation that chlamydial hsp60 cross-reacts with human hsp60 have driven the vaccine research toward using a protein or subunit vaccine rather than the whole organism vaccines used in the original clinical trials. In addition, the trials told us that it is extremely difficult to elicit a protective response which is effective for more than 1–2 years, even with a whole organism or live vaccine. However, those studies were addressing immunity to trachoma, in which the organism is being directly deposited to the target tissue. With respect to a genital tract vaccine in women, the site of pathology is the upper tract, so there is a window of time before the organisms ascend the genital tract for existing effectors such as antibody to neutralize organisms and for an anamnestic T cell response to be generated. This anatomical difference in target tissues may facilitate a longer period of protection against upper genital tract disease. Studies in guinea pigs have shown that IgG which is derived from the serum can be detected in the genital tract for well over 2 years and that an exuberant anamnestic response occurs within a few days of challenge (Rank et al., 1988).

There are still some practical issues which must be solved before a vaccine can go to clinical trials. The primary issue is what surrogates for infertility and ectopic pregnancy can be used to determine vaccine effectiveness. The association of antibody to hsp60 and upper tract disease may be one parameter that can be monitored to determine vaccine effectiveness as well as simply the reduction in chlamydial infection and clinical disease in a prospective group.

Social issues regarding a vaccine against a sexually transmitted infection have always been of concern; however, the climate is now ripe for a vaccine since the HPV vaccine has been successfully marketed, and there is now an adolescent vaccine panel, including vaccines against the meningitis and pertussis, something which was not present only a few years ago. Thus, it is entirely conceivable that a vaccine against chlamydial infection could be easily attached to that panel.

The development of a vaccine against trachoma is a more difficult task because one must consider that the vaccine will have to be both prophylactic and therapeutic. It is reasonable to assume that the same vaccine candidates being investigated for genital tract vaccines could be potentially used, taking into consideration the different serovars associated with trachoma. However, a key factor in the success of a vaccine is that there is no time interval between the exposure to the organism and the arrival of the organism at the target site, so that the pathologic process, even in a reinfection situation, can begin immediately before an anamnestic response can be initiated. Moreover, because of practical economic reasons, the geographic distribution of trachoma, and the relative success of the SAFE program, there is less incentive for companies to invest a great deal of resources in a vaccine for trachoma. With these issues in mind, the prospects for a trachoma vaccine in the near future are somewhat bleak.

KEY ISSUES

- It is important that a vaccine does not exacerbate pathologic response or increase the incidence of clinical disease. There is precedent for this occurring in the trachoma trials, and the pathology produced by chlamydial infection is host mediated.
- A vaccine must be able to elicit long-term immunity, something which did not occur with the original trachoma trials and which does not occur with natural infection. A strategy of preventing ascending infection may in part facilitate long-term protection.
- Because there are multiple serovars that cause both genital and ocular infections, it is critical that a vaccine contain either multiple serovars or genus-specific antigens. It is likely that a vaccine will have multiple antigens.
- Persistence of chlamydial infection, although still undefined and uncharacterized in humans and animals, is still a major concern. A vaccine must be evaluated to determine whether it can prevent persistence or whether the organism is still present but prevented from causing disease.
- Before a vaccine can go to clinical trials, appropriate surrogates for infertility and ectopic pregnancy must be determined and evaluated in animal models.
- The success of the HPV vaccine and other vaccines administered to adolescents provides a golden opportunity for the addition of other vaccines against sexually transmitted infections to the adolescent panel.
- A vaccine for genital infections should target adolescent females before the beginning of sexual activity. Considering the lack of significant sequelae, it needs to be determined whether males should be targeted as well, although it would be reasonable so that infection is either prevented or reduced. This would also reduce the risk for women.
- Developing a vaccine against trachoma while feasible based on early clinical trials, may not have economic incentives for industry. Because of the emphasis on genital infections in recent years, there needs to be renewed efforts to understand the ocular immune response to chlamydial infections in animal models.

ACKNOWLEDGMENTS

I would like to thank Dr. Cho-chou Kuo and Dr. Bernhard Kaltenböck for the valuable information they provided me in the writing of this chapter. I also would like to acknowledge Dr. H. Marie Lacy for her helpful feedback in reviewing this manuscript.

OUTLINE

ABSTRACT

Cholera is a life-threatening diarrheal disease with epidemic potential caused by the Gram negative bacterium *Vibrio cholerae*, serogroups O1 and O139. Since most cases of cholera are either not detected or not reported, the global burden of cholera is not known with certainty; however, cholera causes significant morbidity and mortality worldwide, with an estimated 5–7 million cases occurring each year, resulting in greater than 100,000 deaths per year. At present, the world is experiencing its seventh recorded pandemic, and cholera is endemic in many countries in Asia, Africa, and Latin America. Large outbreaks, especially among impoverished or displaced persons, occur on a regular basis, and cholera may spread through travel or migration of infected individuals, including even short-term travelers or visitors. Natural infection with *V. cholerae* O1 or O139 induces long-lasting protective immunity against subsequent disease. Protection against cholera correlates best with the vibriocidal antibodies thought to be largely directed against *V. cholerae* lipopolysaccharide (LPS), although anti-LPS serum IgG levels have not been shown to correlate with protection against cholera. It is hypothesized that the vibriocidal response may be a surrogate marker for as yet poorly understood mucosal immune responses, since it is unclear why a serum complement-binding-based assay would predict protection against a noninvasive intestinal pathogen such as *V. cholerae*. In an effort to ameliorate the morbidity and mortality associated with cholera, several parenteral and oral cholera vaccines have been developed since the 1880s. Commercial production of the killed parenteral vaccine most widely available in the 20th century was recently discontinued. Currently, an oral killed cholera vaccine (rBS-WC) is the only international commercially available cholera vaccine, and is only available in some countries. No cholera vaccine is currently commercially available in the United States. Following repetitive administration in large field trials, rBS-WC induces approximately 85% protective immunity for at least 6 months, although protection wans over the subsequent 2–3 years following vaccination. An oral killed whole vaccine that targets both *V. cholerae* O1 and O139 is also available and used programmatically in Vietnam. A number of live attenuated cholera vaccines have also been developed, including classical O1 derivative CVD 103-HgR, and El Tor O1 derivative Peru-15. These live attenuated vaccines have been shown to be safe and immunogenic in volunteers, although their protective efficacy has not yet been demonstrated in large randomized field trials. Subunit vaccines and additional anti-O139 cholera vaccines are presently in earlier stages of development. To better understand immunity protective against cholera, high throughput genomic, proteomic, and immunomic technologies are being applied to *V. cholerae*.

INTRODUCTION

Vibrio cholerae serogroups O1 and O139 are the causative agents of cholera, a severe, dehydrating diarrheal illness of humans with epidemic potential, and *V. cholerae* is a category B agent. At present, the world is experiencing its seventh recorded cholera pandemic, and cholera is endemic in many countries in Asia, Africa, and Latin America. Cholera remains a disease of poverty, social disruption, and poor sanitation, and large and explosive outbreaks occur on a regular basis.

HISTORY OF DISEASE

Although scattered written historic reports of epidemics of severe watery diarrhea exist in Sanskrit, Chinese, and Arabic, perhaps one of the first written reports that may with some degree of certainty be ascribed to a cholera outbreak was written by the Portuguese explorer Gaspar Correira in 1543 in his work "Lendas da India," in which he described an outbreak of diarrhea among military troops in Calicut and Goa that left thousands dead. Correira wrote of a "Disease… (with) vomiting, with drought of water accompanying it, as if the stomach were parched up, and cramps that fixed the sinews of the joints…. Disease sudden-like, which struck with pain in the belly, so that a man did not last out eight hours of time." Although other large outbreaks were reported in the 1600s and 1700s in Asia, the global spread of cholera mirrored the growth of the global economy. By convention, since 1817, there have been seven global cholera pandemics, all of which have begun in Asia. The world is currently experiencing its seventh pandemic, which began in modern day Indonesia in 1961, spread to Africa and Europe in the 1970s, and then to the New World in the 1990s. The first six pandemics are historically ascribed to *V. cholerae* O1 classical biotype. The current pandemic is caused by *V. cholerae* O1 El Tor biotype (named for the El Tor medical field station in the Sinai Peninsula where this biotype was first isolated among religious pilgrims in the early 1900s). *V. cholerae* O139 first appeared in 1992 in South Asia, and since then has accounted for a minority of disease in 11 Asian countries.

It is hard to overstate the role that cholera has had on human societal, scientific, and biomedical development. Along with plague and smallpox, cholera was one of the pathogens of the highest historical global

import. In large measure, attempts to control cholera drove the sanitary revolution of the 1800s, including the establishment of governmental and international boards of health, laws pertaining to hygiene, water treatment, and international travel, and construction of large public works including municipal sewer and water systems. Cholera was the first human illness ascribed to transmission by water, as suggested by John Snow in "On the Mode and Transmission of Cholera," and it was John Snow's epidemiological analysis of the London cholera outbreak surrounding the Broad Street pump of 1854 that is credited with initiating the field of evidence-based epidemiological intervention.

V. cholerae was also the first human pathogen identified microscopically when Filippo Pacini observed a curved bacillus in the stool of cholera victims in Florence during an 1854 outbreak. Pacini named the organism *Vibrio cholerae* since it appeared to vibrate under the microscope. Robert Koch then "rediscovered" the organism in the 1880s, and unaware of Pacini's work, referred to the organism as *Komma bacillus* (since it was comma shaped). Importantly, Koch was able not only to view the organism under the microscope, but also to develop the techniques required to grow the organism in pure culture in the laboratory. This permitted characterizing the cholera bacillus (and typhoid bacillus) by reactivity with specific antisera, leading to the agglutination assay still used to serogroup bacteria today. Koch also postulated production of a toxin by the cholera organism. Attempts to isolate this toxin led Pfeiffer to the identification of heat stable lipopolysaccharide (LPS) (i.e., "endotoxin"). Pfeiffer further observed that *V. cholerae* injected into the peritoneum of immunized guinea pigs became immobilized and lyzed, an observation which then led to the discovery of the complement system, which itself led to the development of the first specific laboratory-based serological assay for a human pathogen, the serum vibriocidal assay. In 1959, cholera toxin (CT) was also the first enterotoxin specifically identified.

CT causes a severe secretory diarrhea and cholera played a central role in advancing the understanding of fluid and salt physiology in the human body, was the indication for the first therapeutic use of intravenous fluid replacement therapy in humans (when Jaehnichen injected water into a cholera patient in 1830, and Latta injected water and salt into cholera patients in 1832), and played the central role in the development of oral replacement therapy (ORS), a simple and inexpensive intervention that has saved millions of lives from all causes of diarrhea in the last 40 years. Cholera has also played a central role in the history of vaccinology (see below).

ETIOLOGIC AGENT

Classification

V. cholerae is a Gram negative curved bacillus. The organism is flagellated and motile with a characteristic "shooting star" appearance in the watery diarrheal stools of cholera patients. *V. cholerae* are differentiated by the LPS component of the organism's outer membrane, and *V. cholerae* is currently classified into approximately 200 serogroups. *V. cholerae* strains belonging to serogroups O1 and O139 are capable of causing epidemic cholera. Non-O1, non-O139 *V. cholerae* strains have been associated with isolated cases or small outbreaks of gastroenteritis, cellulitis, or bacteremia, the latter two manifestations usually reported in individuals with chronic hepatic dysfunction. *V. cholerae* O1 strains can also be divided into two biotypes, classical and El Tor, based on phenotypic differences in hemolytic assays, phage characteristics, hemaglutination, and polymyxin B sensitivity. Based on O antigen differences, each O1 biotype can be further subdivided into three serotypes: Ogawa, Inaba, and Hikojima. During outbreaks or sustained transmission, *V. cholerae* O1 may switch between Ogawa and Inaba serotypes. The Hikojima serotype is rare and thought to be unstable. *V. cholerae* O1 EL Tor type strain N16961 is currently annotated to contain 3885 open reading frames on two circular chromosomes: a large chromosome containing approximately 2.96 mbp and a smaller chromosome containing approximately 1.07 mbp (Heidelberg et al., 2000). Although *V. cholerae* may contain plasmids that alter susceptibility to antimicrobial agents, full virulence of *V. cholerae* does not require virulence plasmids.

Antigens

Perhaps the two best studied *V. cholerae* antigens are LPS and CT. LPS is comprised of a lipid A domain associated with the *V. cholerae* outer membrane, a core antigen, and repetitive specific polysaccharides. Ogawa and Inaba specific polysaccharides differ by the replacement of a hydroxyl group with a methyl group on the terminal sugar (Villeneuve et al., 2000). The LPS of *V. cholerae* O1 and O139 are distinct and non cross protective, and *V. cholerae* O139 is surrounded by a polysaccharide capsule (Comstock et al., 1995).

CT is a heterodimeric exotoxin that contains an enzymatically active A subunit attached to a pentamer of nonenzymatically active B subunits. The B subunit pentamer mediates binding of CT to monosialoganglioside GM_1 on brush border intestinal epithelial cells.

The A subunit is an ADP-ribosylating enzyme that elevates intracellular cAMP, eventually resulting in a secretory diarrhea in infected humans. CtxA and CtxB are expressed as an operon, and are encoded on a filamentous phage CTXφ (Waldor and Mekalanos, 1996). CT of *V. cholerae* O1 El Tor and O139 are identical.

A number of other important antigens have also been identified in *V. cholerae*. Toxin coregulated pilus (TCP) is a type IV pilus colonization factor essential for colonization and virulence (Taylor et al., 1987; Herrington et al., 1988). The major structural unit of TCP is TcpA, and TcpA from El Tor and classical strains are approximately 80% homologous (Sun et al., 1990; Iredell and Manning 1994). TcpA from El Tor and O139 strains are identical. In addition to playing a role in intestinal colonization by *V. cholerae*, TCP functions as the *V. cholerae* receptor for the filamentous phage CTXφ (Waldor and Mekalanos, 1996). The *V. cholerae* genome encodes 11 other type IV pili, many of which have either not been studied in detail or have not been shown to be essential to intestinal colonization, and other less-well defined antigens possibly associated with virulence (Hang et al., 2003).

PROTECTIVE IMMUNE RESPONSE

Previous infection with *V. cholerae* induces long-lasting protective immunity (Cash et al., 1974a, 1974b; Levine et al., 1979). For at least 3 years after infection of North American volunteers, infection with *V. cholerae* O1 classical strain organisms provides 100% protection against rechallenge with a homologous strain, and El Tor infection provides 90% protection (Levine et al., 1981). Previous infection with either O1 biotype provides slightly less protection against challenge with the heterologous strain O1 biotype organism, and immunity is serogroup-specific (previous infection with *V. cholerae* O1 does not provide protection against O139 disease). Mirroring volunteer studies, infection with *V. cholerae* O1 El Tor in Bangladesh, an area of the world endemic for cholera, decreases the likelihood of symptomatic cholera over the next several years by approximately 90% (Glass et al., 1985). Unfortunately, the nature of immune responses protective against cholera are not currently well understood.

Antibody-Mediated Immune Responses

Serum Responses

The serum vibriocidal antibody response, measured in an assay that detects complement-mediated bactericidal activity, is currently the best identified predictor of protection against cholera. In Bangladesh, vibriocidal antibodies are detectable in 40–80% of individuals by adolescence, and in one study, every two-fold rise in vibriocidal titer was associated with an approximately 40% decrease in the risk of developing symptomatic cholera (Glass et al., 1985; Mosley et al., 1968a, 1968b). Despite this, symptomatic cholera has been reported in individuals with high baseline vibriocidal titers on exposure (greater than or equal 320), and no vibriocidal titer has been identified above which *V. cholerae* O1 infection is completely prevented (Saha et al., 2004). Adsorbing sera with *V. cholerae* LPS removes a majority of vibriocidal antibodies (Holmgren and Svennerholm, 1977), although serum IgG anti-LPS antibody levels do not correlate with protection from cholera. Interestingly, recent data suggest that serum IgA anti-LPS responses do correlate with protection against cholera (Harris et al., 2007). These and other data suggest that the serum vibriocidal response may be a surrogate marker of mucosal immune responses that are themselves truly protective against cholera.

Although serum IgG antibody levels to CT increase after cholera, serum anti-CT IgG responses have not been shown to correlate with protection against cholera (Glass et al., 1985). Serum IgA anti-CT responses have, however, recently been found to correlate with protection against *V. cholerae* infection, perhaps further supporting the importance of mucosal immune responses in mediating protection (Harris et al., 2007); however, previous infection with El Tor *V. cholerae* O1 does not confer protection from infection with *V. cholerae* O139, despite the fact that *V. cholerae* O1 El Tor and O139 express essentially identical CTs (Albert et al., 1993; Ramamurthy et al., 1993).

Anti-TcpA responses are also common following cholera in an endemic setting, occurring in serum, stool, or circulating mucosal lymphocytes of over 90% of Bangladeshis recovering from cholera caused by *V. cholerae* O1 El Tor (Asaduzzaman et al., 2004), and serum IgA anti-TcpA antibody levels have recently been shown to correlate with protection against cholera in Bangladesh (Harris et al., 2007). Immunization of mice with El Tor TcpA also reduces mortality following *V. cholerae* challenge by 50% (Rollenhagen et al., 2006); however, in humans, infection with El Tor *V. cholerae* O1 has not been associated with protection from infection with *V. cholerae* O139, even though both serogroups of organisms produce identical TcpA molecules.

Mucosal Immunity

Acquired protection against noninvasive mucosal pathogens is in large part mediated by secretory IgA

(sIgA) produced locally at mucosal surfaces. Directly and reliably measuring local production of anti-*V. cholerae* sIgA at the intestinal surface can be problematic. As such, immune responses that are surrogate markers of intestinal immunity are often measured. In the case of *V. cholerae* infection, the serum vibriocidal and serum IgA antibody responses may be such markers. Following intestinal presentation of antigen, mucosal lymphocytes transiently migrate in the systemic circulation before re-homing to the intestinal mucosa. This transient migration peaks 7 days following intestinal exposure, and is measurable in an ELISPOT-format in an antibody-secreting cell (ASC) assay (Czerkinsky et al., 1988; Qadri et al., 1997). Following infection of North American volunteers with *V. cholerae*, anti-CT and anti-LPS IgA ASC responses were detectable in 50 and 83% of recipients, respectively (Losonsky et al., 1996), although protection from disease was 100% if rechallenge was done within 6 months of primary infection, suggesting that although anti-LPS and anti-CT IgA ASC responses correlate with protection from cholera, that protection against disease could occur even in the absence of detectable ASC responses to CT and LPS. Among Bangladeshi adults recovering from cholera, ASC responses against TcpA were also detectable in the majority, although no longitudinal study has been performed to see if such immunity correlates with protection from subsequent disease (Asaduzzaman et al., 2004).

Cell-Mediated Immune Responses

V. cholerae is a noninvasive mucosal pathogen, and although not investigated in detail, there are no current data to suggest that cell-mediated immune responses correlate with protection against cholera. Despite this, immune responses to CT, which is a potent immunoadjuvant in addition to being a potent enterotoxin, have been shown to be T cell dependent and MHC class II restricted (Cong et al., 1996).

EPIDEMIOLOGY

Significance as a Public Health Problem

V. cholerae is a human pathogen. There is no zoonotic infection of importance. *V. cholerae* exist in the environment in brackish water, especially favoring the mixed salinity of estuarine waters. *V. cholerae* has been shown to bind to chitin of crustacea, and outbreaks of *V. cholerae* are associated with zooplanktonic blooms (Schwartz et al., 2006; Huq et al., 2005) *V. cholerae* multiplication is inhibited by bacterial lysis mediated by strain-specific phages (Jensen et al., 2006). Reflecting these modifiers, *V. cholerae* outbreaks are often seasonal, and inversely correlated with the presence of environmental phages specific to *V. cholerae* (Jensen et al., 2006).

Humans usually acquire cholera through the ingestion of contaminated water or food. Infection usually involves the ingestion of a large inoculum of organisms (often 10^8–10^{11} organisms in individuals with normal gastric acidity), although lower inocula may be infectious in hypochlorhydric individuals. Infected humans excrete up to 10^8 organisms per milliliter of stool, and may expell 10–20 L of stool a day. Recent data suggest that passage of *V. cholerae* through an infected host may induce a "hyperinfectious" phenotype that may contribute to ongoing epidemic potential (Hartley et al., 2006; Alam et al., 2005; Merrell et al., 2002). Rapid spread of cholera is facilitated by lack of access to clean water and optimal sanitation.

Cholera is a reportable disease that causes significant morbidity and mortality worldwide, but the true global burden of cholera is not known since a specific diagnosis is often not made in areas of the world where cholera imposes its largest burden, and since many countries with cases do not report cholera to the World Health Organization (out of a fear of travel or trade-restrictions). Despite this, in 2005, 52 countries reported 131,943 cholera cases and 2272 cholera-related deaths to the WHO (Fig. 45.1) (WHO, 2006), although cholera may affect 5–7 million individuals each year, resulting in greater than 100,000 deaths per year. At present, the world is experiencing its seventh recorded pandemic, and cholera is endemic in many countries in Asia, Africa, and Latin America. Although the historic home of cholera is Asia, the majority of cholera cases currently reported to the WHO are occurring in Africa (WHO, 2006). Large outbreaks, especially among impoverished or displaced persons, occur on a regular basis, and cholera may spread through travel or migration of infected individuals, including even short-term travelers or visitors (Goma Epidemiology Group, 1995). Once introduced into an area, *V. cholerae* may become endemic, and the organism may persist in the local water supply and contribute to yearly outbreaks, especially following floods (Schwartz et al., 2006). Although previously unexposed individuals of all ages are affected during new outbreaks, cholera is often a disease of children and previously unexposed adults in endemic areas. Since its explosive appearance in 1992, cholera caused by *V. cholerae* O139 has been reported in 11 Asian countries, where it currently accounts for a minority of disease (Albert et al., 1993; Ramamurthy et al., 1993).

FIGURE 45.1 Countries reporting cholera cases to World Health Organization in 2005. Shaded countries reported locally acquired cases. Triangles represent countries reporting imported cases. Note that many countries in Asia, Africa, and Latin America do not report cholera to the WHO. Adapted from Map 1, p301, WHO (2006).

Use as Biothreat

V. cholerae is not transmitted by the respiratory route, usually requires the ingestion of a fairly large inoculum, does not exist in a spore form, is readily killed in appropriately treated water supplies, and is unlikely to result in secondary spread in areas of the world with adequate hygienic facilities. In addition, previously unexposed individuals with cholera are often symptomatic, can be readily identified by standard laboratory assays, and can be readily treated with fluid therapy. Despite this, *V. cholerae* does have potential as a biothreat agent. Introduction of *V. cholerae* in areas of the world with poor infrastructure can cause chaos, mass migration, and collapse of health and societal infrastructures, and can lead to social, political, and economic instability with global ramifications. Also, due to its historical connotations, even a small-scale intentional introduction of cholera among a resource-rich population would lead to public fear, bioterror, and the diverting of critical resources and personnel.

CLINICAL DISEASE

Depending on inoculum size, gastric pH, and absence of preexisting immunity, the incubation period for symptomatic cholera is usually 1–3 days (Cash et al., 1974a). Although asymptomatic intestinal colonization or mild-to-moderate diarrhea may occur in individuals with preexisting immunity, the hallmark clinical presentation of a nonimmune individual with cholera is explosive onset of a profuse watery diarrhea. Affected individuals may lose 10–20 L/day, and may progress to unconsciousness and shock within a few hours of initial onset of diarrhea (cholera gravis) (Fig. 45.2). As intestinal contents are flushed out, diarrheal stools become increasingly watery with flecks of white mucus ("rice water stool") (Fig. 45.3). Vomiting is common. Since *V. cholerae* is a noninvasive organism, intestinal contents do not characteristically contain blood or fecal leukocytes. Despite this classic presentation, the severity of cholera actually reflects not only inoculum size and preexisting immunity, but also the identity of the infecting

FIGURE 45.2 Adult with severe dehydration from cholera in Bangladesh. Patient is unresponsive and hypotensive. Note sunken eyes and tenting of skin on abdomen.

FIGURE 45.3 "Rice water" cholera stool. Following evacuation of bowel contents, the diarrhea of cholera patients may become progressively more watery, containing flecks of mucus.

biotype (classical biotype organisms cause more severe disease than El Tor organisms), and the blood type of the infected human (individuals with blood group O are less likely to become infected with *V. cholerae* following exposure, but are more likely to develop severe disease once infected) (Harris et al., 2005).

Individuals with cholera should be classified by level of dehydration as having mild, moderate, or severe disease. Individuals with mild dehydration may report thirst, but will have no or mild signs of dehydration, and will have lost ≤5% of their total body weight from diarrhea, with a fluid deficit of less than 50 ml/kg. Individuals with moderate dehydration will report thirst, may be restless, irritable, tachypneic and tachycardic, but will have preserved blood pressure and mentation. Mucus membranes will be dry, skin may retract slowly when pulled, eyes may be partially sunken, and urine output may be decreased. Individuals with moderate dehydration will have a fluid deficit of 60–100 ml/kg, representing 7–12% of total body water, and 6–10% of total body weight. Individuals with severe dehydration will have a nonpalpable or weak pulse, sunken eyes and dry mucus membranes, their skin will slowly retract when pulled, and they will produce no or minimal urine. Affected individuals will be tachypneic, often with labored breathing, and may be lethargic or comatose. Individuals with severe dehydration will have a fluid deficit of >100 ml/kg, representing >15% of their total body water, and >10% of their total body weight.

Symptomatic cholera is usually most severe within the first 2 days of onset, and usually lasts for 2–6 days. Hypoglycemia (especially in children) is common, as is acidosis (contributed to in part by the loss of bicarbonate in stool). Electrolyte abnormalities are common, and may contribute to persistent ileus. Rapid infusion of bicarbonate-containing intravenous fluid may lead to calcium shifts and tetany, which, with electrolyte abnormalities, most commonly manifest as muscle spasms. Pre-renal azotemia and acute tubular necrosis are common, although usually reversible upon rehydration. Among elderly individuals, the hypotension associated with severe dehydration may precipitate strokes and other ischemic events.

Although enterotoxigenic *E. coli* (ETEC) and rotavirus may cause similar diarrheal illnesses that can be quite severe in individual patients or among cohorts of young children, ETEC (see Chapter 51) and rotavirus (see Chapter 35) are unlikely to cause explosive epidemics that affect individuals of all ages, as does cholera. Definitive diagnosis of cholera rests on detection of *V. cholerae* O1 or O139 in the stool or vomit of a symptomatic human. Stool may be cultured on selective media to facilitate recovery of *V. cholerae*, and organisms may then be serogrouped and serotyped using slide agglutination assays. A rapid and preliminary diagnosis may also be made using darkfield microscopy to detect "shooting star" organisms in the stool of potentially infected individuals, or by using antigen detection strip assays. Retrospectively, a diagnosis of cholera can be confirmed serologically by detecting a fourfold change in the serum vibriocidal assay (when comparing convalescent to acute stage samples).

TREATMENT

Death from untreated cholera usually results from dehydration. Adequate, appropriate, and rapid fluid

replacement is the cornerstone of effective treatment. Although fluid may be administered orally or intravenously, every effort should be made to replace fluid orally. Intravenous replacement should be reserved for initial treatment of individuals with severe dehydration or shock, or individuals progressing to those states despite initiation of oral rehydration therapy. Frequent reassessment of fluid status and diarrheal output is mandatory. Fluid replacement should involve solutions containing sodium, potassium, chloride, bicarbonate (or citrate), and sugar. Oral rehydration therapy rests upon the fact that despite CT's action causing the movement of chloride (and therefore sodium and water) out of affected intestinal epithelial cells (resulting in secretory diarrhea), that another transport system exists permitting simultaneous uptake of sodium (and therefore chloride and water) with glucose in intestinal epithelial cells, irrespective of the action of CT. The fundamental approach to effective treatment of individuals with cholera is, therefore, to first replace any fluid and electrolyte deficits, and then to match all ongoing losses.

Antibiotics play a secondary role in the treatment of individuals with cholera. The secretory diarrhea of cholera is due to the cellular action of CT on intestinal epithelial cells. Although antibiotics do not reverse the effects of CT once a cell is affected, administration of antibiotics decreases the intestinal burden of *V. cholerae*, and can thus decrease additional production of CT. Administration of antibiotics thus can decrease the duration and total volume of diarrhea, allowing critical resources to be used for more individuals in resource-poor areas of the world. Administration of antibiotics also decreases the likelihood of secondary spread and ongoing transmission of cholera. Unfortunately, *V. cholerae* are increasingly resistant to many antimicrobial agents (Saha et al., 2006; Guerrant, 2006).

Without treatment, the death rate from cholera during outbreaks may exceed 10–20%, with death rates of 70–100% of individuals with cholera gravis (Goma Epidemiology Group, 1995). Although death may occur in hours, it usually occurs 1–3 days after onset of diarrhea. With appropriate fluid replacement therapy, the death rate from even severe cholera should be lessened to <1% (Ryan et al., 2000).

PATHOGENESIS

Disease Process

Following ingestion of *V. cholerae*, the majority of organisms are killed by gastric acidity. Organisms that survive may multiply in the lumen of the small intestine. *V. cholerae* are flagellated and motile, and organisms that penetrate the intestinal layer of mucin may then colonize the intestinal epithelial surface. A recently proposed model suggests that TcpF and TcpA (members of the toxin coregulated pilus operon) and other factors are involved in this colonization process (Kirn and Taylor, 2005). Following colonization of the intestinal surface of the small bowel, additional environmental signals may be recognized, leading to the additional induction of the primary virulence factor of *V. cholerae*, CT. As mentioned above, CT is a secreted protein exotoxin that consists of a single, enzymatically active A subunit noncovalently associated with five B subunits. The pentamer of B subunits binds CT to ganglioside on the small bowel intestinal epithelial cell, and the A subunit is nicked, reduced, and translocated intracellularly, where it elevates cAMP, affecting the cystic fibrosis transmembrane conductance regulator (CFTR) chloride channel, leading to secretory diarrhea (Mekalanos et al., 1979; Cassel and Pfeuffer, 1978; Gill and King, 1975; Gill and Meren, 1978). Expression of the genes in the TCP operon, as well as expression of CT, are coordinately regulated by two pairs of membrane-localized transcription factors, ToxR/ToxS and TcpP/TcpH (Miller and Mekalanos, 1984; Miller et al., 1987, 1989; DiRita and Mekalanos, 1991; Carroll et al., 1997; Hase and Mekalanos, 1998). These pairs of transcription factors act via ToxT to activate transcription of both *ctxAB* and *tcpA* (DiRita et al., 1991).

VACCINES

History of Cholera Vaccine Development

Within 1 year of Koch's development of the techniques required to culture *V. cholerae* in the laboratory, a broth-cultured "attenuated" strain was incorporated into a parenteral vaccine by Ferran and administered to over 30,000 individuals during a cholera outbreak in Spain in 1884. Despite uncertain efficacy of this vaccine, this was the first large-scale roll out of a laboratory-derived vaccine strain of the modern microbiological era. By 1891, Haffkine and researchers at the Pasteur Institute developed a two-stage parenteral vaccine comprised of injection of an attenuated *V. cholerae* strain followed 6 days later with injection of a "hypervirulent" strain (serially passaged in guinea pigs). This vaccine was administered to over 40,000 individuals in India in 1893–1894. During this vaccine campaign, researchers administered the vaccine to subgroups on tea plantations and prisons, and analyzed results by vaccine status, representing the first

attempt at determining vaccine efficacy in a large controlled field trial. Although the vaccine was thought to provide some efficacy, its production was hard to standardize, leading to the development of a killed parenteral vaccine by Kolle in 1896. This vaccine was used extensively in the early 1900s in Japan.

Cholera was also the target of the first oral vaccine when in 1893 Sawtschenko and colleagues ingested killed whole *V. cholerae* organisms in an attempt to induce immunity. By the 1920s, Bezredka and colleagues had developed an oral killed cholera vaccine mixed with bile, setting the stage for one of the first large comparative vaccine trials which occurred in the 1920s in India. In this trial, killed parenteral cholera vaccine was compared to the killed oral cholera vaccine (both vaccines were found to be approximately 80% effective at preventing cholera in the short-term). Since the bile salts caused diarrhea in some individuals, and since vaccine production was hard to standardize, the oral route was then abandoned for more than 50 years. By the 1960s, the parenteral whole cell vaccine was being mass-produced, and the World Health Assembly made cholera vaccination (as well as smallpox and yellow fever vaccination) required for certain international travel.

Current Licensed Vaccines

At present, there are a number of cholera vaccines licensed in various countries, as well as a number of candidate vaccines in various stages of development, evaluation, or licensure (Tables 45.1 and 45.2). At present, no cholera vaccine is commercially available and licensed in the United States.

Killed Parenteral Vaccine

A number of parenteral cholera vaccines have been developed, including a purified LPS vaccine (Oseasohn et al., 1965), a polysaccharide–CT conjugate vaccine (Gupta et al., 1998), killed whole cell vaccine with various adjuvants (Pal et al., 1980; Saroso et al., 1978), and killed whole cell vaccine (Mosley et al., 1972, 1973; Azurin et al., 1967; Ryan and Calderwood, 2000, 2001). Use of these vaccines has been associated with induction of relatively short-term immunity. Until approximately 1999/2000, the only FDA-approved cholera vaccine available in the United States was the whole cell killed vaccine, and was comprised of 4×10^9/ml of phenol-killed *V. cholerae* O1 Ogawa and 4×10^9/ml phenol-killed *V. cholerae* O1 Inaba organisms (usually classical strains NIH 41 and NIH 35A3). The organisms were grown on agar, suspended in sodium chloride, and killed with 0.5% phenol.

The vaccine was usually administered as a primary series of two injections separated by 7–28 days, and could be administered intramuscularly, subcutaneously, or intradermally (the latter route was approved for use in individuals 5 years of age or older). For children 6 months–4 years of age, the dose was 0.2 ml per inoculation. For children 5–10 years of age, the dose was 0.3 ml per inoculation. For individuals older than 10 years, the dose was 0.5 ml per inoculation. The vaccine was not administered to children younger than 6 months of age or pregnant women. The parenteral phenol-killed vaccine was associated with a high rate of moderate-to-severe local reactions (50%) including local induration, erythema, and pain, as well as a high rate (10–30%) of headache, malaise, and fever in vaccine recipients, especially following intramuscular or subcutaneous inoculation (Kaper et al., 1995; Tacket et al., 1992a). Intradermal inoculation was often better tolerated; however, there were minimal data on vaccine efficacy in immunologically naive individuals following intradermal administration (Ryan and Calderwood, 2001). Simultaneous administration of the killed parenteral cholera vaccine with yellow fever vaccine was associated with induction of decreased antibody levels to both vaccines, although there was no clinical evidence to suggest that protection against either disease was significantly altered. Although the vaccines were often administered simultaneously, if possible, an interval of 3 weeks between immunization against yellow fever and cholera was suggested.

Approximately 90% of individuals immunized with the killed parenteral whole cell vaccine developed a vibriocidal response following vaccination, with the highest response rates being observed in older children and adults in cholera-endemic areas (Mosley et al., 1969). Vibriocidal titers would, unfortunately, fall significantly by 6 months following vaccination. For approximately 6 months following vaccination, the vaccine provided approximately 50% protection against cholera caused by *V. cholerae* (Mosley et al., 1972, 1973; Azurin et al., 1967; Kaper et al., 1995; Levine and Pierce, 1992). Protection was thought to be present 6 days following the second injection. The vaccine was most thoroughly evaluated for efficacy in areas of the world endemic for cholera, confounding the ability to predict protective efficacy among immunologically naive populations. The vaccine was not very effective during cholera outbreaks, required more than one immunization, did not interrupt transmission of *V. cholerae*, and could divert critical resources during a cholera outbreak (Bart et al., 1970; Clemens et al., 1994a; Sommer and Mosley, 1973).

TABLE 45.1 Currently licensed, commercially-available, or programmatically used cholera vaccines

Vaccine	Composition	Route	Schedule	Age	Protective efficacy	Time to protection	Booster	Comments
Oral killed whole cell-recombinant B subunit vaccine (rBS-WC) (Dukoral, SBL Vaccin AB, Stockholm, Sweden/ Crucell Holland BV, Leiden, Netherlands))	Heat and formalin killed *Vibrio cholerae* O1, classical and El Tor strains, Inaba and Ogawa, with recombinant CtxB	Oral	>6 years of age: two doses separated by 7–42 days; 2–6 years of age: three doses, each separated by 7–42 days	≥2 years	Approximately 80% for 6 months, 50% at 3 years	Seven days after final dose	>6 years of age: 2 years; 2–6 years of age: 6 months	Well studied and well tolerated; licensed and commercially available in Europe; held effect increase population – Level protection
Oral live attenuated *V. cholerae* strain CVD 103-HgR (Orochol, Orochol E, Mutacol; Berna Swiss Serum Vaccine Institute, Bern, Switzerland/ Crucell Holland BV, Leiden, Netherlands)	Live attenuated *V. cholerae* O1 classical strain 569B derivative	Oral	Single dose	⩾2 years	62–100% in volunteer studies for 3 months; 14–80% in field studies	Within 8 days of dose	Six months	Well tolerated; licensed in Canada, Latin America, Europe, Asia; not currently manufactured/ available
Parenteral phenol-inactivated vaccine (Cholera vaccine, USP; Wyeth Laboratories, Inc., Marietta, PA)	Phenol-killed *V. cholerae* O1, Ogawa and Inaba	Intramuscular, subcutaneous, or intradermal (intradermal only approved for >5 years of age)	2 doses: >1–4 weeks apart	⩾6 months	Up to 50% for 3–6 months	Six days after second dose	Six months	High adverse event profile; only cholera vaccine licensed in United States; no longer commercially manufactured/ available
Bivalent oral killed whole cell vaccine (biv-WC) (Company for Vaccine and Biological Production No. 1 (VABIOTECH), Hanoi, Vietnam)	Heat and formalin killed *V. cholerae* O1 and O139	Oral	Two doses: 14 days apart	⩾2 years	50% against *V. cholerae* O1 3–5 years after vaccination	Probably within 7–14 days after second dose	Unknown	Only available in Vietnam where it is used programmatically; recently reformulated

If ongoing protection was indicated, booster immunizations were also required every 6 months. For these and other reasons, the World Health Assembly removed cholera vaccination from the list of required vaccines for certain international travel in 1973 (WHO, 1974). Although this vaccine is the only cholera vaccine licensed in the United States, the previous manufacturer of this vaccine (Wyeth Laboratories, Inc.) stopped commercial production of the vaccine in 1999/2000.

Oral Cholera Vaccines

Due to the poor immunogenicity, requirement for frequent booster vaccinations, and high adverse event profile of parenteral cholera vaccines, and due to the desire to induce immunity directly at the mucosal surface where *V. cholerae* pathogenic events unfold, researchers in the 1980s turned back to the development and evaluation of oral cholera vaccines (Ryan et al., 2006). At present, a number of oral cholera

TABLE 45.2 Candidate oral cholera vaccines thus far evaluated in humans[a]

Vaccine	Composition	Status
Vaccines targeting *V. cholerae* O1		
Peru-15	Live attenuated *V. cholerae* O1 El Tor Inaba C6709 derivative	Evaluated in volunteer studies in North America and Bangladesh, and Phase 1, 2 field studies in adults and children in Bangladesh
V. cholerae vaccine 638	Live attenuated *V. cholerae* O1 El Tor Ogawa C7258 derivative	Evaluated in volunteer studies in Cuba
Vaccines targeting *V. cholerae* O139		
B-O1/O139 WC	Killed *V. cholerae* O1 and O139 strains with CtxB	Evaluated in volunteer studies in Europe and Bangladesh
Biv-WC[b]	Killed *V. cholerae* O1 and O139 strains	Evaluated in volunteer studies in Vietnam
Bengal-15	Live attenuated *V. cholerae* O139 MO10 derivative	Evaluated in volunteer studies in the United States
CVD 112	Live attenuated *V. cholerae* O139 AI1837 derivative	Evaluated in volunteer studies in the United States

[a] A number of parenteral killed and subunit vaccines have been evaluated in small human volunteer studies since the 1980s.
[b] Biv-WC was recently reformulated and evaluated in a volunteer study.

vaccines are licensed in some countries (none in the United States).

Oral Whole Cell-B Subunit Vaccine (BS-WC and rBS-WC)

The oral whole cell killed vaccine contains 10^{11} killed *V. cholerae* O1 organisms (including classical and El Tor, Inaba, and Ogawa organisms of three strains, either formalin killed [to preserve protein antigens] or heat killed [to display LPS]), and 1 mg of nontoxic CT B subunit. Initial versions of the vaccine used nonrecombinant B subunit (BS); current formulations use recombinant B subunit (rBS). rBS-WC is manufactured by SBL Vaccin AB, Stockholm, Sweden/Crucell Holland BV, Leiden, Netherlands, and this vaccine is marketed in Europe as Dukoral/oral cholera vaccine, and is available in a number of countries (but not in the United States). To protect against cholera, the manufacturer has recommended the vaccine be administered in two doses (in individuals over 6 years of age) or three doses (in children 2–6 years of age), with each dose separated by 7–42 days (Wiedermann and Jong, 1997; Quiding et al., 1991; Svennerholm et al., 1984; Black et al., 1987). If more than 6 weeks separate the two doses, it has been recommended to restart the series. The vaccine comes in a 3 ml suspension in a glass vial, and is taken reconstituted in a glass of water with an alkaline buffer on an empty stomach (total volume 75 ml for children 2–6 years of age; 150 ml for individuals older than 6 years of age). The buffer is supplied in a sachet, and contains sodium carbonate, sodium citrate, sodium hydrogen carbonate, citric acid, saccharin, and flavoring. The manufacturer recommends avoiding food and drink 2 h prior and 1 h after ingestion of vaccine. If risk of cholera is ongoing, booster immunizations are recommended after 2 years for adults, and possibly as early as after 6 months for children 2–6 years of age. The vaccine should be stored at 2–8°C. Side effects are rare, with the most common being mild gastrointestinal upset, which occurs at a frequency similar to that among individuals receiving buffer alone. Although the vaccine has not been specifically studied during pregnancy, the manufacturer states that the vaccine may be administered during pregnancy and lactation. At present, there are no known vaccine interactions associated with rBS-WC.

The BS-WC and rBS-WC vaccines have been evaluated in a number of large and well-designed field studies. In Bangladesh, a study involving almost 90,000 individuals who took all of three scheduled vaccine doses showed that individuals receiving three doses of BS-WC at 6-week intervals developed excellent vibriocidal responses, and that immunization had 85% protective efficacy against cholera for 6 months, and 62% protective efficacy over 3 years of follow-up (Clemens et al., 1986). The vaccine protected equally well against severe and mild cholera. At 12 months, the protective efficacy of the vaccine was 62%. At 36 months, the vaccine was 50% protective. Within 6 months of immunization, the vaccine was equally protective among children, adolescents, and adults. However, protective efficacy was most short-lived among young children, falling to 26% at 36 months among children 2–5 years of age, compared with 63% among individuals older than 5 years of age (Clemens et al., 1990). The vaccine trial was carried out when both classical and El Tor *V. cholerae* O1 were circulating in Bangladesh (and before emergence of *V. cholerae* O139). Within 6 months of immunization, the vaccine protected equally well against cholera caused by either O1 biotype; however, by 36 months, protective efficacy was higher against classical biotype cholera (58%) than El Tor biotype cholera (39%) (Clemens et al., 1990). Individuals

with blood group O were less protected than individuals with other blood groups. *V. cholerae* and ETEC express related toxins (CT and LT, respectively), which induce cross reactive antibodies, and individuals vaccinated with BS-WC were also protected in the short-term against ETEC (67% at 3 months, 21% at 12 months) (Clemens et al., 1988a). Initial analysis of the 3-year study of BS-WC disclosed that vaccination with BS-WC led to a 25% reduction in admission for all-cause diarrhea, a 50% reduction in hospital admission for life-threatening diarrhea, and a 45% reduction in mortality in women during a cholera epidemic (Holmgren et al., 1994; Clemens et al., 1988b).

Following replacement of the B subunit in BS-WC with recombinant B subunit, equivalency studies showed that two doses of rBS-WC conferred similar protective efficacy (86%) as did three doses of BS-WC in individuals greater than 5 years of age (Levine and Svennerholm, 1997). Evaluation of rBS-WC in Peru (soon after re-introduction of cholera to the New World in the early 1990s after a 100 year absence, meaning that cholera had not yet become endemic, and previous exposure to *V. cholerae* among vaccine recipients was unlikely) showed that the vaccine was perhaps less immunogenic and protective than in Bangladesh. In Peru, two doses of rBS-WC induced a twofold vibriocidal increase in 50% of individuals, and vibriocidal levels decreased to baseline within 1 year, leading to the recommendation that administration of yearly booster immunizations be considered for previously immunological naive individuals with ongoing risk of cholera (Begue et al., 1995a, 1995b). In a volunteer study in Peru, three doses of rBS-WC over 10 months produced a protective efficacy of 61% over a 2-year follow-up period, and during a mean follow-up period of 18 weeks, the vaccine provided 86% protection against *V. cholerae* O1 El Tor cholera (Sanchez et al., 1994).

In a recent field trial in Beira, Mozambique, a location with annual cholera outbreaks, receipt of one or more doses of rBS-WC was 78% protective against cholera within 6 months of vaccination, and importantly, the vaccine was equally effective in children younger than 5 years of age and in older individuals (Lucas et al., 2005). Of note, although not specifically assessed, this evaluation occurred in a location with a high prevalence of infection (20–30%) with human immunodeficiency virus, suggesting that rBS-WC could be effective even among populations with a high burden of immunocompromised individuals. In a small study that specifically measured virological parameters, administration of rBS-WC was associated with transient increases in HIV viral load, although the significance of this finding is currently uncertain (Ortigao-de-Sampaio et al., 1998; Lewis et al., 1994; Eriksson et al., 1993).

Overall, therefore, one to three doses of the killed oral whole cell cholera vaccine provides over 80% protective efficacy for at least 6 months against cholera caused by *V. cholerae* O1 (in young children as well as adults), and approximately 50–60% protective efficacy over 2–3 years, with the duration of immunity best correlating with increasing age. Protection is present within 7 days of the second immunization in previously nonimmune individuals. Recent reanalysis of the 1980s vaccine study in Bangladesh also suggests that BS-WC conferred herd immunity protection against cholera to neighboring nonvaccinated individuals, extending the efficacy of the vaccine from 62% to over 90% at the population level (Ali et al., 2005), and further strengthening the potential public health utility of the oral whole cell killed vaccine (Glass and Steele, 2005). For these and other reasons, the World Health Organization now suggests that vaccination with rBS-WC (along with other health interventions, including supplying potable water and sanitary facilities) be considered for populations at risk for cholera, including refugees (Lucas et al., 2005; Legros et al., 1999; Dorlencourt et al., 1999; Ivanoff, 2001).

WC and biv-WC Killed Oral Cholera Vaccine

Two killed oral whole cell cholera vaccines have also been developed and licensed for use in Vietnam: a killed oral whole cell vaccine (WC) targeting *V. cholerae* O1, and a bivalent killed oral cholera vaccine (biv-WC) targeting *V. cholerae* O1 and *V. cholerae* O139. The bivalent vaccine replaced the monovalent after introduction of *V. cholerae* O139 to Vietnam in the 1990s. Neither of these vaccines include exogenously added CtxB (as does rBS-WC), and as such, these vaccines are thought to be more acid resistant and do not require administration with buffer (Naficy et al., 2001). In an open, controlled field trial, a two dose regimen of the monovalent vaccine was found to induce a protective efficacy of 66% during a *V. cholerae* O1 El Tor Ogawa outbreak 8–10 months after immunization, and protection was similar among adults and children (Trach et al., 1997). Following programmatic use of the bivalent vaccine in Vietnam, a case-control evaluation showed an overall vaccine effectiveness of 50% (9–63%) against *V. cholerae* O1, 3–5 years after vaccination (Thiem et al., 2006). For programmatic use, 1.5 ml of a vaccine preparation containing a mixture of 2.5×10^{10} heat and formalin-killed *V. cholerae* O1 and O139 organisms are squirted into the mouth of vaccine recipients, who then drink water. A second dose is administered 2 weeks later. The vaccine is administered to nonpregnant individuals at least 2 years of age (Thiem et al., 2006).

Although promising for possible production and use in cholera-endemic areas outside of Vietnam, the biv-WC and WC vaccines are not currently recommended by the WHO for use outside of Vietnam. In order to decrease residual CT in the vaccine, the bivalent vaccine was recently reformulated, and in its current new preparation contains formalin-killed *V. cholerae* O1 Inaba El Tor strain Phil 6973, O1 Ogawa classical strain Cairo 50, and O139 strain 4260b, as well as heat-killed O1 Ogawa classical strain Cairo 50 and O1 Inaba classical strain Cairo 48; and dosage is based on ELISA units of LPS of each component strain (Anh et al., 2007). In a recent randomized placebo-controlled, safety and immunogenicity study among 143 Vietnamese adults, the reformulated vaccine was safe, well tolerated, and immunogenic (as judged by induction of anti-*V. cholerae* O1 vibriocidal responses) following two oral vaccinations separated by 2 weeks. Further evaluation of the vaccine is ongoing. The vaccine is produced by the Company for Vaccine and Biological Production No. 1 (VABIOTECH), Hanoi, Vietnam.

Since killed oral cholera vaccines often require repetitive administration, and since protection against cholera following vaccination with killed whole cell vaccines is often less prominent and of shorter duration than that following wild-type disease, investigators have also developed live, oral, attenuated *V. cholerae* vaccines.

CVD 103-HgR

Live oral cholera vaccines have the theoretical advantage that intestinal colonization and immune stimulation that mimic those that occur following infection with wild-type *V. cholerae* could follow a single oral administration. Over the last few decades, a number of live oral attenuated cholera vaccines have been developed (Ryan and Calderwood, 2000, 2001; Ryan et al., 2006). Although many of these vaccine strains have been immunogenic, many have been too reactogenic, resulting in abdominal cramps, diarrhea, fever, nausea, or anorexia in many recipients (Levine et al., 1988a). Eventually, a derivative of *V. cholerae* O1 classical strain 569B was developed, which was immunogenic without being too reactogenic. This vaccine strain is deficient in CtxA (and as such does not produce cholera holotoxin), and has a mercury resistance gene (HgR) inserted into the *hlyA* hemolysin gene (to permit recovery and identification of the vaccine strain without introducing antibiotic resistance) (Levine et al., 1988b). The vaccine was developed at the Center for Vaccine Development (CVD), University of Maryland, and is referred to as CVD 103-HgR.

CVD 103-HgR is approved for use in a number of countries, including countries in Asia, Latin America, Europe, and in Canada (and has been licensed under various names, including Orochol, Orochol-E, and Mutachol), although the vaccine is not licensed in the United States. In 2004, the manufacturer of CVD 103-HgR, Berna, Swiss Serum Vaccine Institute, Bern, Switzerland/Crucell Holland BV, Leiden, Netherlands, suspended production of CVD 103-HgR, and the vaccine is not currently commercially available anywhere in the world. The vaccine requires cold storage and administration with buffer. When produced, the vaccine was supplied in a sachet separately containing 2 g of lyophilized bacteria (approximately $2–10 \times 10^8$ cfu), sucrose, lactose, ascorbic acid, aspartame, and casein hydrolysate in one chamber, and buffer salts sodium bicarbonate and ascorbic acid in the other chamber. Vaccinees would mix the contents of the two chambers in 100 ml of clean cool or lukewarm water. The vaccine would be ingested 1 h before a meal. The need for booster immunization had not been established in detail; however, the manufacturer recommended that if the risk for cholera were ongoing, that boosters could be administered every 6 months. It was recommended not to administer the vaccine concurrently with antibiotics since it was a live bacterial vaccine. Limited data suggested that concomitant administration of chloroquine (but not mefloquine) decreased immunogenicity of the vaccine. The manufacturer recommended that administration of live oral cholera vaccine and live oral typhoid vaccine be separated by at least 8 h, due to effects of ingestion of the two buffers.

The most common side effects reported following ingestion of CVD 103-HgR were gastrointestinal, with 1–10% of recipients reporting diarrhea, abdominal cramps, or loss of appetite. The safety of the vaccine during pregnancy had not been specifically studied. The vaccine was approved for use in individuals 2 years of age and older.

CVD 103-HgR was both safe and immunogenic in North American volunteers (Levine et al., 1988b), and had not been recovered from the environment in field studies following oral administration. The vaccine strain was grown in fermenters in CF medium, and recovered bacteria were lyophilized, milled, and stored frozen. In North American volunteers, a single dose of 5×10^8 cfu resulted in a significant increase in vibriocidal antibodies in over 90% of recipients (Levine et al., 1988b). In volunteers, the vaccine also provided 94–100% protection against severe and moderate diarrhea caused by wild-type *V. cholerae* O1 (Levine et al., 1988b; Levine and Kaper, 1993; Tacket et al., 1999). Protection was 82–100% against

challenge with classical biotype organisms (irrespective of serotype), and 62–80% protective against El Tor challenge (irrespective of serotype) (Kaper et al., 1995; Levine and Kaper, 1993; Tacket et al., 1999; Levine and Tacket, 1994). Protection was present within 8 days of vaccination, and lasted for at least 6 months in volunteers (Losonsky et al., 1996; Levine and Kaper, 1993; Tacket et al., 1999, 1992b; Losonsky et al., 1993).

Initial field evaluation of CVD 103-HgR showed that 5×10^9 cfu were required to induce vibriocidal seroconversion rates of 75–85% in resource-poor areas of the world (Su-Arehawaratana et al., 1992; Suharyono et al., 1992; Simanjuntak et al., 1993). In a large randomized field trial involving over 50,000 individuals in Indonesia, CVD 103-HgR was well tolerated, safe, and immunogenic, resulting in vibriocidal responses in 64–70% of vaccinees (Richie et al., 2000); however, the incidence of cholera was lower than expected during the study period, especially in the 6 months following vaccination, and only 93 evaluable cholera cases caused by *V. cholerae* O1 were detected in total (50 in placebo recipients, 43 in vaccine recipients, and only 7 within 6 months of vaccination), impeding the ability to judge the short-term protective efficacy of the vaccine. In this study, CVD 103-HgR had a protective efficacy of 14% (Richie et al., 2000). More recently, CVD 103-HgR was administered as part as a response plan to interrupt a cholera outbreak in Micronesia, and contributed to approximately 80% protection against cholera in this focused outbreak (Calain et al., 2004).

CVD 103-HgR has also been evaluated in a limited number of immunocompromised individuals. In a randomized, crossover, double-blind, placebo-controlled trial involving 38 individuals infected with human immunodeficiency virus but without clinical AIDS and 387 HIV-seronegative individuals in Mali, CVD 103-HgR was not recoverable from the stool of any of the vaccine recipients, and adverse events were comparable in the HIV seropositive and seronegative cohorts (Perry et al., 1998). Although CVD 103-HgR was immunogenic, the frequency and magnitude of the immune responses among individuals seropositive for HIV were less than those among individuals seronegative for HIV. The effects of vaccination with CVD 103-HgR on HIV viral load and CD4 cell counts were not measured in this study.

Vaccines in Development

A number of additional cholera vaccines are in various stages of development (Table 45.2).

Candidate Oral Live Attenuated Cholera Vaccines

Peru-15

Peru-15 is a live attenuated nonmotile derivative of *V. cholerae* O1 El Tor C6709 in which the entire CT genetic element and *attRS1* sites (used by CTXφ to insert into the *V. cholerae* chromosome) have been deleted, and the gene encoding CtxB has been inserted under the control of the *htpG* heat shock promoter into *recA* (lessening the likelihood of unwanted recombination events) (Kenner et al., 1995). The vaccine is produced by Avant Immunotherapeutics, Inc., Needham, MA.

In volunteer studies, Peru-15 was safe and immunogenic, with 90–100% vibriocidal seroconversion following single oral vaccination of freshly harvested 2×10^8 cfu (Kenner et al., 1995; Sack et al., 1997). In a pilot study, four of five controls, and two of five vaccinees developed diarrhea when challenged with wild-type *V. cholerae* 1 month following vaccination (Kenner et al., 1995). In a second small study, 12 volunteers received 10^7 or 10^8 cfu of freshly harvested Peru-15, and 50 individuals received either placebo or freeze-dried vaccine (10^8 or 10^9 cfu), in a double-masked three celled study (Sack et al., 1997). The vaccine was well tolerated and immunogenic, with the majority of individuals receiving Peru-15 developing vibriocidal responses. The vaccine strain was recoverable in the feces of approximately 60% of recipients (Sack et al., 1997). Peru-15 was then evaluated in a placebo-controlled, randomized, double-blind challenge study in which 59 individuals received either buffer alone or 2×10^8 cfu of lyophilized Peru-15 reconstituted in buffer. The vaccine was safe, well tolerated, immunogenic (98% of recipients developed vibiocidal responses), and protective (93% protective efficacy against diarrhea following challenge with wild-type *V. cholerae* O1 El Tor 3 months after vaccination) (Cohen et al., 2002).

Peru-15 was recently studied in staged Phase 1 and 2, randomized, double-blind, placebo-controlled studies in Bangladesh. In these studies, Peru-15 was first evaluated in individuals 18–45 years of age, then in children 2–5 years of age, then in infants 9–23 months of age (Qadri et al., 2005a, 2007). Adults received either 2×10^8 cfu of reconstituted lyophilized Peru-15 in buffer, or buffer alone. Peru-15 was safe and immunogenic. Vibriocidal responses were seen in 30 of 40 (75%) vaccine recipients, and 3 of 30 (10%) placebo recipients (Qadri et al., 2005a). Anti-LPS IgA responses were detected in the serum of 88% of vaccine recipients, and anti-LPS IgA and IgM ASC responses were detected in the blood of 78–88% of adult recipients. The vaccine strain was recovered from the stool of one adult recipient, and was identical to the inoculating strain.

Peru-15 was also safe and immunogenic in the studies involving 240 children. Two hundred and forty children 6 months–5 years of age were randomized to receive either buffer alone or 2×10^7 or 2×10^8 cfu of Peru-15 reconstituted in buffer. Among children, the vaccine was safe and immunogenic, with vibriocidal seroconversion rates of 84% (42/50) in children 2–5 years of age, and 70% (35/50) in children 9–23 months of age (Qadri et al., 2007). Overall, among children 5 years of age or younger receiving 2×10^8 cfu, Peru-15 induced vibriocidal seroconversion rates of 77%. Anti-LPS IgA antibody responses occurred in 60% of children 2–5 years of age, and 34% of children 6 months–2 years of age receiving 2×10^8 cfu. Approximately 40% of children developed serum anti-CT IgA responses (Qadri et al., 2007).

Other Live Oral Cholera Vaccines

A number of other live oral cholera vaccines are in earlier stages of development and evaluation. *V. cholerae* vaccine 638 is a live oral attenuated *V. cholerae* O1 Ogawa C7258 derivative from which the entire CTX genetic element has been deleted, and into which the *Clostridium thermocellum* endonuclease A gene has been inserted into the *V. cholerae* hemagglutinin/protease *hapA* gene (permitting identification of the vaccine strain on indicator media) (Ryan et al., 2006; Benitez et al., 1999). Among healthy Cuban adult volunteers, 4 of 42 vaccine recipients and 1 of 14 controls developed diarrhea or loose stools following ingestion of vaccine or placebo, respectively, and the vaccine strain was recoverable from the stool of 37 of 42 recipients. Volunteers received a range of doses (4×10^7–2×10^9 cfu). Serum vibriocidal responses occurred in 71–82%, and anti-Ogawa LPS IgA ASC responses occurred in 85–100% of vaccine recipients (Benitez et al., 1999). In a separate study involving 24 vaccinees, 96% developed vibriocidal responses, and 50% developed serum anti-LPS IgA responses in serum (Garcia et al., 2005). When challenged with 7×10^5 cfu of wild-type *V. cholerae* 3008 one month following vaccination, none of 12 vaccinees, and 7 of 9 placebo recipients developed diarrhea (Garcia et al., 2005).

Other live oral cholera vaccines include candidate vaccines VA1.3 in India, and IEM108 in China (Thungapathra et al., 1999; Liang et al., 2003). Although these strains have been immunogenic in animals, they have not yet been evaluated in humans.

V. cholerae O139

After its explosive emergence in 1992, *V. cholerae* O139 has been reported in 11 Asian countries, although *V. cholerae* O139 now accounts for the minority of disease even in affected areas. The reasons for the appearance, waning, but persistence of *V. cholerae* O139 are not well understood; however, *V. cholerae* O139 can cause explosive epidemics of cholera, even among individuals previously immune to *V. cholerae* O1, and as such, *V. cholerae* O139 has the potential to be a significant pathogen of global importance and a potential pandemic strain. *V. cholerae* O139 is surrounded by a capsule (*V. cholerae* O1 is not), and the presence of capsule complicates the ability to perform and standardize vibriocidal assays (important when judging immune responses following wild-type disease or vaccination) (Qadri et al., 2005b).

The only currently licensed vaccine that targets *V. cholerae* O139 is the biv-WC vaccine which is produced and used programmatically in Vietnam. Since the 1990s, millions of doses of biv-WC have been used in Vietnam, which remains the only cholera-endemic country with programmatic use of a cholera vaccine. As described above, biv-WC was recently reformulated and evaluated in a safety and immunogenicity volunteer study involving adults in Vietnam (Anh et al., 2007). Further evaluation is ongoing.

A bivalent oral whole cell cholera vaccine containing formalin-killed *V. cholerae* O139 and *V. cholerae* O1 organisms (B-O1/O139 WC) and CtxB has also been found to be both safe and immunogenic among Swedish volunteers (Jertborn et al., 1996). Following vaccination with B-O1/O139 WC, 10 of 12 vaccine recipients (83%) developed anti-O1 vibriocidal responses, and 8 (67%) developed anti-O139 vibriocidal responses. The magnitude and frequency of anti-CtxB and anti-O1 LPS responses were similar to those induced following vaccination with monovalent rBS-WC vaccine. Bivalent B-O1/O139 WC was also safe and immunogenic among 30 Bangladeshi volunteers, inducing vibriocidal responses in 50% (Qadri et al., 2005b).

A number of live oral attenuated anti-O139 vaccines have also been developed, including CVD 112, a derivative of *V. cholerae* O139 strain AI1837 made deficient in components of the CT genetic element (Waldor and Mekalanos, 1996; Tacket et al., 1998). Twelve volunteers have received either 10^6 or 10^8 cfu of CVD 112, with three of six receiving the higher dose developing mild diarrhea (Tacket et al., 1995, 1998). One of 8 vaccinees (13%) and 12 of 15 controls (80%) developed diarrhea when challenged with 10^6 cfu of wild-type *V. cholerae* O139 AI1837 five weeks after vaccination (protective efficacy, 84%) (Tacket et al., 1995, 1998). In other evaluations, 83–92% of 24 vaccine recipients developed anti-O139 vibriocidal responses, depending on which O139 strain was used in the vibriocidal assay (Losonsky et al., 1997).

Another live attenuated anti-O139 cholera vaccine candidate is Bengal-15, a nonmotile derivative of *V. cholerae* O139 MO10 from which the CT genetic element has been deleted and a copy of *ctxB* inserted into *recA* (Waldor and Mekalanos, 1994). In a small study involving four vaccine recipients, Bengal-15 produced fewer symptoms and was almost as immunogenic as MO10 (Coster et al., 1995). Among 10 vaccinees receiving 10^8 cfu of Bengal-15, no recipient developed diarrhea; 1 of 7 vaccine recipients and 5 of 6 controls developed diarrhea when challenged with 5×10^6 cfu of *V. cholerae* O139 one month following vaccination (protective efficacy, 83%) (Coster et al., 1995).

POSTEXPOSURE IMMUNOPROPHYLAXIS

V. cholerae is a noninvasive intestinal luminal pathogen. No effective postexposure immunoprophylaxis has been developed.

PROSPECTS FOR THE FUTURE

There are a number of potential uses for cholera vaccines. A prime indication for cholera vaccination would be to assist in preventing or controlling cholera outbreaks and epidemics. The WHO currently recommends that cholera vaccination (especially preemptively administered), along with efforts to supply safe water, improve sanitation, and identify and appropriately manage cases, be considered in emergency situations to control outbreaks among populations at high risk for cholera (Legros et al., 1999; Dorlencourt et al., 1999; Ivanoff, 2001; WHO, 1999, 2004). The effectiveness of killed oral whole cell vaccine is best substantiated in this regard (Lucas et al., 2005; Legros et al., 1999; Dorlencourt et al., 1999; Ivanoff, 2001; WHO, 2001, 2004), although live attenuated cholera vaccines could also assist in preventing or limiting outbreaks, and have the theoretical advantage of requiring a single immunization, and perhaps inducing more prominent early immune responses in immunologically naive individuals (WHO, 2001, 2004). As such, live oral cholera vaccines may be most beneficial if an outbreak has already started (WHO, 2001, 2004).

Although international travelers and workers can and do develop cholera (Taylor et al., 1996; Wittlinger et al., 1995; Sanchez and Taylor, 1997; Centers for Disease Control and Prevention, 1993), the risk is low (0.01–0.001% per month of stay in a developing country) (Ryan and Calderwood, 2001; Sanchez and Taylor, 1997; Steffen et al., 1987). There are fewer than 20–30 reported infections with *V. cholerae* each year in the United States, and the majority of these cases are often locally acquired in states bordering the Gulf of Mexico where *V. cholerae* is endemic. International travelers and workers who would be at highest risk for cholera are those who would be unable to secure safe water, especially individuals visiting or working within resource-poor areas during cholera outbreaks. Individuals who are hypochlorhydric may become infected following ingestion of even relatively small inocula. Although rBS-WC has been noted to provide protective immunity against ETEC, a very common cause of travelers' diarrhea, the relatively low protective immunity afforded by rBS-WC against "all causes of travelers' diarrhea" has limited use of this vaccine for this indication.

At present, the largest burden of cholera occurs in countries where *V. cholerae* is endemic. In these locations, cholera often exacts a large toll on children, much of the population may be undernourished or deficient in critical micronutrients, may be coinfected with other pathogens that may modify or misdirect immune responses, or be frankly immunocompromised. The majority of cases of cholera currently reported to the WHO are being reported from African countries where infection with human immunodeficiency virus is prevalent. A cholera vaccine with the greatest global benefit would, therefore, be safe and effective in children and immunocompromised individuals, inexpensive, and logistically simple to administer. Although a number of effective cholera vaccines are currently available in at least some countries, at present we do not fundamentally understand what mediates protective immunity against cholera, and why vaccines that appear promising in volunteer studies are less promising when evaluated in resource-poor areas. We also do not know why vaccine efficacy is often relatively short-lived, nor do we currently know how to improve the duration of vaccine efficacy. Although cholera can be prevented if safe water and proper sanitation are available, in reality, with 40% of the world's 6 billion human inhabitants currently subsisting on less than $2 a day, the growth of major mega-cities without proper infrastructure in many developing countries, and the potential impact of global warming on water supplies and flooding, it would perhaps be most prudent to assume that cholera will continue to be a plague of humans for the foreseeable future, and that the need for safe, inexpensive, and effective cholera vaccines may only continue to grow.

KEY ISSUES

- Cholera continues to be a pathogen of global importance, with the world currently experiencing its seventh pandemic, and an estimated 5–7 million cases per year, resulting in approximately 100,000 deaths.
- Cholera remains a disease of poverty, social disruption, and poor sanitation, and large and explosive outbreaks occur on a regular basis.
- Parenteral whole cell cholera vaccines require repetitive dosing and boosting, are associated with frequent adverse events, and are no longer commercially available.
- Oral cholera vaccines have been developed that are safe and protectively immunogenic.
- Only one oral cholera vaccine is currently commercially available and licensed in more than one country: the oral whole cell killed vaccine (rBS-WC, Dukoral, SBL Vaccine AB, Stockholm, Sweden/Crucell Holland BV, Leiden, Netherlands); this vaccine is not licensed or commercially available in the United States.
- Although rBS-WC is well studied, well tolerated, safe, and effective, vaccination with rBS-WC may require more than one immunization among immunologically naive populations, induces protective immunity of relatively short duration compared to that which occurs following wild-type disease, and is not protective against cholera caused by *V. cholerae* O139.
- *V. cholerae* O139, a cause of cholera that emerged in the 1990s, continues to be a cause of cholera in Asia, may have pandemic potential, and is not protected against by any presently internationally licensed, commercially available cholera vaccine.
- A killed oral cholera vaccine that targets both *V. cholerae* O1 and O139 is currently being locally produced and programmatically used in Vietnam. Efforts are underway to meet international standards and to evaluate effectiveness of this product.
- Oral live cholera vaccines, as well as other oral killed and parenteral subunit vaccines are also in various stages of development and evaluation.
- The role of cholera vaccines to control outbreaks needs to be more fully addressed.
- Public health strategies to optimally use cholera vaccines among populations in resource-poor areas need to be developed, evaluated, and implemented.
- The need of cholera vaccination among children in the developing world needs to be more fully addressed.
- The duration of protective immunity following vaccination against cholera needs to be lengthened.
- The safety and efficacy of cholera vaccination among immunocompromised individuals, including individuals infected with human immunodeficiency virus, needs to be more fully addressed.

Botulinum Toxin

Lance L. Simpson
Center for Research on Bioterrorism and Biodefense,

Philadelphia, PA, USA

OUTLINE

ABSTRACT

Botulinum toxin is a remarkably potent substance that acts preferentially on cholinergic nerve endings to block transmitter release. Botulism, which is the disease caused by the toxin, can occur in several variations, but it most commonly presents as a form of food poisoning. Patients ingest food that is contaminated with the toxin, or they ingest organisms that can manufacture the toxin in the gut. Absorption occurs when the toxin binds to epithelial cells, then undergoes receptor-mediated endocytosis, transcytosis, and eventual release into the general circulation. Absorbed toxin is distributed throughout the periphery, but mainly to the cholinergic nerve endings. The toxin acts intracellularly to cleave polypeptides that are essential for transmitter release. Blockade of exocytosis produces muscle weakness and autonomic dysfunction. In extreme cases, patients suffer complete paralysis, including paralysis of the muscles of respiration.

In addition to being the etiologic agent in naturally occurring disease, botulinum toxin figures prominently in two other clinical settings. The toxin is recognized as a potential agent of bioterrorism and biological warfare, but it is also a valuable medicinal agent for the treatment of dystonia and related disorders. The fact that the toxin is a potential bioweapon has prompted intense efforts to develop a vaccine that can protect vulnerable populations. However, there is a keen awareness that administration of a vaccine would be detrimental to patients who receive the toxin as a medicinal agent. The existence of a vaccine that can be both indicated and contraindicated, depending on patient populations, is highly unusual in the practice of medicine. This unusual state of affairs means that rational development of a vaccine must address two broad areas of concern: *conventional issues*, such as choosing antigen, adjuvant, and route of administration; and *unconventional issues*, such as potential adverse consequences of vaccine administration.

There are no licensed, polyvalent vaccines against botulism. There are toxoids available under Investigational New Drug status, but these are likely to be replaced by recombinant or synthetic vaccines. The three major candidates for vaccines are: (1) holotoxin that has been rendered inactive by site-directed mutations, (2) nontoxic polypeptide fragments that represent functional domains of the holotoxin (i.e., tissue binding domain), and (3) short peptides that represent epitopes.

Preclinical studies indicate that recombinant vaccines can be highly effective against challenge doses of toxin. Unfortunately, this means that they would also be highly effective in negating therapeutic actions of the toxin. To date, no federal agency has advocated universal administration of a vaccine. However, the counterposing roles of any vaccine in protecting against botulism while simultaneously abolishing therapeutic benefits of the toxin raises questions about the ideal duration of vaccine action. This is a daunting question that requires serious attention.

INTRODUCTION

Botulinum toxin is one of the more extraordinary molecules encountered in medicine and science. There are many factors that contribute to this special status, but several are particularly well known. To begin with, botulinum toxin is generally considered the most potent of all biological toxins (Gill, 1982; Lamanna, 1959). In addition, this remarkably potent molecule must go through an unusually long and complex sequence of events to reach and poison its target organ, which is the peripheral cholinergic nerve ending (Simpson, 2004). However, the characteristic of the toxin that is most troubling in the context of vaccine development is the number and variety of clinical settings in which it is encountered. On the one hand, botulinum toxin is the etiologic agent that causes the disease botulism (Hatheway, 1995; Horowitz, 2005; Sobel, 2005). This disease can be naturally occurring, but it can also be the product of malice (i.e., bioterrorism or biological warfare). On the other hand, botulinum toxin is an approved medication for the treatment of a variety of disorders, such as dystonia (Comella et al., 2005). In the absence of botulinum toxin, patients would not have access to equally efficacious alternatives.

These contrasting clinical settings have fundamentally different relationships to the field of vaccine development. For patients who require active immunization, resistance would be the desired outcome; but for patients who receive toxin for its clinical benefit, resistance would be a therapeutic obstacle. The existence of a vaccine that can be either an enormous benefit or a serious detriment, depending on patient population, is rarely encountered in the practice of medicine.

This unusual conflict between benefit and risk would not be an issue if the real or potential incidence of botulism were limited to the naturally occurring disease. The number of outbreaks, and the number of cases per outbreak, is far too low to justify either vaccine development for, or vaccine administration to, the general public. Instead, the conflict between benefit and risk arises from the fact that botulinum toxin can be used as a weapon in acts of bioterrorism or biological warfare. The perceived threat posed by the toxin has greatly intensified the effort to find a vaccine.

For those investigators who are seeking to develop a vaccine, there is one observation upon which everyone can agree. There already exist techniques that can be used to evoke resistance to botulinum toxin. In fact, there are several and somewhat varied techniques that could be employed to evoke immunity. This means that not only is there urgency to finding a vaccine, but there is also urgency to identifying the strategy that will yield the best-possible product.

One of the factors that will facilitate the search for an ideal vaccine candidate is the substantial body of information that exists on the botulinum toxin molecule and on the epidemiology and clinical presentation of the disease botulism. For example, a great deal is known about the cellular, subcellular, and even molecular aspects of the many steps in the long progression of events that leads to poisoning. This means that it should be possible to engage in rational vaccine design that is tailored to the mechanism of toxin action (Levine and Sztein, 2004). Similarly, there is much known about the populations that are most at risk of contracting botulism, and about the signs and symptoms and the clinical course of the disease in patients who succumb to poisoning. This too is a fertile area that can provide clues on rational vaccine design.

BOTULINUM TOXIN

Structure of the Toxin

Botulinum toxin is produced by the organisms *Clostridium botulinum*, *Clostridium beratii*, and *Clostridium butyricum* (Smith and Sugiyama, 1988). The toxin is manufactured in seven different serotypes designated A, B, C, D, E, F, and G (Sakaguchi, 1983; Simpson, 1989). Each of these serotypes has been shown to occur, or is presumed to occur, in multiple subtypes (Arndt et al., 2006; Smith et al., 2005).

The complete primary structure for at least one representative of each serotype has been determined (Minton, 1995; Popoff and Marvaud, 1999). Sequence identity across all serotypes occurs only with low frequency, which in part explains why the different proteins are serologically distinct. Much less is known about the tertiary structures of the various serotypes. To date, complete three-dimensional structure data are available for serotypes A and B (Lacy and Stevens, 1999; Swaminathan and Eswaramoorthy, 2000), and partial structural data are available for serotypes D, E, F, and G (Agarwal et al., 2004, 2005; Arndt et al., 2005, 2006).

Early work on the protein structure of botulinum toxin indicated that it is composed of a light chain (LC) (N-terminus of the molecule; ca. 50 kDa) and a heavy chain (C-terminus of the molecule; ca. 100 kDa) linked by a single disulfide bond (DasGupta, 1989). The heavy chain in turn is composed of two domains of about 50 kDa each. The structural arrangement of the molecule, which suggests three somewhat independent lobes, is illustrated in Fig. 46.1. The three lobes in the tertiary structure represent the LC, the amino-terminal half of the heavy chain, and the carboxy-terminal half of the heavy chain. This structural organization of the molecule is key to understanding both mechanism of action and immune response (see below).

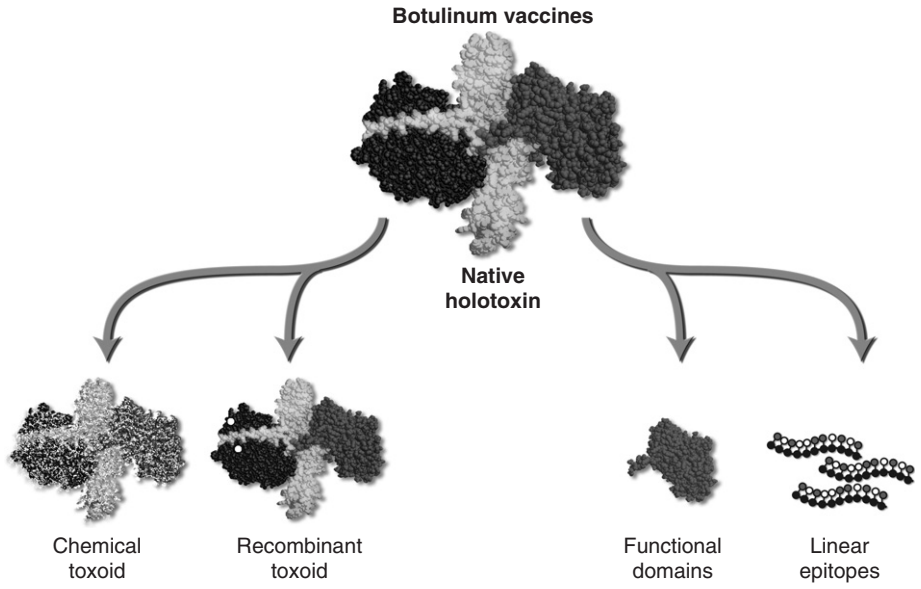

FIGURE 46.1 Botulinum vaccines. Botulinum toxin is a 150 kDa protein that is composed of three distinct domains (lobes). These represent the 50 kDa light chain (LC) (black tone), the 50 kDa amino-terminal half of the heavy chain (grey tone), and the 50 kDa carboxy-terminal half of the heavy chain (intermediate tone). Initial attempts to develop a vaccine relied upon chemical inactivation of impure preparations of the holotoxin (e.g., formalin treatment). More recent attempts have focused largely on homogeneous preparations of recombinant polypeptides. This approach has led to evaluation of three types of preparations: (a) a holotoxin that has been rendered nontoxic by point mutations in the histidine motif of the LC (white dots), (b) isolated functional domains, such as the carboxy-terminal half of the heavy chain (e.g., binding domain), and (c) relatively short linear epitopes. Each of these three can be administered either as a polypeptide vaccine or as a nucleic acid vaccine.

Botulinum toxin does not typically occur in bacterial cultures as an isolated neurotoxin. Instead, it is ordinarily part of a noncovalent complex that includes hemagglutinins of various sizes and a single nontoxin, nonhemagglutinin (Sakaguchi, 1983). These auxiliary proteins are not known to play any role in the signs and symptoms that are characteristic of the disease botulism.

As a matter of historical observation, one must note that initial efforts to develop a vaccine against botulinum toxin predated almost all work to define the structures of, and the interrelations among, the neurotoxin and the other molecules in the noncovalent complex (Byrne and Smith, 2000; Siegel, 1988). Hence, it is not surprising that early vaccine candidates are not considered equivalent to those currently under investigation. This is a matter of some importance because the only vaccine candidates that are presently available for patient administration are those that use the technologies that predate knowledge of toxin structure.

Mechanism of Action

Stated simply, botulinum toxin acts at vulnerable nerve endings in the periphery to block transmitter release. However, the sequence of events that culminates in blockade of exocytosis is rather complex. Fortunately, tremendous progress has been made in elucidating these events (Schiavo et al., 2000; Simpson, 2000, 2004; Simpson et al., 2001).

Most cases of botulism are oral in nature, although the disease can also be caused by inhalation exposure (Holzer, 1962). This means that the toxin must have an efficient mechanism to escape the lumen of the gut or the airway. In the case of the gut, absorption of botulinum toxin involves two distinct phenomena (Maksymowych and Simpson, 1998). Firstly, the toxin escapes metabolic degradation in the stomach by virtue of being intertwined with auxiliary proteins. This noncovalent complex is remarkably resistant to acid conditions and endoprotease exposure (Chen et al., 1998). When the toxin is stripped of auxiliary proteins, it is much less potent as an oral poison (Maksymowych et al., 1999). Secondly, the toxin traverses epithelial barriers in the small intestine to reach the general circulation (Fig. 46.2). It does this by binding exploitatively to receptors on the apical surface of epithelial cells. This is followed by receptor-mediated endocytosis, transcytosis, and eventual release of unmodified toxin on the basolateral surface of cells (Maksymowych and Simpson, 1998; Maksymowych and Simpson, 2004).

The airway does not contain the same harsh metabolic conditions as the gut, and thus there is little need for auxiliary proteins to protect the toxin. Nevertheless, the toxin does need to escape the airway to reach the general circulation, and it achieves this by active penetration of epithelial barriers. Similar to the gut, there is exploitative binding, endocytosis, transcytosis, and release (Park and Simpson, 2003).

There has been a limited amount of work to identify the epithelial cell population that transports the toxin, as well as to visualize the pathway used by the toxin as it crosses individual cells in this population (Ahsan et al., 2005). Interestingly, absorptive enterocytes are the key transport cells involved in poisoning. The M cell–Peyer's Patch complex is capable of transporting toxin, but it is not essential. Thus, knockout mice that do not develop M cell–Peyer's Patch

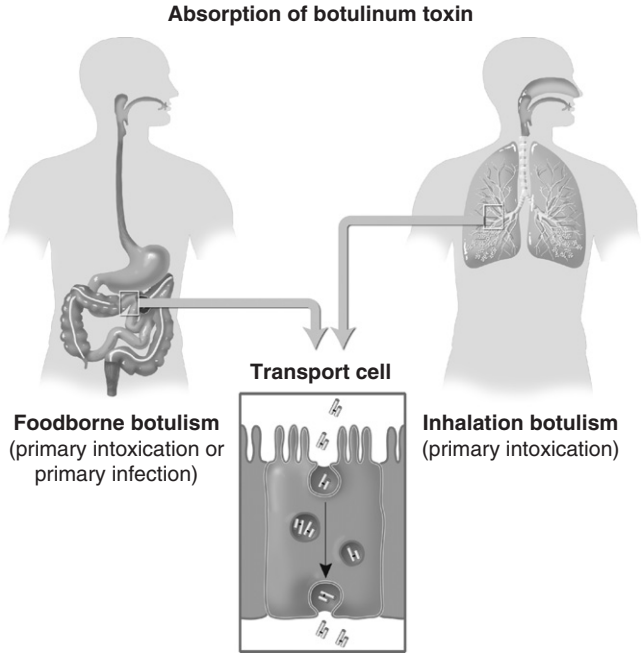

FIGURE 46.2 Absorption of botulinum toxin. The primary motive for vaccine development is to protect vulnerable populations against potential incidents of bioterrorism and biological warfare. Such incidents would likely be due to exposure by the oral route (which is also the route for most cases of naturally occurring botulism) or by the inhalation route. Oral poisoning leads to two variants of food-borne botulism: primary intoxication, or primary infection with secondary intoxication (see Box 46.1 for descriptions of clinical etiology). Inhalation poisoning leads to only one variant of the disease: primary intoxication. Regardless of route of exposure, the toxin escapes the gut or airway by interacting with epithelial cells that transport the toxin into the general circulation. The transport process involves binding to receptors on the apical surface of cells, followed by receptor-mediated endocytosis, transcytosis, and eventual release of the toxin on the basolateral surface of cells. Toxin that enters the general circulation is distributed to peripheral cholinergic nerve endings, where it acts to block transmitter release.

complexes have the same oral and inhalation sensitivity to the toxin as the wild-type strain.

Botulinum toxin that is delivered to the general circulation is distributed throughout the periphery. The toxin has little ability to penetrate the blood–brain barrier, and therefore the central nervous system is largely spared from its effects. Although the toxin is potentially available to all tissues and organs in the periphery, the molecule demonstrates high-affinity binding only at presynaptic nerve terminals of cholinergic fibers. The most exquisitely sensitive site is the cholinergic neuromuscular junction (Simpson, 1986, 2000). By virtue of acting on cholinergic nerve endings that govern motor activity, the toxin can produce flaccid paralysis. By acting on cholinergic fibers that innervate intercostal muscles and the diaphragm, the toxin can paralyze respiration.

The sequence of events that underlies poisoning at all cholinergic nerve endings is the same (Humeau et al., 2000; Schiavo et al., 2000; Simpson, 2004). The carboxy-terminal portion of the heavy chain binds to receptors on the surface, and this in turn leads to receptor-mediated endocytosis. There is evidence that binding actually involves two sites: a low-affinity receptor that brings the toxin into the plane of the membrane, and a high-affinity receptor that is presumably linked to endocytosis (Montecucco, 1986). For two of the toxin serotypes the dual receptor may have been identified [serotype A: polysialoganglioside and synaptic vesicle protein 2C (Dong et al., 2006; Mahrhold et al., 2006); serotype B: polysialoganglioside and synaptotagmin (Bullens et al., 2002; Dong et al., 2003; Kozaki et al., 1998; Nishiki et al., 1994, 1996; Yowler et al., 2002)]. In the case of serotype B, investigators have recently reported the three-dimensional structure of the toxin in association with its receptors (Chai et al., 2006; Jin et al., 2006).

The toxin that enters the cell by endocytosis is briefly trapped. However, as the proton pump in the membrane acidifies the lumen of the endosome, the toxin molecule undergoes a dramatic change in conformation. The amino-terminal half of the heavy chain exposes a previously occult hydrophobic domain, and this interacts with the membrane and with the LC to facilitate translocation of the latter (Hoch et al., 1985; Koriazova and Montal, 2003). At some point in this process, the interchain disulfide bond is reduced and the free LC reaches the cytosol (Simpson et al., 2004).

The LCs of all serotypes of botulinum neurotoxin are zinc-dependent endoproteases that are remarkably specific with respect to substrates and scissile bonds (see Table 46.1). The substrates for the toxins are three polypeptides that act cooperatively in the process of transmitter release (Humeau et al., 2000; Schiavo et al., 2000; Simpson, 2004). When these polypeptides are cleaved, exocytosis is blocked. It is this blockade of exocytosis that accounts for toxin-induced paralysis of movement and paralysis of respiration.

TABLE 46.1 Botulinum toxin and its substrates

Toxin	Histidine motif	Substrate
Serotype A	H · E · L · I · H	SNAP-25
Serotype B	H · E · L · I · H	VAMP
Serotype C	H · E · L · N · H	Syntaxin and SNAP-25
Serotype D	H · E · L · T · H	VAMP
Serotype E	H · E · L · I · H	SNAP-25
Serotype F	H · E · L · I · H	VAMP
Serotype G	H · E · L · I · H	VAMP

Note: Botulinum toxin exists in seven serotypes (A–G), each of which can occur in multiple subtypes. The mechanism of action of the various serotypes was deduced from primary sequence analysis. The light chain of each serotype has a "histidine motif" (H·E·X·X·H), which is a signature sequence for metalloendoprotease activity. The substrates for the various serotypes are SNAP-25 (synaptosomal protein of 25 kDa), VAMP (vesicle-associated membrane protein, also known as synaptobrevin), and syntaxin.

Implications for Vaccine Development

When one examines the information on structure and function of the toxin molecule, there are several points that emerge that bear on efforts to develop a vaccine. The most important of these are:

(1) Botulinum toxin can enter the body by absorption across the gut and airway epithelium. This suggests that it would be desirable to create a vaccine that can evoke a local IgA response. A mucosal immune response could serve as a barrier to block toxin absorption.
(2) Regardless of route of toxin absorption, the general circulation serves as a conduit to transport toxin to sensitive nerve endings. This suggests that a circulating IgG response could contribute to neutralization of toxin. The underlying mechanism for IgG-mediated neutralization could be enhanced clearance from the circulation secondary to enhanced accumulation in nontarget tissues (e.g., liver and spleen).
(3) The fact that the toxin progresses through multiple steps to produce neuromuscular blockade suggests that antibodies could act at one or more of these steps to diminish toxicity. Most obviously, an immune response could evoke antibodies that block toxin binding to, or entry into, cholinergic nerve endings.

It is worth noting that these several approaches to vaccine development are not mutually exclusive. Indeed, there are rational ways to design vaccine candidates that could evoke protection at all three levels.

HISTORY OF THE DISEASE

Evolutionary Timescale

The nucleotide sequences of the seven botulinum serotypes, as well those of numerous subtypes, are known (Minton, 1995; Popoff and Marvaud, 1999; Smith et al., 2005). Work has also been done to sequence the messages that encode some of the auxiliary proteins found in the botulinum toxin complex (East et al., 1996; Ohyama et al., 1995). These sequences have been used to construct genealogical trees that establish: (a) relatedness between and among the serotypes, and (b) likely points when precursors divided to give rise to descendants. These analyses provide insight into the evolution of botulinum toxin.

There are two other kinds of analyses that would also be helpful, and work in these areas is currently underway, but no results have actually been published. Several groups have sought to determine whether there is structural relatedness between botulinum toxin and any other proteins, with a particular emphasis on identifying the parent molecule from which the toxin might have evolved. To date, no precursor has been found. Another line of investigation would be to utilize a molecular clock, in combination with genealogical trees, to determine how ancient any supposed precursor might be. Nothing has emerged in this realm either.

In the absence of a molecular approach to describing and quantifying evolution, one can tentatively turn to a "victim clock." The target organ for botulinum toxin action is the cholinergic nerve ending. If there were no cholinergic nerves, there would be no obvious survival value that could select for emergence and persistence of the toxin. Interestingly, botulinum toxin is not a disease that is confined to mammals, nor even to vertebrates. There are cholinergic nerve endings in invertebrates, and some of these are susceptible to botulinum toxin action. This could mean that the toxin has an origin that reaches far back in time.

Ancient Origins and Innate Resistance

For any biological toxin that has a long evolutionary history, there is the possibility that organisms have emerged that are resistant. The study of innate resistance can help to clarify the mechanism of pathogen action, and it can also be helpful in analyzing phenomena such as host–pathogen interactions. Perhaps most importantly, the study of innate resistance can provide clues on ways to evoke resistance.

The identification of organisms that are resistant to botulinum toxin, and the use of these organisms to explore the nature of innate resistance, is a nascent field of research. Nevertheless, there are several observations that should be mentioned. The best-known example of resistance to botulinum toxin was reported in the middle of the last century. Burgen et al. (1949) found that rats were unusually resistant to serotype B, and this characteristic was not shared by mice. The underlying basis for this observation remained unknown for decades, until the subcellular actions of botulinum toxin were described. Serotype B acts in the cytosol to cleave a substrate (e.g., VAMP; Table 46.1) that is needed for exocytosis (Schiavo et al., 2000). Montecucco and his colleagues (Patarnello et al., 1993) found that VAMP in the peripheral nervous system of rats has a single modification (Gln → Val) at the cleavage site for serotype B. This same modification was found in chickens, which are also resistant to serotype B.

There are other examples of organisms that are resistant to botulinum toxin, but certainly the most provocative example pertains to human beings. Naturally occurring type C and type D botulism are so rare in the human population as to raise questions about resistance. This observation is all the more dramatic because of the widespread and devastating impact these serotypes have on other animals, such as birds. It can be stated with certainty that the human neuromuscular junction is not resistant to poisoning (Coffield et al., 1997). When studied on excised and viable human preparations, serotype C is as active as any other serotype in blocking transmission. In addition, the human substrate for serotype C (e.g., syntaxin) does not have any mutations at the scissile bond (Zhang et al., 1995). This means that any real or apparent resistance must relate to: (a) the relative absence in the human diet of foods contaminated with *C. botulinum* types C and D, or (b) the failure of these serotypes to be absorbed and distributed to the neuromuscular junction.

There is another and quite different area of investigation in which the question of human resistance has been raised. As discussed more fully below, botulinum toxin is an approved medication for the treatment of a variety of disorders in which efferent activity in cholinergic nerves must be managed. In the course of using the toxin as a medicinal agent, clinicians have encountered two types of resistance: (a) there are reportedly

a small number of patients who do not respond when botulinum toxin therapy is initiated, and (b) there are patients who respond initially but who become refractory over time.

The underlying basis for the first phenomenon has not been explained, though most investigators agree that it is not an antibody-based mechanism (viz., prior unknown exposure to toxin or to a structurally similar antigen). If it should eventually prove true that some in the human population are inherently resistant to one or more serotypes, the underlying bases may be similar to those shown for other animals (e.g., alterations in receptors or substrates). The story that has emerged for patients who lose responsiveness over time is quite different. The underlying basis for most if not all cases of lost responsiveness is evoked immunity. When botulinum toxin is administered in sufficient amounts and frequencies, the therapeutic goal may be modulation of efferent cholinergic activity, but the occasional and unintended outcome is vaccination. It is appropriate to note here—and the matter will be explored more fully in a later section—that vaccination against botulinum toxin in certain patients should be described as an adverse event.

The conclusions that can be drawn from this narrow field of investigation are limited, although there is one notable point that does emerge. For most proteins that enter the body by the oral route, a powerful form of innate resistance is the combination of proteolysis and epithelial barriers. It is fascinating that botulinum toxin has evolved mechanisms to evade both. As explained earlier, the toxin is not ordinarily found as an isolated neurotoxin in bacterial culture. It is more customary to find the toxin as part of a noncovalent complex with auxiliary proteins, and the intertwining of these proteins confers substantial resistance to gut proteolysis (Chen et al., 1998). In addition, the toxin molecule possesses structural determinants that allow it to bind exploitatively to receptors on epithelial cells that mediate endocytosis and transcytosis. Thus, part of the extraordinary potency of the toxin molecule can be attributed to its ability to evade obstacles that for other pathogens would be the essence of innate resistance.

There is the possibility that not all serotypes have efficiently overcome the obstacles. For example, the low incidence of type C botulism in human beings could in part be due to the relative inability of this particular toxin to breach epithelial barriers (Maksymowych and Simpson, 1998). For those serotypes that do penetrate epithelial membranes, there are ways to recreate barriers and thus confer resistance. The most obvious of these is to induce an adaptive mucosal immune response that leads to clinically significant titers of luminal IgA that will block toxin absorption.

CLINICAL PRESENTATION OF THE DISEASE

Etiologic Factors

Almost all cases of human botulism are due to serotypes A, B, and E (Lindstrom and Korkeala, 2006). The signs and symptoms of types A, B, and E botulism can be attributed to the inherent pharmacologic properties of the toxins, as described above, and to the adverse effects of microbial products other than the toxins. It is intuitively clear that the former will always be present. The likelihood of the latter depends upon the circumstances of the exposure as well as the route of exposure.

Botulism can occur either as a primary intoxication or as a primary infection with secondary intoxication (Box 46.1). Primary intoxication occurs when clostridial organisms produce botulinum toxin outside the body, and this toxin subsequently enters the body to produce blockade of cholinergic transmission. Primary infection occurs when organisms enter the body and produce the toxin in situ. As before, the toxin will ultimately produce blockade of cholinergic transmission.

Primary intoxication and primary infection with secondary intoxication can occur in several reasonably well-defined variations (Box 46.1). As suggested above, all of these variations are associated with peripheral cholinergic blockade. Those variations that involve oral exposure may also present with a variety of gastrointestinal problems, including nausea, vomiting, and diarrhea. Some of these problems may be caused by botulinum toxin, but others are likely due to microbial products that are consumed as part of the disease process.

Signs and Symptoms

Botulinum toxin acts preferentially on peripheral cholinergic nerve endings to inhibit acetylcholine release. The two principal populations of vulnerable neurons are those at the neuromuscular junction and those at various autonomic sites.

Depending on severity, neuromuscular blockade can vary from slight weakness to frank paralysis (Hatheway, 1995; Horowitz, 2005; Sobel, 2005). Generally speaking, blockade tends to be both descending and bilateral. A classic patient might present with bilateral weakness of head and facial musculature, followed by weakness in the upper limbs, trunk, and lower limbs. The fact that weakness or paralysis is bilateral is understandable. The toxin is fully capable of poisoning transmission on both sides of the body. The fact that neuromuscular involvement is descending has not been so easy to explain.

BOX 46.1

CLINICAL PRESENTATION OF BOTULISM

There are two broad categories of botulism: (1) primary intoxication, and (2) primary infection with secondary intoxication. Each of these broad categories can be further subdivided, as follows:

1. Primary intoxication
   a. *Foodborne botulism*, which is caused by consumption of foods that are contaminated with preformed botulinum toxin. This form of the disease occurs when food that harbors *Clostridia* is prepared and/or stored in a way that allows bacterial growth. Toxin is released during microbial lysis, and thus it is available to cause disease when ingested.
   b. *Inhalation botulism*, which is due to inhalation of airborne particles or droplets contaminated with toxin. There is only one documented outbreak of human inhalation poisoning, which occurred in a laboratory that was handling the toxin.
   c. *Iatrogenic botulism*, which can be due to administration of the toxin for therapeutic or aesthetic purposes. If the administered dose is inappropriately high, or if a patient is unusually sensitive, disease can occur.
2. Primary infection with secondary intoxication
   a. *Foodborne botulism*, which is due to consumption of food that is contaminated with clostridial spores. These organisms colonize the gut and produce the toxin in situ. This form of the disease can present in two variants. *Infant botulism*, which is more prevalent, occurs in infants who have not yet acquired a normal gut flora. The relative absence of competing organisms allows *Clostridia* to establish a niche. *Adult botulism* occurs in people who have endogenous or exogenous factors that diminish or eliminate natural gut flora (e.g., antimicrobial agents). This creates a situation that is conducive to subsequent colonization by *Clostridia*.
   b. *Wound botulism*, which is due to introduction of clostridial spores, with subsequent colonization and production of toxin in situ. This form of the disease is usually secondary to puncture wounds associated with injection of illicit drugs (e.g., heroin). However, it can also be secondary to surgery.

The need for medical intervention is greatest when there is involvement of the muscles of respiration (diaphragm; intercostal muscles). It is likely that throughout most of human history severe poisoning resulted in death due to respiratory failure. The introduction of sophisticated intensive care practices and facilities, combined with heightened awareness and early diagnosis of the disease, has dramatically reduced morbidity and mortality in modern times.

Botulinum toxin can also produce a constellation of adverse autonomic effects. Among the more well-documented of these are fixed and unresponsive pupils; decreased salivation, with dryness of the mouth and throat and difficulty swallowing; orthostatic hypotension; paralytic ileus; and bladder and urinary dysfunction. Autonomic problems would not typically be a cause of death.

In contrast to peripheral cholinergic systems, other parts of the nervous system are generally preserved in terms of function. Sensory responses are normally intact, and there is little evidence to support any direct action of the toxin on the central nervous system. The toxin is a large protein and would not be expected to penetrate the blood–brain barrier. It has often been noted that the absence of overt effects of the toxin on the brain means that patients, including those who are fully paralyzed, are aware of their difficult circumstances.

Duration of Action

Botulinum toxin is generally viewed as the most potent biological substance known. However, this is only one of its remarkable features. Yet another is its ability to exert an unusually sustained effect.

In most respects the signs and symptoms associated with the various serotypes of botulism are similar. One striking exception is duration of illness. It appears that the signs and symptoms associated with serotype A poisoning are the longest, with a potential duration of months. However, the incidence of naturally occurring botulism is very low, and therefore efforts to quantify accurately the true duration of action are problematic. Ironically, most of the definitive work on duration of effect arises not from the study of botulinum toxin as a disease, but rather from work related to use of the toxin

as a medicinal agent. Botulinum toxin is administered to patients by local injection to reduce the adverse and sometimes debilitating effects of uncontrolled efferent traffic in cholinergic fibers. The major drawback to this form of intervention is that the therapeutic benefits of the toxin wane with time, thus requiring readministration of toxin. The length of the intervals between administrations is an indicator of the duration of toxin action. Both clinical observation and research related to clinical use have verified that serotype A has the longest duration of action (Adler et al., 2001; Eleopra et al., 1998; Foran et al., 2003; Keller, 2006). This work has also shown that there is great variability in duration of effect, with recovery at certain sites occurring in 2–3 months, but recovery at other sites perhaps requiring more than 1 year. This is a stunning duration of effect for an exogenous protein.

Therapeutic Intervention

Treatment of patients can be somewhat arbitrarily divided into three categories: methods to reverse poisoning; methods to halt the progression of poisoning; and methods to provide supportive care while patients recover from poisoning. Sadly, there is nothing to report that falls into the first—and conceptually the most desirable—category. No clinically acceptable agent or procedure has been identified that can reverse the enzymatic actions of the toxin that account for blockade of exocytosis. When a toxin substrate has been cleaved, the only known intervention is to wait until the poisoned nerve synthesizes new substrate and reconstitutes the exocytotic process.

There are two possible ways to halt the progression of disease, which are passive immunization and pharmacologic antagonists (Arnon et al., 2001). There is an equine antitoxin, and administration of the material can lead to neutralization of circulating toxin. There is also a human immune globulin preparation that is intended for infants who ingest clostridial spores that manufacture toxin in situ (Arnon et al., 2006; Arnon, 2007). In either case, treating physicians must face this sobering reality: if signs and symptoms have begun to emerge, the therapeutic value of immune serum or neutralizing antibodies is much diminished. This loss of antibody effect is related to the ability of the toxin to enter nerve endings and block transmitter release. Neutralizing antibodies cannot chase the toxin because they have no mechanism for productive internalization by cells.

Many investigators have tried to identify drugs that can halt the progression of the disease. For example, there are several research groups trying to develop drugs that can block the enzymatic actions of the LC. There are reports of success in laboratory test systems, but there is nothing that is on the verge of clinical testing. One challenge to clinical progress is drug delivery. Toxin antagonists tend to be polar, and as such they may not be good candidates for mucosal delivery. Having to administer an antagonist by injection could be a difficult proposition when dealing with a toxin whose duration of action could be many weeks to months. A second challenge relates to membrane barriers. To antagonize botulinum toxin, a drug should be found that can cross neuronal membranes to reach toxin but not cross other membranes to enter non-neuronal cells. There are as yet no clear strategies for achieving selective membrane penetration, with one potential exception. There is the possibility that nontoxic variants of the toxin could be used as carriers to transport antagonists or even antibodies into cholinergic cells.

The third category of intervention is supportive care, and this is the one area in which there has been authentic success. The early literature on botulism indicated that fatal outcomes often reached 50% or more. With the advent of modern intensive care procedures, this fatality rate has fallen dramatically. This means that even those patients who become fully paralyzed, and who may need respiratory support for extended periods of time, have a good prospect of recovery.

Implications for Vaccine Development

There is an emerging body of information on the history of the disease botulism, as well as on the clinical presentation and treatment of the disease. This body of information supports several conclusions regarding vaccine development, as follows:

(1) Unless and until experimental or licensed therapeutic antibodies and/or drug antagonists become available for human administration, there will be a disproportionate reliance on current experimental vaccines. This reliance is heightened by the facts that: (a) the equine antitoxin that is currently available is not desirable for widespread use, either preincident or postincident; and (b) postincident use of antibody preparations, whether equine or human, has limited value in patients who have begun to manifest signs and symptoms. There is the additional limitation that therapeutic antibodies and pharmacologic antagonists may have durations of action that are much shorter than that of the toxin. This could, for example, create the necessity to administer

a pharmacologic antagonist repeatedly over an extended period of time.

(2) Botulinum toxin exists in seven serotypes, but only three of these are typically associated with human illness (A, B, and E). This suggests that the most immediate need for a product would be a polyvalent vaccine that evokes simultaneous resistance to serotypes A, B, and E.

(3) Botulinum toxin is released from bacteria as part of a noncovalent complex that includes auxiliary proteins. However, it has not been established when this complex dissociates to release free toxin, and this uncertainty applies both to primary intoxication and to primary infection with secondary intoxication. If it were to be found that toxin in the gut is always associated with auxiliary protein, this would raise the interesting possibility that a local IgA response against an auxiliary protein could block absorption and diminish toxicity (Kobayashi et al., 2005; Mahmut et al., 2002).

(4) In a similar vein, the botulinum toxin complex is able to defeat two of the most prominent mechanisms that contribute to innate immunity against toxic proteins. Firstly, the heteromolecular complex can withstand the conditions that ordinarily lead to gastric metabolism. Secondly, the toxin can bind exploitatively to receptors on epithelial cells, leading to absorption of the molecule rather than elimination. This serves to re-affirm the premise presented above (#3). Whether directed against the neurotoxin, the auxiliary proteins, or both, a secretory IgA response would create a barrier to toxin absorption that could substitute for circumvented mechanisms of innate resistance.

(5) For patients who are at risk of primary infection, there is the theoretical possibility that an attenuated vaccine could combat colonization by clostridial spores in the gut. However, there are powerful factors that weigh against this as a realistic option. The number of patients who develop primary infection as a natural disease is too low to warrant development of an attenuated vaccine. In addition, primary infection would be relatively difficult to implement as an act of bioterrorism, and it has essentially no relevance as an act of biological warfare.

(6) Botulinum toxin is not known to exert direct effects on the central nervous system. This means that an immune response must attack and neutralize serotypes A, B, and E before they enter peripheral nerve endings, but not central nerve endings.

EPIDEMIOLOGY

Naturally Occurring Disease

Reports have appeared at irregular intervals describing the incidence of botulism in the US (e.g., Sobel et al., 2004; Gupta et al., 2005). Over an extended period of time, both the number of outbreaks per year and the number of cases per outbreak has been low. An exact insight into the frequency of the disease can be gained from the epidemiologic report by Shapiro et al. (1998). Reviewing the data that were available for approximately a quarter of a century (1973–1996), these authors found that the median number of cases reported annually to the Centers for Disease Control and Prevention was ca. 100.

Few equivalent reports exist that quantify the worldwide incidence of botulism over time (but see Todd, 1997). However, given the way in which the disease presents when it is naturally occurring (Table 46.1), and given that the disease is not transmitted from patient to patient, one can deduce that the worldwide incidence is likely to be relatively low.

Bioterrorism and Biological Warfare

Botulinum toxin is considered a prime candidate as a potential bioweapon (Arnon et al., 2001). Indeed, there is strong evidence that the toxin, or cultures containing the toxin, have been isolated for the purpose of intentionally poisoning civilian (viz., bioterrorism) and military (viz., biological warfare) populations (Caya et al., 2004; Christopher et al., 1997; Klietmann and Ruoff, 2001; Zilinskas, 1997). For example, during the first half of the 20th century, cultures of *C. botulinum* were fed to Manchurian victims by their Japanese occupiers. Shortly thereafter, during World War II, a number of Western nations began accumulating clostridial cultures and semipurified toxin. This was often described as being for defensive purposes (i.e., toxoid production), but it is likely that offensive purposes were part of the primary motive. During the second half of the 20th century, certain nations that had signed the international convention banning offensive use of biological toxins accumulated frightening amounts of botulinum toxin (e.g., Iraq, the former Soviet Union), and there is no doubt that this was intended for use as a weapon. In addition, the Japanese cult Aum Shinriko not only accumulated the toxin, but also used it in aerosol attacks against civilian and military targets. Thankfully, these attempts at intentional poisoning have largely failed.

This unsettling history has caused botulinum toxin to become one of the agents that is on Select List A (NIAID, 2002). Each of the agents on this list possesses properties that contribute to a high level of risk. For botulinum toxin, the principal characteristics are:

- The extreme potency of the toxin.
- The relative ease with which the toxin can be isolated and then used with malice.
- The severity of the disease caused by the toxin, coupled with the prolonged and intensive medical care needed to treat serious poisoning.

Concerns about the potential use of the toxin as a bioweapon are heightened by the absence of adequate and targeted medical countermeasures. The three most obvious forms of intervention would be vaccination, therapeutic antibodies, and pharmacologic antagonists. At present there is no licensed polyvalent vaccine against botulinum toxin. Until the relatively recent past the only therapeutic antibody available was equine in origin. However, a significant advance occurred with the introduction of a licensed botulism immune globulin (BIG) (Arnon et al., 2006). This product is intended for use in infants with foodborne botulism (primary infection; see Table 46.1) due to serotypes A and B. In addition, substantial progress has been made in preclinical studies aimed at generating a new class of therapeutic antibodies (Nowakowski et al., 2002). It is likely that these antibodies will soon enter clinical trials.

Concerns about the potential use of botulinum toxin against civilian or military populations have dramatically intensified efforts to identify pharmacologic antagonists. Most investigators have focused on agents that either block toxin binding to neuronal membranes or that block intracellular expression of toxin catalytic activity (Dickerson and Janda, 2006). Unfortunately, none of these agents has entered clinical trials.

THE SEARCH FOR VACCINES

It would be gratifying to report that the field of vaccine development has been governed by the various principles that apply to rational design, but this would not be entirely true. Perhaps a truer assessment would be that the field has been governed by widely separated episodes of urgency, and two of these episodes have figured prominently in product development. The first began early in the last century, was intensified in the wake of World War II, and culminated in a chemical (formalin-inactivated) toxoid (Anderson and Lewis, 1981; Smith, 1977). The second began slightly before the turn of the present century, was intensified in the wake of the terrorist attacks on the World Trade Center and the bioterrorist attacks with anthrax, and culminated in a recombinant toxoid (Byrne and Smith, 2000; Smith, 1998). Both efforts should be viewed as milestones, and both resulted in Investigational New Drug status. However, neither toxoid has been licensed.

It is commendable that progress has been made toward developing a vaccine against botulinum toxin, but at the same time one must note that there are obvious and important ways to improve on the existing technology. Therefore, the sections that follow will survey the current field of vaccine development. The goal is to lay a framework for gauging the distance between current technologies and an "ideal" technology based on rational design.

Chemical Toxoids

Efforts to develop a vaccine against botulinum toxin predated knowledge about structure and structure–activity relationships of the molecule. For that matter, vaccine research began before the techniques for isolation and purification of toxin were fully developed. This meant that investigators who pioneered vaccine research were effectively limited to only one strategy: chemical inactivation of a bacterial culture fraction that was enriched in toxin (Fig. 46.1).

The initial work to develop a vaccine began almost 60 years ago, in response to concerns that the toxin would be used in biological warfare. The effort to generate a pentavalent product (A–E) required an extended period of time (Byrne and Smith, 2000). The process involved growing individual cultures that were acid-precipitated, processed to remove unwanted bacterial debris, and then precipitated again. The final product, which was still highly impure, was treated with formalin to denature, cross-link, and inactivate the toxin that was present. The individual formalin preparations were then combined to create a pentavalent toxoid. In subsequent work, a monovalent toxoid was generated against serotype F (Hatheway, 1995; Montgomery et al., 2000). In this case, a greater effort was made to fractionate material, and thus there was greater enrichment of toxin in the mixture treated with formalin. Both the pentavalent and the monovalent preparations were adsorbed to aluminum hydroxide, and both formulations were designed for parenteral administration.

Neither the pentavalent nor the monovalent toxoid has progressed through the entire regulatory process needed to secure United States Food and Drug Administration approval. However, both have

received Investigational New Drug status, and limited quantities of the pentavalent toxoid are distributed by the Centers for Disease Control to persons for whom immunity is appropriate (i.e., laboratory workers who handle toxin).

Relatively little work is now being done on traditional toxoid preparations (for example, Montgomery et al., 2000; Mahmut et al., 2002; Torii et al., 2002; Kobayashi et al., 2005). This diminished interest in chemical toxoids can be attributed entirely to advances in alternative technologies. Recombinant techniques can now be used to express a holotoxin that is devoid of the ability to poison cholinergic transmission (e.g., point mutations that abolish LC catalytic activity; Kiyatkin et al., 1997). In addition, polypeptide domains within the toxin have been identified that are capable of evoking a robust immune response (Byrne et al., 1998). This means that a vaccine can be prepared without ever having had active toxin as a precursor or as an ingredient.

Recombinant Toxoids

There are three lines of investigation that have been pursued in an attempt to identify a recombinant vaccine that will evoke a neutralizing antibody response: (1) expression of holotoxin in an inactive form, (2) expression of large polypeptides that represent functional domains within the toxin, and (3) synthesis of small polypeptides that could represent linear epitopes. In all cases, the principal goal has been to elicit a high circulating titer of neutralizing IgG antibody.

Inactive Holotoxin

There is an obvious advantage of using the entire toxin molecule as an antigen: every epitope in the native toxin will be present. Furthermore, when compared to a formalin-inactivated toxoid, a recombinant holotoxin can be generated that has little or no change in structure. Yet another advantage is that the holotoxin, unlike specific functional domains (e.g., LC) or small polypeptides, retains the ability to bind and penetrate epithelial barriers. Therefore, the modified holotoxin could be evaluated as an oral or inhalation vaccine.

There are several possible ways in which a holotoxin can be expressed as an inactive variant. The most well-documented of these is to perform site-directed mutagenesis to alter the histidine motif in the LC that is essential for catalytic activity. This was the technique that was used to generate and test the first recombinant holotoxin as a parenteral and nonparenteral vaccine. Kiyatkin et al. (1997) expressed a full-length serotype C holotoxin that had three amino acid mutations (H229 → G; E230 → T; H233 → N) The isolated and mutated LC was also expressed. When tested in vivo (mouse toxicity assay) and in vitro (murine phrenic nerve-hemidiaphragm bioassay), the mutated holotoxin was devoid of neuromuscular blocking activity. When tested in a broken cell assay (isolated and ruptured synaptosomes) neither the mutated holotoxin nor the mutated LC possessed catalytic activity.

When mice were immunized with the two recombinant polypeptides, the results were largely in keeping with expectations (Fig. 46.3). Intramuscular administration of

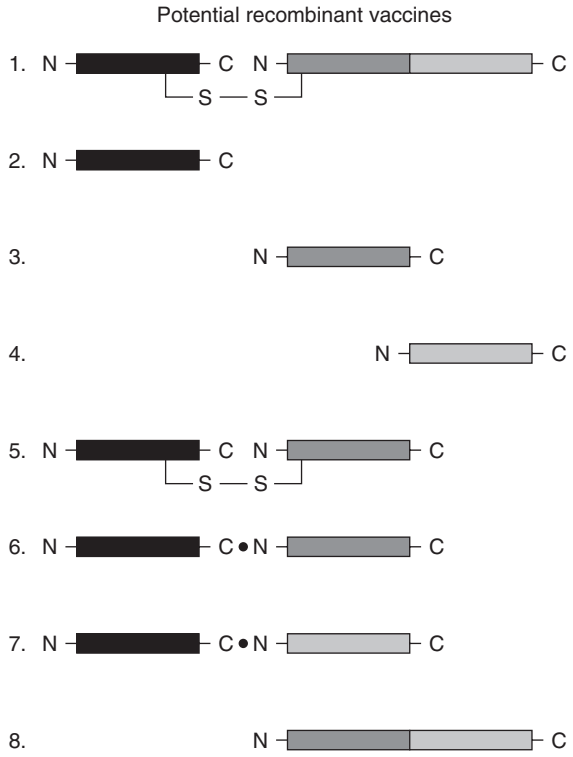

FIGURE 46.3 Potential recombinant vaccines. There are several different recombinant functional domains that are candidates as vaccines against botulinum toxin. These candidates represent the LC (black tone; 50,000 Da), the amino-terminal half of the heavy chain (HCN; grey tone; 50,000 Da), and the carboxy-terminal half of the heavy chain (HCC; intermediate tone; 50,000 Da), either individually or in combination, as follows: (1) holotoxin with point mutations to render it nontoxic, (2) the isolated LC, (3) the isolated HCN, (4) the isolated HCC, (5) a dipeptide containing LC linked to HCN, with a disulfide bridge that mimics that in the holotoxin (1), (6) a single-chain molecule in which LC and HCN are linked by an amide bond, (7) a single-chain molecule in which LC and HCC are linked by an amide bond, and (8) HC. The strategies of testing inactive holotoxin, individual functional domains, and combinations of functional domains have all been tested in laboratory animal experiments. To date, the only candidate that has reached human clinical trials is HCC (4).

either the holotoxin or the LC evoked a circulating titer of neutralizing IgG antibody and resistance to native toxin. Oral administration of the holotoxin similarly evoked an immune response, but oral administration of the LC did not evoke protection. The latter result could be attributed to the inability of the LC to bind and penetrate epithelial barriers.

Results such as these are promising, but there are issues that must be addressed, particularly regarding route of vaccine administration. If the goal is simply to create an injectable vaccine, a nontoxic holotoxin would be acceptable. If the goal is to create an oral vaccine—which is clearly preferable—there is a hurdle that must be overcome. When botulinum toxin is synthesized and released from clostridia, it is part of a noncovalent complex that contains other proteins, including hemagglutinins and a so-called nontoxin, nonhemagglutinin. These proteins intertwine in a way that produces remarkable resistance to the harsh conditions of low pH and proteolytic enzymes in the gut. When the toxin is stripped of this protective complex, it is less potent as an oral poison. It is, nonetheless, active by the oral route, and it is even more active when injected directly into the upper small intestine to bypass gastric metabolism (Maksymowych et al., 1999).

The concept of artificially wrapping a recombinant holotoxin with recombinant proteins may sound reasonable, but in practical terms it is not feasible. Fortunately, there is a relatively simple and straightforward alternative. The science of drug delivery has identified several techniques for protecting oral medications from metabolic degradation in the gut. Perhaps the best-known strategy involves encapsulation combined with enteric coating. This would appear to be an ideal approach for a botulinum vaccine. An appropriately designed delivery system could protect the molecule during its transit through the stomach, and the molecule itself could then bind and penetrate epithelial barriers in the intestine to reach the general circulation. This is an entirely feasible strategy that deserves serious consideration.

Functional Domains

The tactic of using recombinant functional domains as vaccines shows great promise, and it appears to be one that is en route to winning clinical approval. This approach could involve any one of six potential candidates: the isolated LC, the amino-terminal half of the heavy chain (HC_N), the carboxy-terminal half of the heavy chain (HC_C), a dimer of LC and HC_N, a dimer of LC and HC_C, or a dimer of HC_N and HC_C (i.e., intact heavy chain). Several of these candidates are being explored (Byrne et al., 1998, 2000; Byrne and Smith, 2000; Jensen et al., 2003; Kiyatkin et al., 1997; Park and Simpson, 2003; Yang et al., 2004), but greatest progress has been achieved with HC_C (Baldwin et al., 2005; Byrne et al., 1998, 2000; Byrne and Smith, 2000; Clayton et al., 1995; LaPenotiere et al., 1995). Vaccination of animals with this domain of serotypes A, B, C, D, E, and F has been shown to evoke protective antibody formation (circulating IgG) and resistance to the respective parent toxins.

The concept of using HC_C as a vaccine against botulinum toxin can be traced to earlier work on tetanus toxin. Botulinum toxin and tetanus toxin are both clostridial in origin; they have similar macrostructures (viz., functional domains); and they both act on nerve terminals to block transmitter release. Early work on the protein structure of tetanus toxin revealed that this molecule could be cleaved by trypsin to yield two main fragments: the LC still associated with the amino-terminal half of the heavy chain, and the remaining carboxy-terminal half of the heavy chain. The latter, which was called "fragment C", was shown to be an excellent immunogen (Fairweather et al., 1987; Helting, 1984; Makoff et al., 1989). These observations on cleavage products of tetanus toxin were the forerunners in efforts to use HC_C as a vaccine against botulinum toxin.

Work to demonstrate that the HC_C domain can be used as an injectable vaccine has been pioneered by investigators at the U.S. Army Medical Research Institute for Infectious Diseases (Byrne and Smith, 2000). In its initial iteration, this work focused on expression of the serotype A polypeptide in a traditional system (e.g., *Escherichia coli*). This approach worked, but it had notable limitations. Codon usage in clostridia is different from that in *E. coli*, and therefore expression efficiency of the HC_C polypeptide was only modest. Also, *E. coli* is generally not an adequate expression system for generation of the amounts of protein needed for eventual clinical testing and use. The first problem was addressed by creating a synthetic gene that was designed for optimization of HC_C expression in *E. coli* (Clayton et al., 1995). The second problem was solved by moving to an alternate and large-scale expression system (*Pichia pastoris*), while retaining the concept of using a synthetic gene that optimizes expression (Bouvier et al., 2003; Byrne et al., 1998; Potter et al., 2000).

The work on expression of the HC_C domains of serotypes A and B has progressed very nicely (Potter et al., 2000). Procedures for optimization of expression under GMP conditions have been achieved, and both an absence of toxicity and the presence of efficacy in preclinical models have been demonstrated. The U.S. Food and Drug Administration has granted

Investigational New Drug status to these products, and they are currently in clinical trials (Byrne and Smith, 2000; Smith et al., 2004).

Work similar to that with serotypes A and B is underway with other serotypes, including C and D (Arimitsu et al., 2004; Lee et al., 2007; Webb et al., 2007; Woodward et al., 2003), E (Smith et al., 2004), and F (Byrne et al., 2000; Holley et al., 2001; Johnson et al., 2003). There is reason to be optimistic that this approach could ultimately generate a polyvalent vaccine that combines HC_C domains of the various serotypes to produce multivalent resistance.

The discussion so far has focused on generation of an injectable vaccine against botulism. Interestingly, these same polypeptides can also be used as oral and inhalation vaccines. In a series of structure–function studies intended to localize the minimum essential domain that is needed for binding and penetration of human epithelial cells, Maksymowych and Simpson found that only a fraction of the holotoxin was necessary (Maksymowych and Simpson, 2004). Neither the LC nor the amino-terminal portion of the heavy chain was required. The isolated HC_C polypeptide possessed the same ability to penetrate human gut and airway epithelial cells as the parent holotoxin. The fact that HC_C retains the ability to cross epithelial barriers, combined with the fact that it can evoke a robust immune response, suggests that HC_C would be an excellent candidate for a mucosally administered vaccine (Lamm, 1997; Ravichandran et al., 2007).

Specific Epitopes

Ideally, the exact number, nature, and location of every epitope on each serotype of botulinum toxin would be mapped. This would be invaluable both to investigators trying to develop vaccines and to those trying to generate therapeutic antibodies. Sadly, this ideal is far from being realized. Of the seven serotypes, only one can be characterized as having been the subject of intense research (e.g., serotype A); and even for this serotype a complete epitope map is not yet available.

It is not clear whether the total number of epitopes in the intact botulinum toxin type A molecule is known. In the most detailed study quantifying the number of monoclonal (single chain variable fragment) binding sites, Chen et al. (1997) reported a total of 40 sites that were exposed in the intact molecule. An additional four sites were occult. Epitope mapping indicated that 22 of the exposed sites were in the carboxy-terminal portion of the heavy chain (receptor binding domain; HC_C), 3 were in the amino-terminal portion of the heavy chain (translocation domain; HC_N), and 15 were in the LC (catalytic domain).

Efforts to localize epitopes as potential vaccines have focused overwhelmingly on the heavy chain, and on the carboxy-terminal end of this chain in particular. This is simply a reflection of the fact that this portion of the molecule has long been known to be an efficient immunogen. Given that this is the only functional domain that has been advanced to the stage of initial clinical trials, attention will likely remain focused on this region of the molecule.

Two general strategies have been pursued in the quest to find clinically relevant epitopes (also known as putative vaccines). One approach has been to use the heavy chain or its isolated carboxy-terminal as an immunogen to raise monoclonal antibodies. Various techniques are then used to deduce or to determine the region or even the specific amino acid sequences that are antibody-binding sites. The second approach has been to synthesize relatively small (and sometimes overlapping) peptides on the premise that toxin epitopes are represented somewhere in this population of molecules. Each of the amino acid sequences is then tested to determine which will elicit antibodies, and preferably neutralizing antibodies. As far as linear epitopes are concerned, these two strategies should ultimately generate compatible outcomes. As far as conformational epitopes are concerned, the synthetic polypeptide approach will have limitations. This will certainly be true when conformational components arise from amino acids that are well separated in the primary sequence. The impact of this limitation cannot be stated with certainty because the relative number of linear and conformational epitopes is not known.

There are more than two decades of research in which investigators have generated monoclonal antibodies against inactive holotoxin or polypeptide fragments. Virtually none of the early work had vaccine development as a primary motive; instead, the typical goal was to use the antibodies as tools to map the structure and function of the toxin molecule (for a representative early paper, see Kozaki et al., 1986). More recently, several laboratories have sought to identify monoclonal antibodies that have significant neutralizing activity. This work has utilized toxoid preparations of holotoxins or specific functional domains, such as the HC_C domain, as antigens (for representative papers from different laboratories, see Amersdorfer et al., 1997; Brown et al., 1997; Kubota et al., 1997; Rosenberg et al., 1997; Wu et al., 2001; Yang et al., 2004). One encouraging point that emerges from all these and related studies is that it is possible to isolate antibodies that have appreciable neutralizing activity.

Unfortunately, the effort to translate monoclonal antibody binding sites into putative vaccine candidates has not met with great success. Thus, as an illustration, Wu et al. (2001) have identified monoclonal antibodies that have substantial neutralizing activity. Using phage display, they were able to identify a specific amino acid sequence which, when expressed, could bind to the antibodies. For technical reasons, it was not possible to use a small polypeptide representing the putative antibody-binding domain to evoke a meaningful immune response.

Bavari et al. (1998) used a somewhat different approach. Rather than generating an entire phage display library of polypeptides, they instead focused on two 25-mers that had been predicted to be antibody-binding sites based on conformational modeling studies that suggested the location of solvent-exposed loops. These synthetic polypeptides were indeed binding proteins for neutralizing antibodies, but when tested as immunogens only one of the peptides was active, and the level of induced resistance was modest.

This line of investigation sets the stage for the complementary approach, in which putative epitopes are the starting point. However, there is a cautionary note that must be inserted, especially in the context of using small polypeptides from HC_C as vaccines. Tavallaie et al. (2004) performed a comparison study in which they examined HC_C as well as each of the two ends of this polypeptide as vaccine candidates. They made the interesting discovery that neither half of the HC_C domain, nor the two used in combination, was equivalent to the intact HC_C as a vaccine. These results suggested that the interfacial region between the two halves of HC_C is critical to evoking a maximal protective response.

The effort to localize epitopes to specific and small linear sequences has been almost wholly the providence of one laboratory and its collaborators (Atassi and Oshima, 1999). The essence of this work has been to synthesize small, overlapping peptide sequences that reflect the linear sequence of the toxin. Most of this work has focused on HC_C (Atassi et al., 1996; Oshima et al., 1997, 1998), although HC_N has also been examined (Atassi and Dolimbek, 2004; Atassi et al., 2005). This work has contributed considerably to an understanding of the antibody-binding domains that are linear in nature. However, the investigators have set a high standard that, with respect to botulinum toxin, has not been entirely met. In earlier work on α-bungartoxin, Dolimbek and Atassi (1996) made the observation that a conjugate containing three synthetic peptides mimicking three domains within α-bungartoxin was a better vaccine than the holotoxin itself. A similar accomplishment has not been achieved with botulinum toxin, but if it were to be achieved, it would deservedly draw considerable attention.

Superantigens

It is inherent in the concept of serotypes that the different botulinum toxins are relatively or completely immunologically distinct. Generally speaking, investigators have accepted the premise that a vaccine must be polyvalent to afford protection against multiple serotypes. This could mean having to develop and subsequently mix seven monovalent preparations to achieve full spectrum protection. The issue becomes even more problematic when one considers subtypes. There is an emerging literature showing that individual serotypes can have multiple subtypes, these subtypes can have notable differences in amino acid sequences, and antibodies that efficiently neutralize one subtype may not be efficient in neutralizing others (Smith et al., 2005). The implications this has for vaccine development—and even more so for therapeutic antibody development—are obvious.

The existence of so many variants of botulinum toxin encourages the effort to re-examine and re-think the issue of distinctness. At a minimum, it would be desirable to identify shared epitopes across any given family of subtypes (e.g., serotype B subtypes); even better, it would be desirable to find common epitopes across all serotypes (e.g., A–G). This search is given added impetus by the two major lines of research summarized above. Both those who use antibodies to map epitopes and those who use putative epitopes to map antibody-binding sites agree on one fundamental premise. The evoking of antibodies, whether for active immunization or for passive immunization, is optimized with oligoclonal or polyclonal preparations. This simple and fundamental premise takes on considerable weight when discussing the possible existence of superantigens. It is not essential that each of the clonal members of a group be highly active. Even relatively weak antibodies can combine to produce a potent neutralizing outcome (Nowakowski et al., 2002). Thus, a superantigen does not have to evoke neutralization of all toxin variants, or for that matter even one variant, to be useful. If a superantigen can combine with a small number of other antigens to produce a highly protective response, it will have served an important purpose.

The effort to identify and localize superantigens for botulinum toxin cannot be described as a hotbed of current research! One might even say that the most important findings to date are relics from the past. For example, it has been known for decades that there is

substantial cross-reactivity between serotypes C and D (Oguma et al., 1980). As another example, one often quoted paper that describes an antibody recognizing serotypes B, C, D, and E was published almost 20 years ago (Tsuzuki et al., 1988).

The tools for localizing putative superantigens are much more powerful now than they were in the recent past. In addition, immunologists are skilled at evoking immune responses to peptides and other agents that are ordinarily poor antigens. In the face of the growing multiplicity of botulinum toxin variants, the need to explore superantigens is urgent.

Mechanism of Vaccine Action

The key extracellular step in botulinum toxin action is association with peripheral cholinergic nerve endings. The carboxy-terminal portion of the heavy chain binds to membrane receptors, and this initiates the sequence of events that culminates in blockade of exocytosis. This is the same portion of the toxin molecule that is being vigorously examined as a vaccine candidate. Many laboratories have reported that this portion of the molecule possesses numerous epitopes. It has also been reported that antiserum raised against this domain can neutralize toxin action when tested in vivo, and it can delay onset of neuromuscular blockade when tested in vitro. This would seem to be a compelling argument that a vaccine possessing the HC_C domain leads to neutralization of toxin action by occluding the receptor-binding domain (Kozaki et al., 1989). Toxin that cannot bind to its target organ is left stranded until it is eliminated from the body.

The concept that an antibody can associate with the HC_C domain in a way that prevents subsequent toxin binding to vulnerable cells is absolutely sound. Furthermore, if the affinity constant governing the antibody–antigen reaction is respectable, and if the antibody titer following immunization is respectable, then it is a certainty that occlusion of the binding domain can delay or even prevent poisoning. However, these sound concepts should not be extrapolated to mean that occlusion of receptor binding is the only mechanism that underlies vaccine action. Indeed, it may not even be the most important action.

A recent series of studies on the systemic pharmacokinetics of botulinum toxin has revealed that there is another mechanism for antibody-induced protection, and this mechanism precedes that of protection at the neuromuscular junction. It has been reported that the circulating half-life for botulinum toxin in mouse and rat blood is several hours (Ravichandran et al., 2006). The majority of toxin in the circulation is in the free form, and as such it is available for distribution to other parts of the body, including the neuromuscular junction. The fate of toxin in the presence of a neutralizing titer of antitoxin is dramatically different. Within approximately 5 min, the majority of the toxin is cleared from the circulation. Enhanced clearance was due mainly to the accumulation of toxin in liver and spleen (Dodd et al., 2005; Ravichandran et al., 2007).

There are two implications that stem from these findings. Firstly, a botulinum toxin vaccine can provide multiple layers of protection. It initially removes a large fraction of the toxin from the circulation and thereby prevents its delivery to the neuromuscular junction. Of the fraction that does reach peripheral nerves, toxicity is antagonized by antibody occlusion of the binding domain. Secondly, it is the enhanced clearance that is quantitatively more important. When exposed to a sufficient titer of antitoxin antibodies, most of the toxin is removed from the circulation and thus never reaches its target organ. It is reassuring to know that a vaccine can evoke resistance by more than one mechanism, each of which by itself is quite effective (Ravichandran et al., 2007).

VARIATIONS ON A THEME

The preponderance of current vaccine research deals with one mode of administration (injection), one type of antigen (recombinant polypeptide), and one type of response (circulating IgG). Although this is an excellent starting point, it would not be appropriate to claim that this is the best approach that can be envisioned. There are a number of ways to improve an injectable vaccine that evokes a circulating IgG response. Furthermore, many of these improvements are within technical reach. Some of the more promising of these potential improvements are considered below.

Route of Administration

All agencies that have a major stake in vaccine development, such as the National Institutes of Health, the World Health Organization, and the Bill and Melinda Gates Foundation, have encouraged efforts to develop "needle-free" vaccines. The benefits that arise from oral, inhalation and other "needle-free" methods of administration are numerous, well known, and compelling (Mitragotri, 2005; Neutra and Kozlowski, 2006). These benefits would apply to a botulism vaccine as much as they would apply to any other vaccine.

One might argue that there is a biological imperative to developing an oral or inhalation vaccine against

botulinum toxin. This statement is based on the fact that the toxin molecule itself has the inherent ability to bind and penetrate gut and airway epithelial barriers. Thus, it should not be surprising that a variant of the toxin that was engineered to lack catalytic activity (and therefore neurotoxicity) has been shown to be an oral vaccine (Kiyatkin et al., 1997). More recently, the native heavy chain (Park and Simpson, 2003) and the recombinant carboxy-terminal fragment (HC_C) have also been shown to be active when administered by mucosal routes (Ravichandran et al., 2007; Simpson et al., 2003).

The inhalation route might seem particularly desirable because the airway does not have the harsh conditions of low pH and proteolytic enzymes found in the stomach. This should mean that the auxiliary proteins that ordinarily protect the toxin from metabolism in the gut, or surrogates for these proteins such as enteric coatings, would be unnecessary. Even so, the advantages of not needing an enteric coating may be outweighed by other factors. It is well established that there are mechanisms by which xenobiotics delivered by the inhalation route can gain direct access to the brain. It is also well known that there are many common and not-so-common disorders of respiratory function that could mitigate attempts to deliver a vaccine by the inhalation route.

Perhaps the most prudent strategy at this point is to encourage research that would foster any viable "needle-free" vaccine. The development of an oral formulation that utilizes an enteric coating is not a particularly daunting challenge. Similarly, the design of experiments that could determine whether an inhalation formulation delivers foreign products to the brain is not difficult. A focused and well-conceived research plan could put a "needle-free" vaccine within reach rather quickly.

Source of Antigen

The ultimate product that a vaccine delivers to the immune system will be a polypeptide that mimics the parent toxin, but this does not mean that the polypeptide itself must be in the vaccine formulation. An alternative is to deliver the message that encodes the polypeptide. All three of the common approaches to delivering message have been reported. DNA vaccines have been tested for serotypes A (Clayton and Middlebrook, 2000; Shyu et al., 2000) and F (Bennett et al., 2003; Jathoul et al., 2004); a viral vector system has been tried with serotype A (Lee et al., 2001); and a bacterial expression system has been tested with serotype F (Foynes et al., 2003). In every instance, the goal was to elicit an immune response to the HC_C domain.

The initial efforts to create a DNA vaccine against serotype A were only partially successful (Clayton and Middlebrook, 2000; Shyu et al., 2000). Although a measurable titer of circulating IgG could be detected, the magnitude of the protective effect was relatively small. Subsequent efforts with a serotype F vaccine were more successful, and thus immunized animals were protected against challenge doses in the range of 10^4 MLD (Jathoul et al., 2004).

A propagation-deficient Venezuelan equine encephalitis virus vector was used to induce immunity to serotype A (Lee et al., 2001). This approach evoked a protective response against challenge doses of 10^5 MLD, and the protective immune response was still substantial 6 months and 1 year after immunization. Favorable results were also obtained with an attenuated *Salmonella enterica* var *typhimurium* expression system (Foynes et al., 2003). Induced immunity to serotype F afforded protection against challenge doses in the range of 10^4 MLD. This study did not monitor the duration of immunity.

The demonstration that high levels of protective immunity can be induced by viral and bacterial systems will no doubt fuel discussion about the relative merits of polypeptide vaccines versus nucleic acid vaccines. That discussion is beyond the scope of this review. On the other hand, it is worth noting that the two types of vaccines do have one feature in common. Depending on the formulation used for polypeptide vaccines, and depending on the virus or bacterium used for nucleic acid vaccines, both could be administered by the oral or inhalation routes.

Nature of the Immune Response

The concept of administering a polypeptide or a nucleic acid vector by a mucosal route has implications beyond those of eliminating the adverse consequences of using, storing, and disposing of needles and syringes. The most important of these is the prospect of evoking a local or universal secretory IgA response. At a minimum, IgA-mediated immunity at the mucosal level would provide an added layer of protection against botulinum toxin. Most cases of botulism are due to ingestion of toxin, or to ingestion of organisms that manufacture the toxin in the gut (see Box 46.1). Similarly, there is the anticipation that most cases of bioterrorism or biological warfare, should such incidents occur, would be due to oral or inhalation poisoning. These observations highlight the importance of an IgA-mediated protective barrier in the gut and airway.

In view of the potential importance of evoking a mucosal immune response, it is surprising that so little

work has been published in this field (Fujihashi et al., 2007). One exception is a recent study that utilized toxoid rather than recombinant polypeptide, and added a mutant form of cholera toxin as an adjuvant (Kobayashi et al., 2005). This cocktail is not likely destined for clinical approval. Nevertheless, the work did demonstrate an awareness of evoking a mucosal immune response. Another example is a recent study in which recombinant HC_C was used as an antigen. This study describes a trivalent vaccine against botulinum toxin (serotypes A, B, and E), and it utilized adjuvants that have already been approved for use in human patients (Ravichandran et al., 2007).

Monovalent versus Polyvalent

There is a consensus among investigators and public health officials that there must be a vaccine that protects against serotypes A, B, and E. At some point, it may be desirable to have a vaccine against all seven serotypes. Regardless of the number of serotypes involved, the expectation is that a vaccine against any particular serotype will provide protection against all subtypes within that serotype.

All previous attempts to develop polyvalent vaccines have involved mixing of monovalent vaccines. There is nothing in the literature to suggest that current workers are approaching matters any differently. This is unfortunate because there may be a viable approach to creating a polyvalent vaccine within a single polypeptide (or nucleic acid encoding the peptide).

As discussed earlier, the botulinum toxin molecule binds and penetrates epithelial cells to enter the general circulation. Studies on the structure–function relationships that govern penetration of epithelial barriers have shown that the carboxy-terminal portion of the heavy chain is fully competent to achieve this task (Maksymowych and Simpson, 2004). Neither the amino-terminal portion of the heavy chain, which is needed for internalization by nerve cells, nor the LC, which acts enzymatically to block exocytosis, is needed. The fact that the HC_C domain can penetrate gut and airway barriers, combined with the fact that it can evoke a robust immune response, is the basis for its being evaluated as an oral or inhalation vaccine (Ravichandran et al., 2007).

There is yet another way to look at these data, and the examination will reveal a creative way for making polyvalent vaccines. The structure–function studies on transcytosis support a new way of envisioning the toxin molecule. The HC_C domain can be viewed as a "carrier," and its role is to transport the remainder of the molecule, which can be viewed as "cargo," across epithelial barriers (Simpson et al., 2003). This means that the 50 kDa HC_C polypeptide can act as a carrier to transport a 100 kDa polypeptide (the rest of the toxin). This view of the molecule prompts a logical question. If the naturally occurring cargo were to be removed from the carrier, would it be possible to substitute novel cargo? To put the question into terms more relevant to this discussion, can the carrier be used to transport heterologous antigens into the body?

There is already a substantial body of evidence to support the carrier–cargo concept. A host of in vitro and in vivo experiments have been conducted that confirm the wide breath of utility of the carrier polypeptide in transporting heterologous molecules across gut and airway epithelial barriers (Simpson et al., 2003). There is no reason why this concept cannot be applied to a polyvalent botulinum toxin vaccine. The carrier domain of one serotype could be used to transport the antigenic domain of another serotype (or two? or three?) across epithelial barriers. One obvious embodiment would be to link the HC_C domain of serotype A to the HC_C domain of serotype B to the HC_C domain of serotype E. The carriers at either end of this trivalent vaccine might even be oriented in a way to expose their respective binding domains. This would mean that a single polypeptide would have two epithelial binding domains working to transport a trivalent vaccine into the body. The author and his colleagues have already made a number of these constructs, which are undergoing biological testing.

A PROVOCATIVE QUESTION

From the Perspective of a Disease

Discussions about vaccine development seldom give serious consideration to the issue of an ideal duration of immunity. When these discussions deal with microbial pathogens, the unspoken premise is usually that an ideal duration would be "eternity." If a patient were to be vaccinated only once, and if this procedure were to evoke lifelong immunity, this would represent the Holy Grail.

It is certainly true that in many instances a sustained immune response would be desirable. Consider for example the tetanus vaccine, which is the most widely administered vaccine in the world. Current medical guidelines propose that boosters be given at 10-year intervals, and that these boosters be administered throughout life. A tetanus vaccine that could evoke lifelong immunity without the need for boosters might be described as ideal.

Tetanus toxin is only one of the pathogens for which a sustained immune response would be desirable. However, there are other pathogens for which this would not be true, and botulinum toxin happens to be one of them. If anything, a vaccine against botulinum toxin might be seen as a counterpoint to that against tetanus. Indeed, one might pose this provocative question: Would an ideal vaccine against botulinum toxin have a short duration rather than a long duration of action?

The answer to this question may emerge from a close examination of the role of the toxin as an agent that causes disease. There are three ways to view the disease, and each is related to a somewhat different population. To begin with, botulism can be a naturally occurring disease, and as such it can affect the entire population. It can also be an unnatural disease—a product of malice—in incidents of bioterrorism and biological warfare. Bioterrorism, by definition, applies to the civilian segment of the total population, whereas biological warfare applies to the military segment of this population.

Naturally occurring botulism has a very low incidence, especially in countries with a well-developed food processing industry. The incidence is so low that there would never be a justification for universal vaccination. Only a tiny fraction of the total population will actually contract the disease, or be at significant risk. It is noteworthy that among those who actually contract the disease, the largest proportion is infants who are only several months to about one year in age (Arnon, 1980; Ferrari and Weisse, 1995; Wigginton and Thill, 1993). It would be meaningless to describe this as a candidate population for lifelong immunization. Among those who are at significant risk, one could cite laboratory workers who handle the toxin. Conceivably there are investigators who could benefit from lifelong immunity, but their numbers are truly small.

Another way to view the disease is as an unnatural outcome that results from bioterrorism. This view is certainly warranted, but at the same time one must note that there has yet to be an incident of bioterrorism for which there was significant morbidity and mortality due to botulinum toxin. This has led many to conclude that, until there is a tragic event, there will be neither policy advocacy for, nor public acceptance of, the concept of universal vaccination. Even if there were to be an incident, it would likely have to be one of substantial proportions before the idea of universal vaccination would receive serious consideration. And even if the level of concern and alarm were to rise to high levels, a vaccine of limited duration of action would be more palatable to the general population than one of lengthy duration of action (see below).

With bioterrorism, as with naturally occurring botulism, the proportion of the population that one could identify as reasonable candidates for lifelong immunity is minuscule. For example, one might consider vaccinating those healthcare workers who would be called upon to handle environmental or patient specimens contaminated with toxin. The needs of this population are unquestionably legitimate, but their numbers are exceedingly small.

With biological warfare there similarly has never been an incident for which there was significant morbidity and mortality due to botulinum toxin. Nevertheless, a respectable proportion of the military population could be at risk in times of conflict, especially if that conflict is in an area where there is evidence that hostile forces possess the toxin. In instances like this, the proportion of the military that is deployed to areas of risk may be a candidate for vaccination. Current events in the Middle East can be taken as a case in point, and it is one that illustrates some key facts. In times of conflict, and even when biological warfare may be a concern, there has never been universal vaccination within the military. For those forces that have been deployed and may have been candidates for vaccination, the average length of deployment is less than 36 months. This duration of deployment is not a strong argument for long-term or lifelong immunity.

A reasonable assessment of the risk of disease, the likely duration of risk, and the likely numbers of persons at risk, does not justify the need for a vaccine that has a lengthy duration of action. A more thoughtful assessment is that the true need is for a vaccine that: (a) evokes a substantial immune response, (b) has a limited duration of action, and (c) can be easily administered, or re-administered, for episodic use.

From the Perspective of a Therapeutic Agent

The absence of justification for a long-acting vaccine is not the same thing as the presence of justification for a short-acting vaccine. Therefore, it is appropriate to ask whether an argument can be mounted that favors actively seeking a vaccine with a limited duration of action. Among those in the botulinum toxin field, such an argument is both well known and widely accepted.

In addition to being an agent that can cause disease, botulinum toxin is also an agent that can relieve disease (Comella et al., 2005). The toxin was first introduced for neuroophthalmologic disorders in which there is excessive and involuntary activity in efferent nerves ("dystonia"). The toxin has since been tested in a truly remarkable array of disorders, ranging from

achalasia to migraine headaches to bladder dysfunction. For many patients who have these disorders, botulinum toxin is the only agent that provides a reasonable measure of relief.

For most of the disorders in which it is used as a medication, the toxin has an underlying mechanism of action that is similar to that described earlier. The toxin acts on target nerve endings to block exocytosis. The therapeutic goal of blocking transmitter release is achieved by injecting toxin locally into the vicinity of overactive nerves. Ideally, the toxin binds and enters nerve endings rather than diffusing away. However, there are patients who receive relatively large doses and/or frequent injections, and a fraction of this toxin does diffuse away, sometimes to evoke a systemic immune response. In essence, this is an unintended form of vaccination.

Clinical experience with patients receiving the toxin for its therapeutic benefit makes clear that an immune response can mitigate a therapeutic response. By extension, one can surmise that patients who are intentionally vaccinated would no longer enjoy the medicinal value of the toxin. Therein lies a quandary. Vaccines would be helpful in the context of bioterrorism or biological warfare, but there has never been an incident that has produced significant morbidity and mortality among any segment of the population. By contrast, vaccines would be detrimental to patients who need the toxin as a therapeutic agent, and the number of such patients among the civilian and military population is steadily growing. Furthermore, the disorders for which the toxin can be beneficial tend to be lengthy or lifelong in duration.

One can easily deduce how an imprudent vaccine policy could have unfortunate consequences. If a significant segment of the population were to receive a long-acting vaccine, sooner or later some fraction of this population would develop disorders for which botulinum toxin would ordinarily be administered therapeutically. These patients would be resistant to the toxin, and therefore unable to obtain satisfactory medical treatment. This creates a troubling risk-to-benefit analysis. One must gauge whether the potential benefit of vaccinating any given population against a biothreat can outweigh the authentic risk of depriving some in this population of a proven medicinal agent.

There is no way to know in advance which members of the population may face incidents of bioterrorism and biological warfare, or to know which will develop dystonia or related disorders. This means that any approach to dealing with the quandary will be less than satisfactory. Nevertheless, there are ways in which one could approach this matter thoughtfully. Vaccines that are intended as medical countermeasures against bioterrorism or biological warfare with botulinum toxin should possess two properties. First, the antigen, the formulation, and the route of administration should be designed in a way that is intended to achieve a robust magnitude but limited duration of action. A duration of immunity of 10 years, as is seen with the tetanus vaccine, is too long. Something closer to one-quarter or one-third of this may be more rational. Secondly, a booster should be designed that is so easy to dispense that re-establishing immunity for those who require long-term resistance could be easily achieved. An oral formulation might be exactly the right thing for this purpose.

LINKING THEORY AND REALITY

The goal of this review is to extract from the basic science and clinical science literature those findings that could be most helpful in terms of designing an ideal vaccination paradigm. The expectation is not that an ideal paradigm has already been determined. To the contrary, the expectation is that a careful survey of the literature will help to clarify the distance between current vaccine procedures and a putative ideal procedure.

Perhaps the most instructive way to proceed is to propose three broad conclusions that reflect the current state of the literature. These conclusions relate to selection of an antigen, selection of a route of administration, and determination of an acceptable duration of action. In addition, these conclusions embody, either directly or indirectly, all of the implications for vaccine development that were enumerated earlier in this review.

1. The vaccine candidate that has drawn greatest attention as a possible antigen is the HC_C domain of botulinum toxin. This polypeptide may not be the best possible candidate one can envision. However, efforts to improve upon it may approach the realm of diminishing returns.
2. The routes of administration that have been the focus of most research are intramuscular and subcutaneous injection. Clearly, this is not ideal. Other routes of administration are superior, both in practical terms and in clinical terms.
3. The duration of vaccine action that has been sought, at least implicitly, is one that is lengthy and may approximate that of the tetanus vaccine. Once again, this is not ideal. Although the concept of seeking a vaccine with a limited duration of action may seem counter-intuitive, there are compelling reasons to pursue this course of action.

An examination of the literature on the structure of the botulinum toxin molecule, as well as the history and clinical presentation of the disease botulism, provides ample evidence to support these three conclusions. This examination also suggests that there are rational ways in which investigators can translate the first and second conclusions into authentic vaccine candidates. Additional information will be needed to translate the third conclusion into practice.

Selection of Antigen

There are relatively sound bases for identifying vaccine candidates that would be desirable, those that would be of questionable value, and those that are not worth pursuing. Beginning with the latter, there is no obvious reason to pursue an attenuated vaccine. Although it is true that most cases of naturally occurring botulism are due to primary infection, the actual number of cases is so small that there is no impetus to develop a vaccine against the organism. In addition, primary intoxication is far more likely than primary infection to be the mode of any acts of bioterrorism or biological warfare, so again there is little impetus for seeking an attenuated vaccine.

In the category of vaccines that are of questionable value, perhaps the most obvious example would be the one aimed at auxiliary proteins in the progenitor toxin complex. Vaccination with these polypeptides has not yielded an efficacy equivalent to that which is customary with vaccines directed against the neurotoxin or its subunits (Mahmut et al., 2002). This is unfortunate because there appears to be conceptual merit to this approach. If the progenitor complex remains intact in the stomach and intestine, then one would expect a secretory IgA response to produce at least one antibody clone that could attach to the complex and block its absorption. A phenomenon such as this would produce the most desirable form of resistance—blockade of toxin entry into the general circulation—and it would have a substantial secondary benefit. An immune response directed against auxiliary proteins would not abolish the therapeutic potential of botulinum toxin. The importance of this secondary benefit suggests that a renewed effort to assess mucosal immunity against auxiliary proteins may be in order.

In the category of vaccines that are desirable, the neurotoxin itself is the prime candidate. The only question is whether to use the holotoxin (viz., mutated holotoxin that does not express catalytic activity) or a polypeptide domain (viz., truncation mutant). The principal argument in favor of the holotoxin is that it possesses all the epitopes. However, it should be noted that the toxin has a large number of epitopes, and most of these are in one domain (HC_C). The number of epitopes in this polypeptide (ca. 20) is so large that a robust, polyclonal antiserum is virtually assured. It would, of course, be possible to use a larger polypeptide, but it is not clear that the presence of additional epitopes would lead to an increase in resistance that could be measured in clinical terms. This conclusion is based on the observation that antibodies directed against the HC_C domain provide all three of the major categories of resistance (i.e., blockade of absorption, enhanced clearance from the circulation, and inhibition of neuronal binding; Ravichandran et al., 2007).

For any given HC_C domain, there is a requirement that it elicit immunity against all subtypes relevant to that domain. For example, the serotype A HC_C should evoke immunity against all known subtypes of A. Little work has been done to assess cross-neutralization within subtypes, so it is too early to know whether this expectation will always be realistic (Baldwin et al., 2005; Smith et al., 2005).

Another issue relates to multivalency. An ideal vaccine candidate would evoke immunity to the seven serotypes, but a more pressing need is for a vaccine that will confer resistance against the three serotypes most commonly implicated in human illness (A, B, and E). A trivalent vaccine could arise from the admixture of three monovalent vaccines. Alternatively, it may be desirable to explore a single chimeric antigen that is the fusion product of multiple HC_C domains.

One final matter relates to the actual nature of the vaccine. Stated as a question, should the preferred embodiment be a polypeptide vaccine or a nucleic acid vaccine? The literature on botulinum toxin vaccines is not sufficient to support strong conclusions, although some investigators may be tempted to extrapolate from the literature on other vaccines. This sort of extrapolation could be misleading or even wrong. One must recall that there is a relatively unique feature of a rational botulinum toxin vaccine. The ideal candidate should evoke strong immunity, but of a limited duration. Unless and until polypeptide vaccines and nucleic acid vaccines against botulinum toxin are compared in all meaningful ways, including duration of action, the effort to anoint one or the other is premature.

Choosing a Route of Administration

The preponderance of research on botulinum toxin vaccines has focused on intramuscular or subcutaneous administration. In other words, research in this field has been much the same as that for most other vaccines.

However, there are sound reasons to abandon the convenience of the status quo. Three of these arguments are especially compelling.

The Modern Era of Vaccine Development

Major healthcare entities that have a stake in vaccine development are virtually unanimous in their advocacy that most injection vaccines should be abandoned in favor of noninjection ("needle-free") vaccines. The reasons cited for this are numerous, with the more prominent being that needle-free vaccines: (a) reduce the need for, and thus the cost of, healthcare personnel; (b) eliminate the possibility of accidental needle sticks, and thus the prospect for accidental transmission of blood-borne diseases; (c) reduce the need to store, monitor, and dispose off needle-related medical waste; and (d) eliminate the possibility of needle-related environmental contamination. There is no reason why a botulinum toxin vaccine should be exempt from these considerations.

Rational Vaccine Design

If a bioterrorism or biowarfare incident were to occur, it would likely involve oral or inhalation exposure. One of the first steps in botulinum toxin action is association with receptors on the apical surface of gut and airway epithelial cells. This is an essential prelude to toxin absorption.

The fact that the toxin must bind and be transported across epithelial barriers makes clear that a needle-free (viz., mucosal) vaccine would be superior to an injection vaccine. The former has the potential to evoke a secretory IgA response that could greatly diminish or even abolish absorption of toxin. If an oral or inhalation formulation could evoke not only a local IgA response but also a circulating IgG response, then the superiority of the needle-free vaccine over the injection vaccine would be beyond dispute.

Logistic Responses to a Biothreat Agent

If the need should ever arise to vaccinate large numbers of the civilian and/or military populations, the difficulty of having patients return for one or more booster injections can pose a logistic challenge. It would be far easier to dispense oral or inhalation formulations in the proper number of doses (viz., blister pack) to achieve the intended outcome.

Duration of Action

The reasons for seeking a vaccine with a limited duration of action have been presented in detail. In that earlier discussion it was not possible to cite a body of work on botulism vaccines that addresses the issue of duration because no such body of work exists.

When one considers the issue of duration, there are two broad categories of concern: the immune system and the antigen. The goal here is to focus on antigen, in three senses: (a) as an agent to evoke initial immunization; (b) as an agent to extend effective immunization; and (c) as an agent that can evoke or extend unwanted immunization.

When evoking an immune response to botulinum toxin, the magnitude of that response and the duration of that response are influenced by the amount and frequency of antigen (and adjuvant) administration. To the extent that there is literature to support these relationships, it does not arise from the field of immunology. Instead, it is a by-product of observations on patients who have been treated with the toxin as a therapeutic agent. This patient literature also contains the finding that, within a finite amount of time, immunity to the toxin wanes.

There is now a need for investigators who are interested in vaccine development to revisit the concept of "optimization." Rather than seeking formulations and dosing regimens that maximize the duration of an initial immunization, the aim should be to produce a robust response of limited duration. This aim is tightly linked to the concept of extending immunization. A vaccination regimen that evokes a limited response will be more acceptable, especially to those who need long-term protection, if there is a simple approach to extending duration. If, for example, there were an oral booster, this would carry two significant benefits. In mechanistic terms, it could evoke mucosal immunity that would serve as a barrier to toxin absorption. In patient compliance terms, it would afford a simple and painless way to extend immunity.

Finally, there is the issue of immunization as an iatrogenic problem. The unintended evoking of immunity as a byproduct of toxin therapy is well documented. The unintended boosting of an earlier and intentional vaccination has not been described, but this may simply be a reflection of the relatively small number of persons in whom such a problem could emerge. If this population were to be significantly larger—which could occur if there were an authentic bioterrorist incident—the prospects for iatrogenic boosting would increase.

To conclude on a positive note, the potential for iatrogenic boosting of an immune response may be diminishing at this very point in time. Botulinum toxin that is given as a therapeutic agent has historically been an impure preparation. The toxin has been administered with auxiliary proteins that are presumed to have an adjuvant-like effect, and there are other proteins that are also present. In the recent past, clinical trials have been initiated with neurotoxin preparations that have fewer impurities, and initial indications are that this material is less likely to evoke unwanted immunity (Jankovic et al., 2003). Thus, local administration of small amounts of pure toxin for therapeutic purposes may have diminished ability to evoke immunity or to boost prior immunity.

KEY ISSUES

- Botulinum toxin, which is produced by the organisms *C. botulinum*, *C. beratii*, and *C. butyricum*, is the agent that causes the disease botulism.
- Naturally occurring botulism is relatively rare, and it does not warrant widespread administration of a vaccine.
- Botulism that results from acts of bioterrorism or biological warfare could affect significant numbers of people. Therefore, a vaccine may be needed to protect vulnerable populations.
- Botulinum toxin is also a therapeutic agent that is used in a wide array of clinical disorders, some of which can be debilitating.
- A vaccine against botulism would protect patients against bioterrorism and biological warfare caused by the toxin, but it would also deprive patients of the therapeutic benefits provided by the toxin.
- There currently exists an experimental vaccine that was generated by formalin inactivation of a bacterial preparation enriched in toxin.
- Efforts are underway to develop a new generation of vaccines that utilize nontoxic recombinant polypeptides derived from the toxin.
- An ideal recombinant vaccine would be one that can be administered by the oral or inhalation route.
- A mucosal vaccine should evoke antibodies that provide at least three layers of protection: (a) in the lumen of the airway or gut to block toxin absorption, (b) in the general circulation to enhance clearance, and (c) at nerve endings to block toxin binding.
- Various recombinant polypeptides are being evaluated as potential vaccines, but none has yet been approved by the Food and Drug Administration.

Ehrlichia

Jere W. McBride
Departments of Pathology and Microbiology and Immunology, Institute for Human Infections and Immunity, Center for Biodefense and Emerging Infectious Diseases, Sealy Center for Vaccine Development, University of Texas Medical Branch, Galveston, TX, USA

OUTLINE

ABSTRACT

Ehrlichiae are small, obligately intracellular, gram-negative, tick-transmitted bacteria responsible for life-threatening emerging human zoonoses and diseases of veterinary importance, and one species is recognized as a significant agricultural biothreat. Organisms in the genus *Ehrlichia* were first described in the early 20th century, and the contemporary genus *Ehrlichia* consists of six named species that have regional or global distribution. The emergence of *Ehrlichia chaffeensis* and *Ehrlichia ewingii* as human pathogens is attributed to a combination of ecologic and demographic factors that have converged to establish these new human zoonoses in North America. Conversely,

Ehrlichia ruminantium, an established pathogen of agricultural importance, is confined to Africa and a few eastern Caribbean islands, causes high mortality in ruminants, and can be efficiently transmitted by *Ambloymma* vectors native to North America. Thus, *E. ruminantium* is considered a potential agricultural biothreat to the United States agricultural industry.

Ehrlichiae have small genomes but have evolved complex mechanisms that allow intracellular survival in arthropod hosts and persistent infections in vertebrate hosts, by evading the innate and adaptive immune responses. Ehrlichiae enter the host cell by receptor-mediated endocytosis that requires cellular signaling events and calcium influx. They reside in cytoplasmic vacuoles that do not fuse with lysosomes, and they alter transcription of host cell genes involved in apoptosis, cell cyclins, membrane trafficking, and various cytokines, by inhibiting MAK phosphorylation and potentially by translocation of ehrlichial proteins to the host cell nucleus that modulate gene expression. Ehrlichiae have a small group of major immunoreactive proteins that include multigene families of paralogous proteins potentially involved in immune evasion and serine/threonine-rich proteins with tandem repeats that elicit vigorous antibody responses. Ehrlichiae elicit an innate immune response dominated by inflammatory chemokines, but the pattern recognition receptors and pathogen-associated molecular patterns involved in innate immune recognition are unknown. Natural killer cells play a role in innate immune recognition of ehrlichiae, and antibodies and cell-mediated immune responses both play a role in ehrlichial clearance. The pathophysiology of the disease appears to involve overproduction of cytokines associated with toxic shock by cytotoxic T cells.

Live, attenuated, killed, nucleic acid, and recombinant vaccines have been developed against *Ehrlichia* spp. However, development of new-generation vaccines that are effective and practical will be facilitated by the availability of the genome sequence of several ehrlichial pathogens, recent characterization of many of the major immunoreactive proteins and pathogenic mechanisms, and a more comprehensive understanding of protective and pathologic immune mechanisms.

INTRODUCTION

Ehrlichioses were once considered diseases only of veterinary importance, but the first recognized human infection with the obligately intracellular bacterium, *Ehrlichia chaffeensis*, in 1986 signaled the emergence of *Ehrlichia* species as zoonotic pathogens (Maeda et al., 1987). Subsequently in 1999, *Ehrlichia ewingii*, a veterinary pathogen associated with granulocytic ehrlichiosis in dogs was molecularly identified in four patients from Missouri presenting with fever, headache, and thrombocytopenia (Buller et al., 1999). By the end of the 20th century, human monocytotropic ehrlichiosis (HME) and ehrlichiosis ewingii were established as tick-transmitted zoonoses caused by *E. chaffeensis* and *E. ewingii*, respectively. Demographic and ecologic factors have contributed to the emergence of human ehrlichioses, and these factors in addition to increased surveillance and diagnostic capability are likely to result in increasing incidence of HME in the future. *E. chaffeensis* is now recognized as a prototypical emerging pathogen, and HME is the most prevalent life-threatening tick-transmitted infectious disease in North America (Paddock and Childs, 2003).

The veterinary pathogen *Ehrlichia ruminantium* (previously known as *Cowdria ruminantium*) causes severe production losses to livestock in Africa and is considered an agricultural biothreat for the United States mainland, and *Ehrlichia canis*, the first ehrichial agent identified in North America, is the primary etiologic agent of canine monocytic ehrlichiosis (CME) and the only globally distributed ehrlichial agent. Progress towards the molecular characterization of these difficult-to-cultivate agents, development of animal models, and understanding of protective and pathologic host immune responses is facilitating the development of vaccines for emerging human ehrlichioses and established veterinary ehrlichioses.

HISTORY OF EHRLICHIAL DISEASES

Ehrlichiae were initially recognized in the 1920s and 1930s in Africa as agents of veterinary importance, when Cowdry (1925) identified *Rickettsia ruminantium* (now known as *E. ruminantium*) as the etiologic agent of heartwater, a highly fatal disease affecting ruminants (Cowdry, 1925). Heartwater was recognized in South Africa as early as 1860, which coincided with the appearance of the vector *Amblyomma hebraeum* in the region (Cowdry, 1925). Subsequently, Donatien and Lestoquard (1935) described a rickettsia-like agent *Rickettsia canis* (now known as *E. canis*) in the monocytes of Algerian dogs. Ehrlichial diseases remained in relative obscurity until the early 1960s when *E. canis* was first described in the United States by the academic veterinarian Sidney Ewing (1963), and was later attributed to epizootic outbreaks of canine tropical pancytopenia (CTP) (Wilkins et al., 1967; Huxsoll et al., 1969, 1972) afflicting British and American military dogs (sentry and scout dogs) in southeast Asia by veterinary pathologist, David Huxsoll. CTP ultimately caused a substantial number of deaths

(19%) in United States military canine units between 1963 and 1970 (Wilkins et al., 1967; Kelch, 1984). CME is now recognized as a prevalent and the only globally distributed ehrlichial disease.

In April 1986, a critically ill 51-year-old man with history of a tick bite was admitted to a Detroit hospital with acute symptoms that included fever, malaise, myalgia, and headache following a trip to Arkansas 3 weeks earlier (Maeda et al., 1987). The agent responsible for his illness was presumptively identified as *E. canis* based on morphologic study of the patient's leukocytes and serologic tests, and the patient recovered after doxycycline treatment and 12 weeks of hospitalization. A few years later, in 1990, an ehrlichial agent was isolated from an ill 21-year-old army reservist at Fort Chaffee, Arkansas. Molecular characterization of this agent revealed a new *Ehrlichia* sp., and was subsequently named *E. chaffeensis* in 1991 (Anderson et al., 1991; Dawson et al., 1991). *E. chaffeensis* is now recognized as an emerging human pathogen of public health importance, and HME is considered one of the most prevalent tick-transmitted diseases in the United States. HME, however, was not the only ehrlichiosis to emerge in humans. In 1999, 12 years after the first recognized case of HME was reported, four patients from Missouri were confirmed by molecular methods to have infections with *E. ewingii*, a pathogen previously considered to be only of veterinary importance as the cause of canine granulocytic ehrlichiosis (CGE) (Buller et al., 1999). This emerging human ehrlichiosis, referred to as ehrlichiosis ewingii, manifests primarily in immunocompromised individuals, and thus, appears to be an opportunistic infection in humans.

ETIOLOGIC AGENTS

Recently, the members of the genus *Ehrlichia* were reclassified using contemporary molecular methods, which have determined that previous criteria used for taxonomy (primarily morphology and intracellular existence) had resulted in incorrect genetic relationships of numerous organisms in several genera containing obligately intracellular bacteria. Hence, a new molecularly based taxonomy of the genus *Ehrlichia* using two highly conserved genes, *rrs* (16S ribosomal RNA genes) and *groESL* (Dumler et al., 2001), has resulted in an amended and now smaller *Ehrlichia* genus consisting of five members (*E. canis*, *E. chaffeensis*, *E. muris*, *E. ruminantium*, and *E. ewingii*) following the reassignment of six previously recognized members to the genera, *Anaplasma* (*E. phagocytophila*, *E. equi*, *E. platys*, and *E. bovis*) and *Neorickettsia* (*E. sennetsu* and *E. risticii*), and acquisition of one new member from the genus *Cowdria* (*C. ruminantium*). *E. chaffeensis* and *E. ewingii* are recognized as human pathogens as well as pathogens of veterinary importance that include *E. canis* and *E. ruminantium* (Table 47.1). The genus *Ehrlichia* is now part of a newly created family *Anaplasmataceae*, which also includes the genera *Anaplasma*, *Wolbachia*, and *Neorickettsia*, but remains in the order *Rickettsiales*.

Ehrlichiae are coccoid and coccobacillary and exhibit two morphologic cell types, reticulate (0.4–0.6 μm by 0.7–1.9 μm) and dense-cored (0.4–0.6 μm in diameter) (Fig. 47.1A–C), and typically reside as microcolonies of bacteria in cytoplasmic vacuoles derived from early endosomes in immature and mature hemopoietic cells (monocytes/macrophages and neutrophils) and endothelial cells (Barnewall et al., 1997). Morulae appear as dark blue to purple intracytoplasmic inclusions by light microscopy using Romanovsky-type stains (Rikihisa, 1991) (Figs 47.1 and 47.2). Examination of infected cells by electron microscopy demonstrates that in each cell numerous (1 to >400) morulae (1.0–6.0 μm) are usually present and contain as few as one, but more often numerous ehrichiae (>40). Both forms have a gram-negative cell wall structure,

TABLE 47.1 Summary of medically important ehrlichiae, vectors, natural hosts, and distribution

Agent	Vector	Natural host(s)	Disease	Distribution
E. chaffeensis	*A. americanum*, *D. variabilus*	White-tailed deer, canines	Human monocytotropic ehrlichiosis (HME), canine monocytic ehrlichiosis (CME)	Southeastern, south-central United States
E. ewingii	*A. americanum* *D. variabilus*	Canines	Ehrlichiosis ewingii, canine granulocytic ehrlichiosis (CGE)	Southeastern, south-central United States
E. canis	*R. sanguineus*	Canines	CME	Worldwide
E. ruminantium	*A. haebreum*	Ruminants	Heartwater	Sub-Saharan Africa; Caribbean

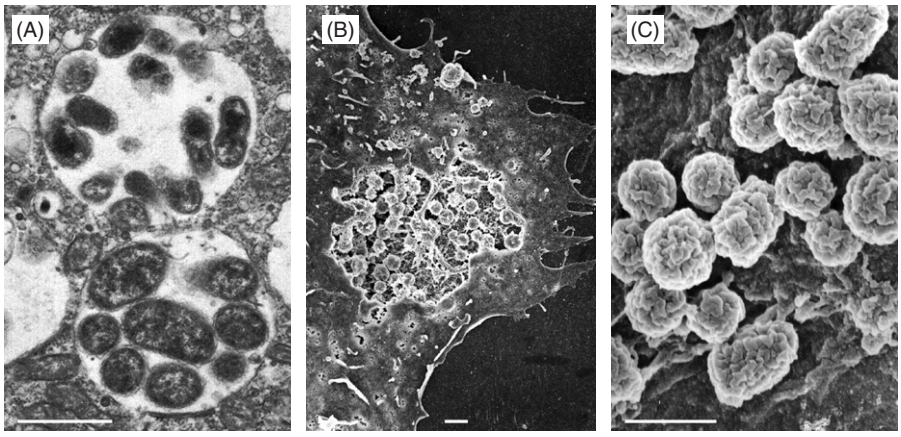

FIGURE 47.1 (Panel A) *Ehrlichia chaffeensis* dense-cored (top) and reticulate cell (bottom) morphologic types; (Panel B) scanning electron micrograph (SEM) of *E. chaffeensis* infected macrophage showing ehrlichial organisms within the cell; and (Panel C) SEM of *E. chaffeensis* attached to the surface of the macrophage prior to entry (Bars = 1μm; reproduced with permission of V. L. Popov, University of Texas Medical Branch).

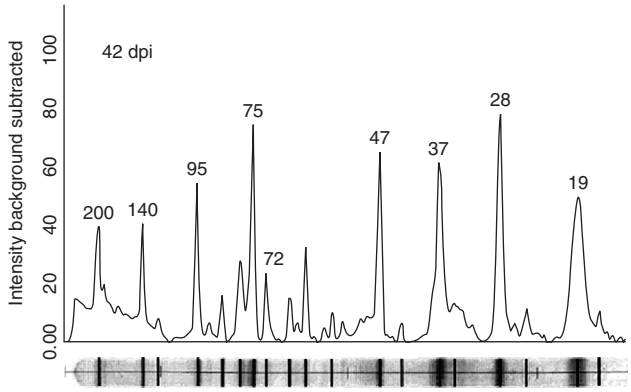

FIGURE 47.2 *Ehrlichia canis* major immunoreactive proteins as determined by Western immunoblotting of convalescent serum from an infected dog. Peak intensity and average relative quantity were used to identify major immunoreactive proteins. Molecular masses of proteins represented are labeled above each peak (Copyright permission ASM Press, McBride et al., 2003).

characterized by a cytoplasmic membrane and outer membrane separated by a periplasmic space, but do not appear to have peptidoglycan. Reticulate cells are pleomorphic and have uniformly dispersed nucleoid filaments and ribosomes, and dense-cored cells are typically coccoid and have centrally condensed nucleoid filaments and ribosomes (Popov et al., 1995, 1998). Small and large morulae containing both reticulate and dense-cored cells or exclusively containing dense-cored cells usually in loosely packed clusters can be observed within a single infected cell (Popov et al., 1995, 1998). The intramorular space in some morulae contains a fibrillar matrix of ehrlichial origin (Popov et al., 1995).

This chapter focuses on the agents of two emerging human ehrlichioses, *E. chaffeensis* and *E. ewingii*, a veterinary pathogen, *E. ruminantium* (heartwater), considered to be a potential agricultural biothreat to the United States, and *E. canis*, a globally distributed ehrlichial agent of dogs. Vaccine development for the ehrlichioses is being fueled by the commercial interest in vaccines for CME (*E. canis*) and heartwater (*E. ruminantium*).

E. chaffeensis

E. chaffeensis is the etiologic agent of HME (Anderson et al., 1992), which is the most severe of the human ehrlichioses, and can also cause mild-to-severe disease in dogs (Dawson and Ewing, 1992; Breitschwerdt et al., 1998). *E. chaffeensis* exhibits tropism for monocytes/macrophages. Many (40–60%) *E. chaffeensis* infections of humans require hospitalization (Eng et al., 1990; Fishbein et al., 1994), and there is case fatality rate of 3% due to the difficulty in making an accurate diagnosis. *E. chaffeensis* is maintained in nature in a zoonotic cycle potentially involving many vertebrate species. However, the white-tailed deer appears to be the primary reservoir for *E. chaffeensis*, but dogs may also be a significant natural reservoir (Paddock and Childs, 2003). The primary vector is the lone star tick, *Amblyomma americanum*, which is distributed from west central Texas throughout the southeastern, south-central, and mid-Atlantic states (Paddock and Childs, 2003; Childs and Paddock, 2003). Larval ticks become infected with *E. chaffeensis* after feeding on an infected vertebrate hosts and maintain a transstadial infection. The emergence of *E. chaffeensis* appears to coincide with changes in demographic and ecologic factors including increases in vector and mammalian host populations and human contact with natural foci,

immunocompromised and aging human populations, and improved diagnosis and reporting (Paddock and Childs, 2003). *E. chaffeensis* can be cultivated in vitro in various mammalian and tick cell lines (Dawson et al., 1991), but causes only transient subclinical infection in immunocompetent mice without any pathology (Winslow et al., 1998).

E. ewingii

Human granulocytic ehrlichiosis (ehrlichiosis ewingii) is caused by *E. ewingii* and is the most recently described emerging human ehrlichiosis (Buller et al., 1999). *E. ewingii* is also a veterinary pathogen first described in 1971 (Ewing et al., 1971), and causes infections with two distinct clinical syndromes, anemia and polyarthritis in dogs (Goldman et al., 1998). *E. ewingii* exhibits host cell tropism for granulocytes (neutrophils), and is transmitted by the lone star tick, *A. americanum* (Anziani et al., 1990). Dogs are likely to be the main reservoir for *E. ewingii*, with many of the documented human cases reporting contact with dogs before onset of symptoms (Buller et al., 1999). Most cases of ehrlichiosis ewingii are manifested in immunocompromised patients, and thus, *E. ewingii* appears to be an opportunistic pathogen (Buller et al., 1999; Paddock et al., 2001). There is some serologic cross reactivity between *E. chaffeensis* and *E. ewingii*, but this is directed at higher molecular weight antigens and not the major outer membrane protein (p28) (Buller et al., 1999). *E. ewingii* has not been cultivated in vitro; thus molecular studies of this agent have been limited.

E. ruminantium

E. ruminantium is strictly a veterinary pathogen that is found on the continent of Africa (sub-Saharan) and on a few eastern Caribbean islands after importation in the 1800s (Uilenberg, 1983). *E. ruminantium* infects the endothelium and causes severe acute infection in wild and domestic ruminants known as heartwater, which can result in high mortality (50–90%) (Uilenberg, 1983). *E. ruminantium* is responsible for major production losses to the African livestock industry, and is also considered to pose a potential danger to the southeastern United States where native competent tick vectors are present (Uilenberg, 1982; Barre et al., 1987a; Mahan et al., 2000) and climate is appropriate for introduction of exotic tick species capable of transmitting the disease (Burridge et al., 2000, 2002a, 2002b). In Africa, *E. ruminantium* is transmitted by *A. variegatum* and *A. hebraeum*, but other *Amblyomma* spp. ticks including two North American species, *A. maculatum* and *A. cajennense*, appear to have similar transmission efficiency (Mahan et al., 2000). *E. ruminantium* can be cultivated in vitro in bovine endothelial cell lines and tick cells (Bezuidenhout et al., 1985; Bell-Sakyi et al., 2000), and various strains of mice can be infected with *E. ruminantium* (du Plessis et al., 1991; Byrom et al., 2000b).

E. canis

E. canis is the type species for the genus *Ehrlichia* and is the primary etiologic agent of CME, a serious and sometimes fatal, globally distributed disease of dogs (Keefe et al., 1982). *E. canis* is transmitted by the brown dog tick, *Rhipicephalus sanguineus* (Groves et al., 1975), and infects monocytes/macrophages in dogs. In the United States, *E. canis* was initially described in dogs in 1963 (Ewing, 1963), but received more attention after *E. canis* was identified as the agent responsible for outbreaks of an idiopathic hemorrhagic disease called tropical canine pancyopenia in American and British military dog units on duty in southeast Asia (Wilkins et al., 1967; Huxsoll et al., 1969; Seamer and Snape, 1970). Human infections with *E. canis* have been reported in Venezuela (Perez et al., 1996, 2006). The clinical manifestations of acute infection with *E. canis* are similar to those observed in humans infected with *E. chaffeensis. E. canis* can be propagated in numerous mammalian cell lines in vitro and acute *E. canis* infections in dogs are a useful comparative model for HME.

Genetic, Antigenic, and Phenotypic Characteristics

The genomes of *E. chaffeensis*, *E. canis*, and *E. ruminantium* are relatively small (1.2, 1.3, and 1.5 Mbp, respectively) and contain approximately 900 protein-encoding genes with an average G + C content of 27–29% (Collins et al., 2005; Mavromatis et al., 2006). These genomes have a substantially lower than average ratio of coding to noncoding sequence (62–72% coding) and contain pseudogenes (17–32) (Collins et al., 2005; Mavromatis et al., 2006). The genomes of these ehrlichiae reveal a high degree of genomic synteny, gene duplications, tandem repeats, proteins with ankyrin domains, a large group of secreted proteins with transmembrane helicies suggestive of a complex membrane structure and protein families that may be involved in immune evasion (Collins et al., 2005; Mavromatis et al., 2006). Comparison of three sequenced *E. ruminantium* genomes suggests active

expansion and contraction of these genomes through addition or deletion of tandem repeats in noncoding regions (Frutos et al., 2006).

Ehrlichia are unable to utilize glucose as a carbon or energy source because they lack essential genes for the glycolytic pathway, ATP/ADP translocases are absent, and they lack genes for the biosynthesis of lipopolysaccharide and peptidoglycan, but have complete pathways for the synthesis of purines and pyrimidines, genes for enzymes involved in aerobic respiration, possess a limited set of genes involved in synthesis of lipids and phospholipids and have tRNAs for all amino acids (Collins et al., 2005; Mavromatis et al., 2006). *E. ewingii* has not been cultivated in vitro, and very little genomic and molecular characterization of this agent has been accomplished.

Prior to genome sequence information, many genes were molecularly characterized in *E. chaffeensis*, *E. canis*, and *E. ruminantium*, including functionally conserved genes, *rrs*, *rrl*, *rrf* (16S, 23S, and 5S rRNA, respectively) (Anderson et al., 1991; Allsopp et al., 1997; Massung et al., 2002), *groEL* and *groESL* (Sumner et al., 1993, 1997; Lally et al., 1995), thio-disulfide oxidoreductase (*dsb*) (Barbet et al., 2001; McBride et al., 2002), ferric-ion binding protein (*fbp*) (Yu et al., 1999a; Doyle et al., 2005), quinolate synthetase A (*nadA*) (Yu and Walker, 1997), citrate synthase (*gltA*) (Inokuma et al., 2001), and a *virB* operon (type IV secretion machinery) (Ohashi et al., 2002). A small group of major immunoreactive proteins of *E. chaffeensis* and *E. canis* has been identified on the basis of immunoblot reactivity, but the functions of these proteins remain largely unknown (Fig. 47.2). Major immunoreactive *E. chaffeensis* proteins are 200, 120, 88, 55, 47, 40, 28, and 23 kDa (Rikihisa et al., 1994; Chen et al., 1994); *E. canis*, 200, 140, 95, 75, 47, 36, 28, and 19 kDa (McBride et al., 2003a, 2003b); and *E. ruminantium*, 160, 85, 58, 46, 40, 32, and 21 kDa (Mahan et al., 1994a). *E. chaffeensis* immunoreactive proteins (gp200, gp120, gp47, p32 [VLPT], p28s [22 genes], and MAP2) have been molecularly characterized as well as the corresponding orthologs in *E. canis* (gp200, gp140, gp36, gp19 [VLPT], p28s [25 genes], and MAP2, respectively). Fewer of these orthologs have been molecularly identified and characterized in *E. ruminantium* (MAP1 [16 genes], MAP2, and mucin-like protein [clone hw26; gp36/47 ortholog]) (Jongejan and Thielemans, 1989; Mahan et al., 1994a; Sulsona et al., 1999), but additional immunoreactive genes have been identified in *E. ruminantium* (Barbet et al., 2001) that have not been described in *E. chaffeensis* or *E. canis.* Immunoreactivity of the *E. chaffeensis* and *E. canis* MAP2 is primarily dependent on a major conformational epitope and does not react by Western immunoblot (Alleman et al., 2000; Knowles et al., 2003), while *E. ruminantium* MAP2 appears to have a linear B cell epitope (Mahan et al., 1994a).

Many of the major immunoreactive *E. chaffeensis* proteins (gp200, gp120, gp47, gp28) that have been identified and characterized, exhibit larger than predicted molecular mass and two (gp120 and gp47) have serine-rich tandem repeats (Yu et al., 1997; McBride et al., 2003; Doyle et al., 2006b). The VLPT protein of *E. chaffeensis* also exhibits a mass twice the predicted size and has characteristics (tandem repeats and serine-rich composition) found in other ehrlichial proteins (Sumner et al., 1999). Strain-dependent sequence polymorphisms have been demonstrated in the number (2–5) of serine/threonine-rich tandem repeats of gp120 (Yu et al., 1997; Chen et al., 1997b; Yabsley et al., 2003) and VLPT (3–6) (Sumner et al., 1999), and in genes encoding the p28 multigene family (Yu et al., 1999b; Reddy and Streck 2000). The observed molecular masses of these proteins vary depending on the number of repeat units (gp120, 80–130 kDa; VLPT, 35–55 kDa) (Chen et al., 1997a, 1997b; Sumner et al., 1999), and variation in sizes of other homologous proteins has been observed on Western immunoblots reacted with monoclonal antibodies (MAb, 7C1-C, and 7C1-B) (Chen et al., 1997b). Antigenic heterogeneity has also been demonstrated with MAb 1A9 specific for p28 proteins, which does not react with all *E. chaffeensis* isolates (Chen et al., 1997b).

The *E. chaffeensis* gp120 is a surface protein differentially expressed on dense-cored cells and is also a component of the fibrillar matrix found in some morulae. The gp120 of *E. chaffeensis* type strain (Arkansas) has four 240-bp repeats. Antibodies in sera from patients with HME recognize the gp120 regardless of the number of repeats (Yu et al., 1997, 1999a). The gp120 is highly reactive with antibodies in convalescent sera from patients with HME and may be useful as a diagnostic antigen (Yu et al., 1996, 1999a). Similarly, the *E. canis* gp140 ortholog is a highly immunoreactive glycoprotein that contains 14 identical 108-bp repeats that have a high serine content appear to contain a major epitope (Yu et al., 2000a). Unlike *E. chaffeensis* gp120, the *E. canis* gp140 is highly conserved in geographically dispersed North American isolates each having the same number of repeat units (Yu et al., 2000a).

The gp200 orthologs are the largest major immunoreactive protein identified in *E. chaffeensis* (1438 amino acids) and *E. canis* (1406 amino acids) by Western immunoblot and have predicted molecular mass of 156 and 153 kDa, respectively, but exhibit larger masses (~200 kDa) by gel electrophoresis (McBride et al., 2003; Nethery et al., 2007). Five major species-specific antibody epitopes have been identified in terminal acidic domains within the *E. canis* gp200

(Nethery et al., 2007). The *E. chaffeensis* and *E. canis* gp200s have eukaryote-like ankyrin repeats (21) that may mediate protein–protein interactions, exhibit chromosomal synteny, but are substantially divergent at the molecular level (nucleic and amino acid). Ankyrin repeats are also present in numerous eukaryotic and prokaryotic proteins including *A. phagocytophilum* AnkA (Caturegli et al., 2000). The gp200s are present primarily in the cytoplasm of ehrlichiae and in the nucleus (on condensed chromatin) of infected host cells where they may be involved in modulation of host cell gene expression (Nethery et al., 2005).

The *E. chaffeensis* gp47 and *E. canis* gp36 are protein orthologs that are differentially expressed on the surface of dense-cored cells and contain variable numbers of serine-rich repeats depending on the isolate (Doyle et al., 2006b) (Fig. 47.3). The tandem repeats (nine amino acids) of *E. canis* gp36 have a conserved amino acid sequence but can vary in number. In contrast, two completely divergent *E. chaffeensis* gp47 repeat units (19 and 33 amino acids) have been identified in different isolates and vary in number (Doyle et al., 2006a; Zhang et al., 2008). Carbohydrate has been detected on recombinant forms of these proteins, and the major epitope of the *E. canis* gp36 has been characterized in a two-repeat unit (18 amino acids) and in a single repeat (19 amino acids) in the *E. chaffeensis* gp47 (Doyle et al., 2006b). The gp47 and gp36 are secreted and observed in the fibrillar intramorular matrix and are released into the supernatant of infected cell cultures (Doyle et al., 2006b).

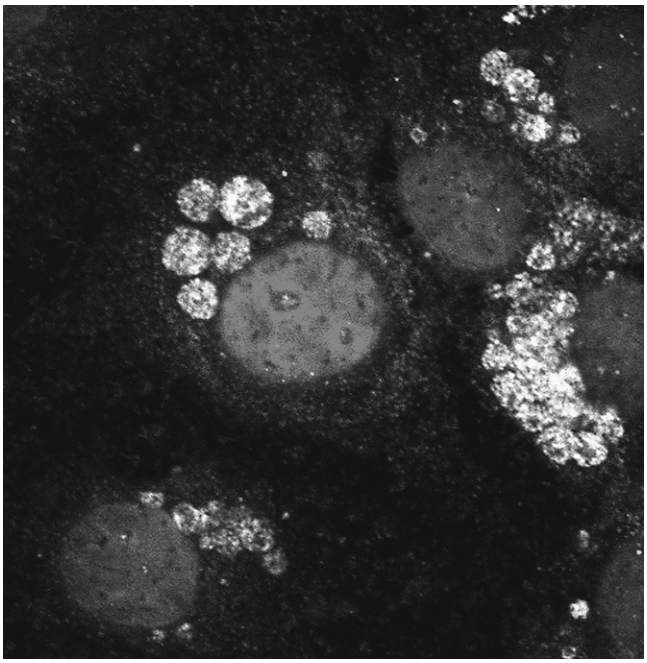

FIGURE 47.3 *E. chaffeensis* infected macrophages (DH82 cells) exhibiting differential expression of gp47 as visualized by three-color scanning laser confocal fluorescent microscopy. *E. chaffeensis* infected cells were dually stained with rabbit anti-*Ehrlichia* disulfide bond formation (Dsb) (green: Alexa Fluor 488), and mouse anti-*E. chaffeensis* gp47 (red: Alexa Fluor 568). Host cell nuclei were counterstained with 4′, 6′-diamidino-2-phenylindole, dihydrochloride (DAPI) and images merged. Infected macrophage (center) exhibits single (green: Dsb or red: gp47) and dual-labeled (yellow) ehrlichiae in individual morulae (reproduced with permission of J.W. McBride, University of Texas Medical Branch) (see color plate section).

The *E. chaffeensis* VLPT is an immunoreactive protein that has 3–6 imperfect 30-amino acid tandem repeats (Sumner et al., 1999; Luo et al., 2008) and has been used to determine genetic diversity of *E. chaffeensis* isolates based on the number of repeat units. The *E. chaffeensis* VLPT gene amplified from blood of infected patients most often contains five repeat units (Standaert et al., 2000). A nonrepeat containing 19 kDa ortholog of VLPT in *E. canis* (gp19) has been identified (McBride et al., 2006). The *E. canis* gp19 elicits an early antibody response, which is directed against a single major serine-rich glycopeptide epitope (25 amino acids) located in the N-terminal region of the protein. The role of this protein in ehrlichial pathobiology remains unknown.

Ehrlichia species have a homologous multigene family that encodes major outer membrane proteins. The *E. chaffeensis*, *E. canis*, and *E. ruminantium* p28 (MAP1 for *E. ruminantium*) multigene families consist of 22, 25, and 16 nonidentical paralogous genes, respectively, that encode mature surface-exposed major outer membrane proteins of 26–32 kDa with 20–80% amino acid sequence identity (Yu et al., 2000b; Ohashi et al., 2001; Collins et al., 2005). All are located in a single chromosomal locus, except in *E. canis* which has a primary locus with 22 genes and an additional three duplicated genes in a separate chromosomal locus. These proteins contain three hypervariable regions, and a major B cell epitope has been identified in the first hypervariable region within *E. chaffeensis* p28 proteins (Li et al., 2002). The homology of p28 proteins among *Ehrlichia* spp. accounts for some antigenic cross reactivity among these agents. The potential for antigenic diversity by differential expression of p28 genes exists, but simultaneous transcription of all p28 genes does occur in vitro and in *E. chaffeensis*-infected dogs after needle inoculation (Long et al., 2002; Unver et al., 2002; Zhang et al., 2004a). The expression of only one paralog (*omp-1B*) has been observed in ticks (Unver et al., 2002), but the p28 genes expressed in the mammalian host after tick inoculation are still unknown. The function of MAP2 is not known, but the protein is conserved (~83% amino acid identity) among *E. chaffeensis*, *E. canis*, and *E. ruminantium*, and sequence analysis of *E. ruminantium* isolates indicates that MAP2 is highly conserved in this species (Bowie et al., 1999).

IMMUNITY

Understanding the adaptive immune mechanisms involved in immunity to *Ehrlichia* has been slowed by resistance of inbred mice to infection with *E. chaffeensis* (Winslow et al., 1998). Conversely, *E. ruminantium*, *E. muris*, and *Ixodes ovatus* ehrlichia (IOE) infect a variety of inbred mouse strains, and important insights to protective innate and adaptive immune mechanisms to ehrlichiae have been provided using these agents in both natural infections and experimental animal models (du Plessis 1970; du Plessis and Kumm 1971; du Plessis et al., 1991; Mwangi et al., 1998a, 1998b, 2002; Byrom et al., 2000a, 2000b). It is becoming evident that both humoral and cellular immunity plays a role in host defense against ehrlichiae. The role of specific immune system elements in immunity to *E. chaffeensis* has been investigated with inbred mice deficient in various immune system components including major histocompatibility complex (MHC), toll-like receptors (TLRs), class II, FcγRI, and B cells, and mice with severe combined immunodeficiency (SCID). Immune mechanisms involved in immunity to *E. ruminantium* have been investigated with immunocompetent mice and in natural hosts (du Plessis, 1970; du Plessis et al., 1991; Byrom et al., 1993, 2000a, 2000b; Totte et al., 1997; Mwangi et al., 1998a, 1998b; Esteves et al., 2004b). All of these investigations utilizing natural infections, established murine models, and newly developed murine models have provided new insight that suggests roles for innate, cellular, and humoral immune mechanisms in the elimination of *Ehrlichia*.

Innate Immunity

Ehrlichial replication appears to be partially controlled by several innate antimicrobial mechanisms. Induction of nitric oxide production by *E. ruminantium* infected endothelial cells via inducible nitric oxide synthase, resulted in a reduction of *E. ruminantium* (Mutunga et al., 1998). Others have reported that mice depleted of complement or deficient for complement receptors (1 and 2) or phox 91 subunit of NADPH oxidase are also susceptible to infection with IOE (Yager et al., 2005), demonstrating the importance of these innate immune components. However, the innate immune response to *Ehrlichia* spp. appears to be driven by atypical pathogen-associated molecular patterns (PAMPs) and a newly recognized innate defense mechanism. *Ehrlichia* lack the genes required for synthesis of two common gram-negative bacterial cellular components, lipopolysaccharide (LPS) and peptidoglycan (PGN) (Lin and Rikihisa 2003a), well-characterized PAMPs recognized by the innate immune response through TLRs. The pattern recognition receptors involved in recognition of *E. chaffeensis* are not known, but *tlr4*-deficient mice have depressed nitric oxide and interleukin-6 production and have more prolonged infections with *E. chaffeensis* than wild-type mice (Ganta et al., 2002), suggesting a minimal role for TLR4 recognition. Others have reported downregulation or no induction of major pattern recognition receptor gene expression by THP-1 cells in response to *E. chaffeensis* (Lin and Rikihisa, 2004; Zhang et al., 2004b), suggesting potential evasion of conventional TLR-mediated innate immune response by ehrlichiae. However, monocytes incubated with live and killed *E. chaffeensis* respond with strong production of IL-8 and minimal production of IL-1β and IL-10, while expression of TNF-α and IL-6 are absent (Lee and Rikihisa, 1996), which suggest that other uncharacterized ehrlichial PAMPs interact with an undefined PRRs present on macrophages. More extensive analysis of cytokine/chemokine response to *E. chaffeensis* revealed a predominant chemokine response to viable and killed *E. chaffeensis* characterized by production of inflammatory chemokines including IL-8, MCP-1, MCP-2, MCP-4, MIP-1β, and RANTES, while in contrast the production of proinflammatory cytokines, including TNF-α, IL-1β, or IL-10, were not observed (McBride, unpublished). Induction of this innate chemokine response is linked to an *E. chaffeensis* carbohydrate component and is abrogated by periodate treatment (Lee and Rikihisa, 1996). The role of this innate immune response by macrophages in pathogenesis or immunity to *E. chaffeensis* is not clear. Other less-characterized innate responses appear to be involved in the clearance of ehrlichiae. Mattner et al. (2005) demonstrated that *Ehrlichia* activate innate-like natural killer T cells (NKT) that are known to recognize glycolipids presented by CD1d, a MHC-like molecule. Futhermore, NKT cell-deficient mice are unable to clear ehrlichial infection (Mattner et al., 2005), suggesting that NKT cells are important for innate immunity to *Ehrlichia* spp. and for generation of the adaptive immune response.

Cell-Mediated Immunity

Numerous studies with *E. ruminantium* suggest that IFN-γ is an essential mediator in protection (Totte et al., 1993, 1996; Mahan et al., 1994b, 1996; Mutunga et al., 1998). IFN-γ production by $CD4^+$ and $CD8^+$ T cells in a protective response to *E. ruminantium* has been demonstrated (Esteves et al., 2004a, 2004b). In addition, transfer of the combination of IOE-specific

polyclonal antibody and IFN-γ producing *Ehrlichia*-specific $CD4^+$ and $CD8^+$ type 1 cells protects naïve mice against lethal challenge (Ismail et al., 2004). A second study also concluded that resistance to sublethal IOE infection was dependent on $CD4^+$ T lymphocytes and required IFN-γ and TNF-α, but not IL-4 (Bitsaktsis et al., 2004). Taken together, these studies provide convincing evidence that classical cell-mediated immune mechanisms involving CD4 cells and type 1 cytokines are responsible for macrophage activation and elimination of *Ehrlichia.* Notably, similar conclusions regarding the importance of MHC class I, $CD4^+$, and $CD8^+$ T cells, the synergistic roles of IFN-γ and TNF-α, and the role of antibody have been reported in mice infected with *E. muris* (Feng and Walker, 2004). A more important role for $CD4^+$ T cells in immunity to *E. ruminanitum* has been suggested in studies using mice and cattle (Totte et al., 1997; Byrom et al., 2000a), and others have reported that γδ T cells contribute substantially to the IFN-γ response in cattle (Mwangi et al., 1998a). Similarly, mice lacking functional MHC class II genes are unable to clear *E. chaffeensis* following infection, suggesting that $CD4^+$ T cells are essential for ehrlichial clearance (Ganta et al., 2002). The roles of specific T cell subsets involved in cellular immunity to *E. chaffeensis* are not well defined.

Humoral Immunity

Humoral immunity appears to play a significant role in clearance of *E. chaffeensis.* Infection of SCID mice (B and T cell deficient) with *E. chaffeensis* results in an overwhelming infection, but passive transfer of anti-*E. chaffeensis* immune serum or MAbs directed against the first hypervariable domain of one (p28-19) of the p28 major outer membrane proteins before or during infection protects SCID mice from disease, but does not eliminate the organism (Winslow et al., 2000; Li et al., 2001, 2002). Futhermore, mice lacking B cells or FcγRI are unable to resolve a sublethal infection by IOE and passive transfer of antibodies in these mice resulted in significant reduction in bacterial load (Yager et al., 2005). Similarly, passive transfer of anti-*E. muris* antibodies, but not Fab fragments, protected mice against lethal infection (Feng and Walker, 2004). The specific anti-ehrlichial antibody-mediated mechanism is not fully understood, but appears to involve binding of antibody to the Fc receptor (Lee and Rikihisa, 1997; Yager et al., 2005) and subsequent generation of a proinflammatory cytokine response (Lee and Rikihisa, 1997) and exposure to oxidative defenses (Yager et al., 2005). Studies with *E. ruminantium* have suggested little role for antibody in immunity to *E. ruminantium*. In fact, the majority of studies suggest that antibodies provide no protection (du Plessis, 1970, 1984); however, one study has demonstrated the ability of antibodies to neutralize *E. ruminantium* in vitro (Byrom et al., 1993). Further studies with *E. ruminantium* are needed address inconsistencies in the role of antibodies in protection compared to that reported with other *Ehrlichia* spp.

PATHOGENESIS

Advances in understanding the molecular pathogenesis of ehrlichial diseases has been obtained primarily through studies with *E. chaffeensis*, *E. canis*, and closely related *E. muris* and IOE. Ehrlichial pathogenesis begins with injection of ehrlichiae by a feeding tick, hematogenous spread, and attachment to the target cell (monocyte/macrophage/neutrophil/endothelial cell), entry, and intracellular survival. Host cell receptors utilized by *E. chaffeensis* include, but are not limited to, E- and L-selectin, and binding of these receptors results in unconventional clathrin-independent receptor-mediated endocytosis (Barnewall et al., 1997; Zhang et al., 2003) involving caveolae and glycosylphosphatidylinositol-anchored proteins (Lin and Rikihisa, 2003b). Endocytosis of *E. chaffeensis* requires signaling events including protein crosslinking by transglutaminase, protein tyrosine phosphorylation, phospholipase C (PLC)-γ2 activation, and calcium influx (Lin et al., 2002). Following endocytosis, tyrosine phosphorylated proteins and PLC-γ2 colocalize with *E. chaffeensis* inclusions (Lin et al., 2002), suggesting their role in bacterial survival and proliferation in the macrophage. The unique endosomes containing *E. chaffeensis* express several early endosomal markers including an early endosomal antigen 1 (EEA1) and rab5, and do not fuse with lysosomes to form phagolysosomes (Barnewall et al., 1997; Mott et al., 1999), but colocalize with vesicle-associated membrane protein 2 (VAMP2), MHC class I and MHC class II molecules, β_2-microglobulin, and transferrin receptor (Barnewall et al., 1997, 1999; Mott et al., 1999). After entry, *E. chaffeensis* modulates the expression of various cytokines, TLRs, transcription factors, apoptosis inhibitors, cell cyclins, membrane trafficking proteins, and transferrin receptor gene expression in the macrophage (Barnewall et al., 1999; Lin and Rikihisa 2004; Zhang et al., 2004b). The inhibition of p38 MAPK by *E. chaffeensis* has been linked to the downregulation of transcription factor PU.1, which can also regulate the expression of TLRs and other genes (Lin and Rikihisa, 2004). Within 24 h of infection *E. chaffeensis* blocks tyrosine phosphorylation of Janus kinase (Jak) and

signal transducer and activator of transcription (Stat) signaling, inhibiting the anti-ehrlichial effect of IFN-γ (Lee and Rikihisa, 1998). *E. chaffeensis* has eight genes encoding type IV secretion machinery that may be associated with intracellular survival and replication by delivering effector macromolecules to the host cell and are transcribed in the blood of acutely ill patients (Ohashi et al., 2002). Some of these genes (*virB3*, *virB4*, and *virB6*) are downstream of superoxide dismutase B (*sodB*) and are cotranscribed with *sodB* through a *sodB* promoter (Ohashi et al., 2002). Iron plays a critical role in the survival of *E. chaffeensis* in the host cell, and iron acquisition mechanisms in *E. chaffeensis* appear to be evolutionarily divergent from those of other gram-negative bacteria (Doyle et al., 2005). A structurally and functionally conserved ferric-ion binding protein (Fbp) has been identified in *E. chaffeensis* and *E. canis* that binds Fe(III), but not Fe(II), and Fbp is preferentially expressed on the surface of dense-cored ehrlichiae and is secreted extracellularly (Doyle et al., 2005). The lack of iron availability prevents the survival of *E. chaffeensis*, which has been demonstrated with the intracellular iron chelator deferoxamine (Barnewall and Rikihisa, 1994). IFN-γ also appears to mediate killing of *E. chaffeensis* by downregulation of transferrin receptor, thus reducing the available labile cytoplasmic iron in human monocytes (Barnewall and Rikihisa, 1994). This anti-ehrlichial effect can be overcome by addition of iron-saturated transferrin, demonstrating the direct role for iron in ehrlichial survival. The role of the p28 multigene family in the pathogenesis of HME is unknown, but differential expression of p28 genes appears to occur in mammalian and tick hosts (Unver et al., 2002). *E. chaffeensis* demonstrates expression of 16 *p28* genes concurrently in vitro and in vivo (Long et al., 2002; Unver et al., 2002). These findings suggest that the p28s may play a role in ehrlichial adaptation in tick and mammalian hosts and are less likely to be involved in immune evasion by antigenic variation.

The relatively low bacterial burden in the blood and tissues in nonimmunocompromised patients with HME suggests that the pathophysiology of ehrlichiosis may involve immunopathologic responses that are manifest as a toxic shock-like syndrome (Maeda et al., 1987; Fichtenbaum et al., 1993). The first murine model of fatal human ehrlichiosis (Sotomayor et al., 2001) has been instrumental in understanding the mechanisms behind the toxic shock-like syndrome of severe and fatal human ehrlichiosis. This model has recently been used to investigate the immunologic mechanisms involved in the development of severe monocytotropic ehrlichiosis. Mice inoculated with an ehrlichia (IOE) closely related to *E. chaffeensis* develop histopathology resembling that observed in HME patients, and a similar disease course is observed in the IOE murine model. Lethal infections with IOE are accompanied by extremely high levels of serum TNF-α, a high frequency of TNF-α producing $CD8^+$ splenic T cells, decreased *Ehrlichia*-specific $CD4^+$ T lymphocyte proliferation, low IL-12 levels in the spleen, and a 40-fold decrease in the number of antigen-specific IFN-γ producing $CD4^+$ Th1 cells (Ismail et al., 2004). Furthermore, in mice lacking TNF receptor I/II were more resistant to IOE induced liver injury, but exhibited higher bacterial burdens (Ismail et al., 2006).

EPIDEMIOLOGY AND PUBLIC HEALTH IMPORTANCE

Many factors have contributed to the emergence of *E. chaffeensis* as a zoonotic pathogen in the United States including increased density of *A. americanum* ticks (Ginsberg et al., 1991), expanded vector geographic distribution (Means and White, 1997), and vertebrate host populations of the tick vector (Means and White, 1997), increase in reservoir host populations for *E. chaffeensis* (McCabe and McCabe, 1997), increased human contact with natural foci of infection through recreational and occupational activities (Tal and Shannahan, 1995; Standaert et al., 1995), increased size, longevity, and immunocompromised status of the human population (Palella et al., 1998; Paddock et al., 2001), and the availability of diagnostic reagents, and improved surveillance (McQuiston et al., 1999; Childs et al., 1999). The most important factor in the emergence of *E. ewingii* appears to be increased immunocompromised populations, because the infection has been observed primarily in human immunodeficiency virus (HIV)-infected individuals and patients on immunosuppressive therapies (Buller et al., 1999; Paddock et al., 2001).

HME is a seasonal disease with most reported cases occurring in the spring and summer months (peak incidence during May–July) (Fishbein et al., 1994; Standaert et al., 1995) and occurring primarily within the geographic range of the tick vector *A. americanum* that extends from west central Texas and east along the Gulf Coast, north through Oklahoma and Missouri, eastward to the Atlantic Coast, and proceeds northeast through New Jersey, encompassing all the south-central, southeastern, and mid-Atlantic states. Passive surveillance of HME underestimates the true incidence of disease due to inadequate clinical and laboratory diagnosis and reporting (McQuiston et al., 1999). Nevertheless, ehrlichiosis has similar

infection rates as those reported for Rocky Mountain spotted fever (Treadwell et al., 2000), with the highest incidence reported in Arkansas, North Carolina, Missouri, Oklahoma, and New Jersey (McQuiston et al., 1999). Active surveillance in HME-endemic locations including southeastern Georgia and southeastern Missouri indicates an incidence that could be 10–100 times higher than those reported by individual states by passive surveillance (Fishbein et al., 1989; Olano et al., 2003). HME is more often diagnosed in male (>2:1) patients >40 years of age, the majority (>80%) report a tick bite (Fishbein et al., 1994; Olano et al., 2003), and HME outbreaks are associated with recreational or occupational activities (Petersen et al., 1989; Standaert et al., 1995). *E. chaffeensis* has been found in 5–15% of *A. americanum* ticks collected from endemic areas in the eastern US (Whitlock et al., 2000; Ijdo et al., 2000; Stromdahl et al., 2001) and has been detected in ticks collected from at least 15 states. *E. chaffeensis* has not been isolated outside the United States, and the only proven tick vector is restricted to North America, but *E. chaffeensis* or a closely related *Ehrlichia* sp. has been detected in other tick species located in other regions of the world, including Russia, Korea, Thailand, and China (Ravyn et al., 1999; Cao et al., 2000; Alekseev et al., 2001; Kim et al., 2003; Parola et al., 2003). Human infections with *E. chaffeensis* or antigenically related ehrlichiae have been reported in Europe (Nuti et al., 1998), Asia (Heppner et al., 1997), South America (Ripoll et al., 1999), and Africa (Uhaa et al., 1992). *A. americanum* readily feed on humans and white-tailed deer, which are considered to be the primary natural hosts for maintaining the *E. chaffeensis* transmission cycle (Lockhart et al., 1997). Antibodies reactive with *E. chaffeensis* have been detected in white-tailed deer (Lockhart et al., 1995), and laboratory-raised *A. americanum* ticks can acquire *E. chaffeensis* infection from deer (Ewing et al., 1995). Other potentially important reservoirs that are naturally infected with *E. chaffeensis* include goats, domestic dogs, and coyotes (Breitschwerdt et al., 1998; Kocan et al., 2000; Dugan et al., 2000).

CLINICAL SPECTRUM

HME and ehrlichiosis ewingii manifest as undifferentiated febrile illnesses 1–3 weeks after the bite of an infected tick, and infected individuals usually seek medical care within 4 days after onset of illness (Eng et al., 1990; Fishbein et al., 1994). For HME, the most frequent clinical findings reported anytime during acute illness are fever, malaise, headache, dizziness, chills, and myalgias (Fishbein et al., 1989, 1994; Eng et al., 1990; Olano et al., 2003). Other signs including respiratory or central nervous system involvement, lymphadenopathy, and rash are less frequent (Eng et al., 1990; Fishbein et al., 1994; Olano et al., 2003). Patients with ehrlichiosis ewingii present with a milder disease and few complications (Buller et al., 1999). A majority of these patients are immunocompromised, further suggesting that *E. ewingii* is less pathogenic. A large portion of HME patients (60–70%), including those that are immunocompromised, develop more serious manifestations or multisystem involvement including renal failure, disseminated intravascular coagulation, cardiomegaly, acute respiratory distress syndrome, spontaneous hemorrhage, and neurological manifestations requiring hospitalization (Eng et al., 1990; Fishbein et al., 1994; Paddock et al., 2001). Prevention of severe manifestations correlates well with diagnosis and treatment with tetracyclines within the first week of illness (Eng et al., 1990). Hematologic and biochemical abnormalities usually include leucopenia, thrombocytopenia, anemia, mildly elevated serum hepatic transaminase activities, and hyponatremia (Fishbein et al., 1994; Paddock et al., 2001; Olano et al., 2003). Lymphocytosis characterized by a predominance of $\gamma\delta$ T cells is often seen in patients during recovery (Caldwell et al., 1995). A high proportion of immunocompetent (41–62%) and immunocompromised patients (86%) require hospitalization (Fishbein et al., 1994; Paddock et al., 2001; Olano et al., 2003). The case fatality rate is estimated to be 3% (McQuiston et al., 1999), and fatal disease is most often described in older patients, and patients debilitated by underlying disease or immunodeficiency (Eng et al., 1990; Paddock et al., 2001). Immunocompromised patients (HIV-infected persons, transplant recipients, corticosteroid-treated patients) have a high risk of fatal infection associated with overwhelming infection not typically observed in immunocompetent patients (Paddock et al., 2001). No deaths have been reported as a result of infection with *E. ewingii* (Buller et al., 1999; Paddock et al., 2001).

TREATMENT AND PREVENTION

Most patients with HME seek medical attention 4 days after onset of symptoms, which is usually before antibodies diagnostic of infection can be detected. Therefore, patients suspected to have ehrlichiosis should be treated empirically with doxycycline or tetracycline because therapeutic delay can result in the development of severe clinical manifestations and fatal outcome (Fishbein et al., 1994; Olano et al., 2003). Doxycycline and rifampin are highly active against *E. chaffeensis* in vitro (Brouqui and Raoult 1992;

Branger et al., 2004). Therefore, tetracyclines are considered to be the drug of choice for treatment of human ehrlichioses, but rifampin may be preferred in pregnant women, and cases have been reported of successful treatment of closely related *Anaplasma phagocytophilum* infections with this antibiotic (Buitrago et al., 1998; Krause et al., 2003). *E. chaffeensis* is resistant to chloramphenicol in vitro (Brouqui and Raoult 1992), but both treatment failures (Fichtenbaum et al., 1993) and successes with this antibiotic have been reported (Eng et al., 1990; Fishbein et al., 1994); thus it should not be considered a primary therapeutic option.

Disease prevention begins with reducing tick exposure through the use of tick repellents containing *n,n*-diethyl-*m*-toluamide (DEET) and barrier clothing when recreational or occupational activities will result in potential tick exposure. Early removal of any attached ticks will lower the risk of transmission, as it may require 24 or more hours for ehrlichiae to be inoculated.

VACCINES IN DEVELOPMENT

Conventional Vaccines

The emergence of human ehrlichioses in the last decade and the risk to public health has elicited interest in the development of vaccines for HME. The use of vaccines to prevent HME may be especially useful for military personnel and other persons who are active outdoors and are at an increased risk level for acquiring the disease. Ehrlichioses, such as heartwater and CME, are important veterinary diseases. Thus, considerable effort has been made to develop vaccines for *E. ruminantium*, which causes large economic losses to the livestock industry in third world countries, and creates limitations on livestock export. Because *E. ruminantium* is present on a few eastern Caribbean islands (Perreau et al., 1980; Birnie et al., 1985), it poses a threat to the United States livestock industry (Barre et al., 1987b; Burridge et al., 2002a). Consequently, much of the vaccine development for ehrlichial diseases has been focused on prevention of heartwater, where various vaccines have been developed and tested, including live, attenuated, nucleic acid, and recombinant compositions.

Animals that survive infection with *E. ruminantium* develop immunity and are solidly protected against challenge. Such observations led to the development of an effective "infection and treatment" strategy introduced by Neitz and Alexander (1941), which has been the only commercially available vaccine strategy for the last 50 years (Zweygarth et al., 2005). This method of vaccination is cumbersome, requires a cold chain delivery system (liquid nitrogen or dry ice) that makes it inconvenient and impractical for most farmers and private practitioners. In addition, this method has vaccine-associated deaths, risk of transmission of other blood-borne pathogens, lack of standardization and heterologous protection, and is time consuming and expensive (Van der, 1987; Mahan et al., 1999). Consequently, the development and testing of attenuated, inactivated, and recombinant vaccines has been ongoing in an effort to replace the current heartwater "vaccine." Spontaneous attenuated strains of *E. ruminantium* (Senegalese and Welgevonden) were obtained by in vitro cell culture passage (Jongejan, 1991; Zweygarth et al., 2005). These attenuated strains do not produce disease when inoculated into animals, but elicit protective immunity against homologous and heterologous strains (Jongejan, 1991; Zweygarth et al., 2005). The ability of attenuated *E. ruminantium* vaccines to induce protection has been established, but attenuated vaccines also require a cold storage delivery system, and they cannot be used in areas where the vaccine strain is not endemic due to the possibility of reversion to wild-type. In order to develop a vaccine absent of the constraints associated with live attenuated vaccines, inactivated *E. ruminantium* vaccines have been produced and tested. Substantial overall protection has been demonstrated in goats (65%), sheep (79%), and cattle (100%) of vaccinated animals to homologous and heterologous experimental and field challenges as determined by numerous studies (Martinez et al., 1994, 1996; Mahan et al., 1995, 1998; Totte et al., 1997). Inactivated vaccines also have the advantage of being useful in regions where the disease is not endemic, but where the vectors and the potential exist for infections to occur.

Recombinant and Nucleic Acid Vaccines

Development of recombinant subunit and nucleic acid vaccines that has been limited primarily to those utilizing a major surface protein ortholog of *Ehrlichia* spp. (designated MAP1 in *E. ruminantium*, p28 in *E. chaffeensis*, and p28/p30 in *E. canis*), which is a member of a paralogous nonidentical multigene family of outer membrane protein genes (16–25 genes, see section "Genetic, Antigenic, and Phenotypic Characteristics") in each respective *Ehrlichia* spp. Partial protection using a recombinant version of the *E. chaffeensis* P28 protein was demonstrated in mice after homologous challenge (Ohashi et al., 1998). More extensive protection studies with this vaccine candidate have been conducted with *E. ruminantium*

demonstrating similar results. Mice vaccinated with a DNA vaccine containing *map1* generated MAP1-specific antibody, had lymphocytes that proliferated in response *E. ruminantium*, secreted IFN-γ, and increased survival of immunized mice against homologous challenge was noted (Nyika et al., 1998). A follow-up study demonstrated significantly increased protection against homologous challenge using MAP1 DNA vaccination and recombinant protein boost in a mouse model (Nyika et al., 2002). Unfortunately there is substantial divergence in *map1/p28* genes among different isolates of *E. ruminantium* and *E. chaffeensis*, and therefore this diversity may complicate development and implementation. Conversely, the *p28/p30* genes of *E. canis* appear to be highly conserved among geographically dispersed strains, and thus, may facilitate more rapid development of effective vaccines utilizing this antigen. Several newly identified protein orthologs (gp120/140, gp36/47, and gp200s) from *E. chaffeensis* and *E. canis*, respectively, are also immunodominant and are consistently recognized by antibodies in convalescent antisera. The ability of these proteins to protect against homologous challenge has not been determined. Additional antigens of *E. ruminantium* have been tested as DNA vaccines with limited, inconsistent, or no protection (Brayton et al., 1998a, 1998b; Pretorius et al., 2002; Louw et al., 2002; Collins et al., 2003).

PROSPECTS FOR THE FUTURE

Many questions remain with regard to our understanding of ehrlichial pathogenesis and mechanisms of protective immunity. The emergence of human ehrlichioses in the late 20th century has focused new resources and efforts to improve diagnosis and treatment, and to understand pathogenic and protective immune mechanisms that will facilitate vaccine development. The completion of several genome sequences from *Ehrlichia* spp. has provided new insight into how these organisms have evolved and clues to the unique strategies that they utilize to survive in both invertebrate and vertebrate hosts and their interaction with and dependence on the host cell for survival. Molecular identification and characterization of the majority of the major immunoreactive proteins has been accomplished. These new prospects coupled with a more complete understanding of ehrlichial pathobiology and interaction with the innate and adaptive host immune responses will undoubtedly stimulate the development of new and more effective nucleic acid or subunit vaccines for human and veterinary use in the future.

KEY ISSUES

- HME is an emerging life-threatening tick-borne zoonosis caused by the obligately intracellular pathogen, *Ehrlichia chaffeensis*.
- *Ehrlichia ruminantium* is considered to be an agricultural biothreat.
- Commercially, vaccines for human and veterinary ehrlichioses are not available.
- Ehrlichiae evade innate and adaptive host immune responses and establish persistent infections in natural hosts.
- Cellular and humoral immune mechanisms are involved in immunity to *Ehrlichia.*
- *Ehrlichia* major immunoreactive proteins that may be protective vaccine candidates have been identified, but immunoprotective antigens of *Ehrilichia* spp. remain relatively undefined.
- Genetic and antigenic variability exists among strains of *E. chaffeensis* and *E. ruminantium*.
- Natural infection solidly protects against challenge (*E. ruminantium*).
- Infection and treatment technique is the only effective immunization strategy for *E. ruminantium.*
- Partial protection has been achieved with inactivated and attenuated *E. ruminantium* vaccines.
- Little is known about the antigenic composition of *Ehrlichia* spp. in the invertebrate host.

OUTLINE

ABSTRACT

Extaintestinal pathogenic *Escherichia coli* (ExPEC) cause a wide variety of infections in humans and domestic animals. This chapter will focus on ExPEC strains as they relate to humans. ExPEC are responsible for significant morbidity, mortality, and costs to our healthcare system. The development of an efficacious ExPEC vaccine will minimize disease and may be cost-effective in women with recurrent urinary tract infection (UTI) and probably other groups at risk for ExPEC infection such as the elderly. Surface polysaccharides, such as capsule, have been traditional targets for vaccine development. Because the surface polysaccharides present in various ExPEC strains exhibit significant antigenic heterogeneity, their use as vaccine candidates will be challenging. ExPEC adhesins (e.g., P fimbriae and the type 1 pilus), iron-regulated outer membrane proteins (e.g., IroN), and lipid A/core saccharides of lipopolysaccharide (LPS) have been identified as potential vaccine candidates and have been shown to confer protection in various animal infection models. Human phase 1 studies have been completed for the adhesin of the type 1 pilus (FimH and its chaperone protein FimC) and for detoxified J5 LPS (lipid A/core saccharides) complexed to Neisseria meningitidis group B outer membrane proteins, but no phase 2/3 data have been published. A variety of killed whole-cell vaccines, administered via the vaginal or oral route for the prevention of recurrent UTI, have been assessed in animal models and human clinical trials in Europe. These hold some promise, but require further evaluation. We envision that one option for a successful ExPEC vaccine will be the development of a polyvalent subunit vaccine comprising some combination of adhesins, outer membrane proteins, and perhaps detoxified lipid A/core saccharides of LPS. An alternative approach will be the development of a killed whole-cell vaccine that contains multiple strains of genetically engineered derivatives of pathogenic wild-type ExPEC designed to generate an optimal immune response. Development of either a polyvalent subunit vaccine or a genetically engineered killed whole-cell vaccine will be challenging. However, achieving this goal is important because of the medical–economic burden attributable to infections due to ExPEC.

INTRODUCTION

A wide variety of infections continue to be responsible for significant morbidity, mortality, and costs to our healthcare system. The development of new vaccines directed against the responsible pathogens will minimize disease and could be highly cost-effective. *Escherichia coli* cause a wide variety of infections in both humans and domestic animals, including intestinal and extraintestinal disease. Strains of *E. coli* responsible for extraintestinal infections are genetically distinct from those that cause intestinal disease and have been termed extraintestinal pathogenic *E. coli* (ExPEC) (Russo and Johnson, 2000). This chapter will focus on ExPEC as they relate to humans. ExPEC are the most common enteric Gram-negative organisms to cause extraintestinal infection in the ambulatory, long-term-care, and hospital settings (McBean and Rajamani, 2001; Gransden et al., 1990; Roberts et al., 1991; Vastag, 2001; Siegman-Igra et al., 2002). Typical extraintestinal infections due to *E. coli* include urinary tract infection (UTI), diverse intraabdominal infections, pneumonia, surgical site infection, meningitis, intravascular device infection, osteomyelitis, and soft tissue infections, any of which can be accompanied by bacteremia. *E. coli* is a leading cause of severe sepsis (Fluit et al., 2001; Bernard et al., 2001; McBean and Rajamani, 2001; Siegman-Igra et al., 2002), with sepsis ranked as the tenth overall cause of death in the United States (Minino and Smith, 2001). In this era in which health news often sensationalizes uncommon infection syndromes or pathogens, the strains of ExPEC that cause extraintestinal infection are an increasingly important endemic problem and underappreciated "killers." Billions of health-care dollars, millions of workdays, and hundreds of thousands of lives are lost each year to extraintestinal infections due to *E. coli*. Therefore, given the large number and diversity of infections due to ExPEC, an efficacious vaccine has the potential to have a significant clinical impact on a wide variety of medically important syndromes.

CLINICAL CLASSIFICATION OF *E. COLI*

From a genetic and clinical perspective, *E. coli* strains of biological significance to humans can be broadly categorized as: (1) commensal strains, (2) intestinal pathogenic (i.e., enteric or diarrheagenic) strains, and (3) ExPEC (Russo and Johnson, 2000).

Commensal *E. coli* variants, which constitute the major portion of the normal facultative intestinal flora in most humans and other mammals, for the most part confer benefits to their hosts such as colonization resistance. These strains generally lack the specialized virulence traits that enable intestinal and ExPEC to cause disease within or outside of the gastrointestinal tract, respectively. However, commensal *E. coli* can participate in extraintestinal infections when an aggravating factor is present, such as a foreign body (e.g., urinary catheter), host compromise (e.g., local

anatomical or functional abnormalities such as urinary or biliary tract obstruction, or immunocompromise), or a high or a mixed bacterial species inoculum (e.g., with fecal contamination of the peritoneal cavity).

Intestinal pathogenic strains of *E. coli* have evolved a special ability to cause gastrointestinal disease, including enteritis, enterocolitis, and colitis. These strains are largely incapable of causing disease outside the intestinal tract. At least five distinct pathotypes of intestinal pathogenic *E. coli* exist: (1) Shiga-toxin-producing *E. coli*/enterohemorrhagic *E. coli*, (2) enterotoxigenic *E. coli*, (3) enteropathogenic *E. coli*, (4) enteroinvasive *E. coli*, and (5) enteroaggregative *E. coli* (Kaper et al., 2004). Diffusely adherent *E. coli* (DAEC) and cytodetaching *E. coli* are additional putative pathotypes (Le Bouguenec and Servin, 2006). Disease due to this group of pathogens occurs primarily in developing countries, with the exception of the enterohemorragic or Shiga-toxin-producing strains of *E. coli* and perhaps enteroaggregative *E. coli* (Nataro et al., 2006). Intestinal pathogenic strains of *E. coli* are rarely encountered in the fecal flora of healthy hosts, at least in the industrialized world, and instead appear to be essentially obligate pathogens. The effort to develop an efficacious vaccine directed against intestinal pathogenic *E. coli* is ongoing and has important medical–economic implications, and is discussed in Chapter 51.

The majority of *E. coli* isolates from symptomatic infection of the urinary tract, bloodstream, cerebral spinal fluid (Johnson and Stell, 2000; Picard et al., 1999), respiratory tract (Johnson et al., 2002a), and peritoneum (spontaneous bacterial peritonitis) (Soriano et al., 1995), as indicated by their virulence factor profiles and phylogenetic background, are distinct from commensal and intestinal pathogenic *E. coli*. It has been recently proposed that these strains of *E. coli* be termed ExPEC, rather than uropathogenic *E. coli* (UPEC), sepsis associated *E. coli* (SEPEC), or neonatal meningitis associated *E. coli* (NEMEC), to reflect their ability to cause disease at multiple anatomical sites (Johnson and Russo, 2002b; Russo and Johnson, 2000). Evaluation of a limited number of strains has established that ExPEC are also capable of causing surgical wound infection, osteomyelitis, and myositis, but the number of cases evaluated to date is too small to reliably assess proportions (Johnson and Russo, 2002a). Like commensal *E. coli* (but in contrast to intestinal pathogenic *E. coli*), ExPEC strains are often found within the normal intestinal flora and do not cause gastroenteritis in humans.

The fact that ExPEC are the major cause of most (and perhaps all) types of extraintestinal infection due to *E. coli* is an important concept. It implies that if preventive measures (e.g., vaccination) or therapies could be developed to specifically target the ExPEC fraction of the *E. coli* population, this could have a major beneficial impact on extraintestinal infections due to *E. coli*. For example, a vaccine strategy that leads to the development of bactericidal or interfering antibodies directed against ExPEC-specific virulence factors has the potential to prevent infections due to ExPEC without perturbing the commensal strains of *E. coli* that make up an important component of the normal intestinal flora.

EPIDEMIOLOGY

In healthy humans, commensal *E. coli* and ExPEC are the predominant species of Gram-negative bacilli in the colonic flora. *E. coli* and ExPEC only transiently colonize the oropharynx and skin of healthy individuals. In contrast, in long-term care and hospital settings, a variety of Gram-negative bacilli, including ExPEC, emerge as the dominant flora of both mucosal and skin surfaces, particularly in association with antimicrobial use, severe illness, and extended lengths of stay; and this colonization may lead to subsequent infection (e.g., oro-pharygeal colonization and pneumonia). Entry of ExPEC into an organ or anatomic location outside of these colonization sites is the limiting step for infection. As a result, ExPEC is a global pathogen and not a potential biothreat agent. All age groups, all types of hosts, and nearly all organs and anatomical sites are susceptible to infection by ExPEC. Previously healthy hosts infected with ExPEC can become severely ill or die; however, adverse outcomes are more likely in the presence of comorbid illnesses and compromised host defenses. *E. coli* is the most common enteric Gram-negative species to cause extraintestinal infection in ambulatory, long-term care, and hospital settings.

PATHOGENESIS

Since ExPEC strains are commonly part of the normal bowel flora, acquisition is not the rate-limiting step for infection. Instead, entry of an ExPEC strain from its site of colonization (e.g., the colon, vagina, or oropharynx) into a normally sterile extraintestinal site (e.g., the urinary tract, peritoneal cavity, or lungs) is the critical step in pathogenesis. Innate host defense systems (urine flow and mucociliary clearance, complement, antimicrobial peptides, professional phagocytes) and humoral immunity are the principal host-defense components. As a result, both susceptibility to and severity of infection

are increased with dysfunction or deficiencies of these components (e.g., neutrophils). Multiple bacterial virulence factors are required for the pathogenesis of infections caused by ExPEC. Many putative virulence factors were identified epidemiologically as being more prevalent among clinical isolates as compared to fecal isolates from uninfected hosts (Arthur et al., 1989; Bingen et al., 1997; Maslow et al., 1993; Mitsumori et al., 1999; Johanson et al., 1993). However, such factors should be considered as "associated with," not necessarily "contributing to," virulence, since epidemiological associations do not guarantee causality. Animal models studies are a more direct test for whether a given factor contributes to pathogenesis and thereby warrants the designation of being a virulence factor (Table 48.1) (Johnson and Russo, 2005). Possession of specialized virulence genes is what defines ExPEC (e.g., versus commensal *E. coli*) and enables them to infect the host efficiently.

It is becoming clear that hosts and their cognate pathogens (e.g., humans and ExPEC) have been coadapting throughout evolutionary history. During this host–pathogen "chess match" over time, various and redundant strategies have emerged in both the pathogens and their hosts that enable these partners to maintain their coexistence. These virulence factors can be grouped by functional category, e.g., adhesins (Connell et al., 1996; Marklund et al., 1992; Mitsumori et al., 1998; Nowicki et al., 1990), toxins (Guyer et al., 2000; Rippere-Lampe et al., 2001b; Scott and Kaper, 1994; Welch et al., 1981), nutrient acquisition systems (iron, etc.) (Russo et al., 1996b, 2001, 2002; Opal et al., 1990; Schubert et al., 1998; Torres et al., 2001), protectins (e.g., surface polysaccharides) (Burns and Hull, 1999; Russo et al., 1994), and traits of miscellaneous or unknown function (Johnson, 2002a, 2003b; Kurazono et al., 2000) (Table 48.1). Clinical isolates often contain multiple virulence factors from a particular functional category. Conversely, many seemingly virulent strains lack known representatives of one or more of these functional categories (Johnson et al., 2001e, 2002c). The biological implications of these apparent redundancies and deficits are poorly understood. However, a given ExPEC strain usually possesses multiple adhesins for binding to a variety of host cells (e.g., in *E. coli*: type 1 fimbriae, sfa/foc fimbriae, P pili), many genes for nutrient acquisition (e.g., iron via siderophores) that are necessary but not sufficient for pathogenesis, and the ability to resist the bactericidal activity of complement and phagocytes in the absence of antibody (e.g., as conferred by capsule or O-antigen of lipopolysaccharide (LPS)), which is one of the defining traits of an extracellular pathogen (Russo et al., 1996a, 1993, 2003a). Host cell damage (e.g., as mediated by hemolysin in the case of ExPEC) may facilitate spread (e.g., intestinal translocation), release nutrients, and/or impair the function of phagocytes (Bhakdi et al., 1994; Russo et al., 2005, 2007b; Troeger et al., 2007). Many important ExPEC virulence genes doubtlessly await identification. ExPEC also possess the ability to induce septic shock. The lipid A moiety of LPS (via interaction with host Toll-like receptor 4) and probably also other bacterial factors stimulate a proinflammatory host response which, if overexuberant, results in shock.

ExPEC virulence factors that are surface exposed and fulfill a number of additional criteria, as will be discussed below, are potential vaccine candidates. Although is it unclear whether vaccination with an antigen shared by commensal *E. coli* will deleteriously affect our normal colonic flora, virulence factors unique to ExPEC are appealing since that consideration becomes a nonissue.

CLINICAL DISEASE

ExPEC are capable of causing infection in nearly every organ and site outside of the intestinal tract (Johnson and Russo, 2002a, 2002b; Johnson, et al., 2003a; Russo and Johnson, 2003; Smith et al., 2007). Several of the major ExPEC-associated infection syndromes are discussed below.

Urinary Tract Infection

The urinary tract is the most frequent extraintestinal site infected by *E. coli* (Johnson, 2003). UTIs are best considered by clinical syndrome (e.g., uncomplicated cystitis, pyelonephritis, catheter-associated, recurrent cystitis, recurrent pyelonephritis, asymptomatic bacteriuria, complicated UTI, and prostatitis) and within the context of specific hosts (e.g., premenopausal women, pregnant women, postmenopausal women, males, compromised host). Uncomplicated cystitis, the most common acute UTI syndrome, is characterized by dysuria, frequency, and suprapubic pain. Furthermore, 20% of women with an initial cystitis episode develop frequent recurrences (0.3 to >20 per year). Fever and/or back pain suggests progression to pyelonephritis. Asymptomatic bacteriuria warrants treatment in pregnant women, prior to urologic procedures, and perhaps in selected compromised hosts (Nicolle, 2006).

Abdominal Infection

The abdomen/pelvis is the second most frequent extraintestinal site for infections due to *E. coli*. A large

TABLE 48.1 Virulence-associated traits of extraintestinal pathogenic *Escherichia coli* (ExPEC) by functional category

Category	Gene(s) or operon	Comment	Evidence for trait as virulence factor	
			Epidemiological[a]	Experimental (in vivo)[b]
Adhesins[c]	*pap*	Pilus associated with pyelonephritis (P fimbriae)	Yes (Arthur et al., 1989; O'Hanley et al., 1985)	Yes (Roberts et al., 1994); no (Mobley et al., 1993)
	sfa/foc	S and F1C fimbriae	Yes (Schönian et al., 1992)	Yes (Marre and Hacker, 1987)
	sfa	S fimbriae (sialic acid-specific)	Yes (Johnson et al., 2002c)	Yes (Marre and Hacker, 1987)
	foc	F1C fimbriae	Yes (Pere et al., 1985)	No
	afa/dra	Dr antigen-specific adhesin operons (AFA I-III, Dr, F1845)	Yes (Nowicki et al., 1989; Zhang et al., 1997)	Yes (Goluszko et al., 1997)
	afaE-8	Afimbrial adhesin VIII	Yes (Le Bougenec et al., 2001)	No
	iha	Iron-regulated-gene-homologue adhesin (from O157:H7 and CFT073)	Yes (Johnson et al., 2000b; Kanamura et al., 2003)	Yes (Johnson et al., 2005a)
	bmaE	Blood group M-specific adhesin	No	No
	gafD	N-acetyl-D-glucosamine-specific (G, F17c) fimbriae adhesin	Yes (Bertin et al., 1996)	No
	clpG	CS31A adhesin (K88-related)	Yes (Bertin et al., 1996)	No
	nfa	NFA-1, -2, -3, -4 (nonfimbrial adhesins)	No (Goldhar et al., 1987; Grünberg et al., 1988; Hoschützky et al., 1989)	No
	csgA	Curli	Yes (Bian et al., 2000)	Yes (Bian et al., 2001)
	fim	D-mannose-specific adhesin, type 1 fimbriae	Yes (Mobley et al., 1987; Sokurenko et al., 1995)	Yes (Connell et al., 1996; Langermann et al., 1997)
	Antigen 43	Self-recognizing adhesin	Yes (Restieri et al., 2007)	Yes (Ulett et al., 2007)
Toxinsb	*hly*	a-Hemolysin	Yes (Brooks et al., 1980)	Yes (O'Hanley et al., 1991; Welch et al., 1981)
	cnf1	Cytotoxic necrotizing factor 1	Yes (Caprioli et al., 1987)	Yes (Khan et al., 2002; Rippere-Lampe et al., 2001a, 2001b)
	cdtB	Cytolethal distending toxin	Yes (Johnson et al., 2002c)	No
	sat	Secreted autotransporter toxin (serine protease autotransporter)	Yes (Guyer et al., 2000)	Yes (Guyer et al., 2002)
	pic, tsh	PIC and TSH, serine protease autotransporters	Yes (Heimer et al., 2004)	Yes (Dozois et al., 2000; Heimer et al., 2004)
	astA	EAST1 (heat-stable cytotoxin associated with enteroaggregative *E. coli*)	Yes (Janben et al., 2001)	No (Savarino et al., 1993)
Nutrition	*irp, fyuA*	Yersiniabactin (siderophore) synthesis and receptor	Yes (Clermont et al., 2001; Schubert et al., 1998)	Yes (Schubert et al., 2002)
	iuc, iutA	Aerobactin (siderophore) synthesis and receptor	Yes (Clermont et al., 2001; Fernandez-Beros et al., 1990)	Yes (Torres et al., 2001)
	iroN	Catecholate siderophore receptor	Yes (Bauer et al., 2002b; Johnson et al., 2000b)	Yes (Negre et al., 2004; Russo et al., 2002)
	ireA	Iron-regulated element (catecholate siderophore receptor)	Yes (Russo et al., 2001)	Yes (Russo et al., 2001)

(*Continued*)

TABLE 48.1 (Continued)

Category	Gene(s) or operon	Comment	Evidence for trait as virulence factor	
			Epidemiological[a]	Experimental (in vivo)[b]
	chuA	Heme receptor	Yes (Clermont et al., 2001)	Yes (Torres et al., 2001)
	entF	Enterobactin synthesis	No	Yes (Negre et al., 2004)
	tonB	Siderophore expression	N/a	Yes (Negre et al., 2004)
	guaA	Guanine synthesis	N/a	Yes (Russo et al., 1996b)
	argC	Arginine synthesis	N/a	Yes (Russo et al., 1996b)
	scrA,B,R,Y	Sucrose-specific phosphotransferase	Yes (Sorsa et al., 2007)	N/a
Protectins	*kpsMT* II	Group II capsular polysaccharide synthesis (e.g., K1, K5, K12)	Yes (Cross et al., 1984; Johnson and Stell, 2000; Orskov et al., 1982)	Yes (Kim et al., 1992)
	kpsMT III	Group III capsular polysaccharide synthesis (e.g., K3, K10, K54)	Yes (Cross et al., 1984; Johnson and Stell, 2000; Orskov et al., 1982)	Yes (Russo et al., 1994, 2003a)
	rfc	O4 lipopolysaccharide (LPS) synthesis	Yes (Korhonen et al., 1985; Opal et al., 1988)	Yes (Russo et al., 1996a, 2003a)
	cvaC	Microcin ColV; on plasmids with *traT*, *iss*, antibiotic resistance genes, *iuc/iut*	Yes (Fernandez-Beros et al., 1990)	Yes (Aguero et al., 1989)
	iss	Increased serum survival (outer membrane protein)	Yes (Delicato et al., 2003, Fernandez-Beros et al., 1990)	Yes (Binns et al., 1979)
	traT	Surface exclusion, serum survival-associated (outer membrane protein)	Yes (Fernandez-Beros et al., 1990)	No (Montenegro et al., 1985)
	proP	Osmoprotection; proline permease	N/a	Yes (Culham et al., 1998)
	oxyR	Global oxygen stress regulator	N/a	Yes (Johnson et al., 2006)
Misc.	*ompT*	Outer membrane protein T (protease)	Yes (Lundrigan and Webb, 1991)	No
	ompA	Outer membrane protein A (cellular invasion)	N/a	Yes (Kim, 2001)
	ibeA-C	Invasion of brain endothelium IbeA (Ibe10), B, and C	Yes (IbeA) (Johnson et al., 2002b)	Yes (Kim, 2001)
	aslA	Cellular invasion (arylsulfatase-like gene)	N/a	Yes (Kim, 2001)
	traJ	Cellular invasion (F-like plasmid transfer region homologue)	No	Yes (Kim, 2001)
	usp	Uropathogenic-specific protein (bacteriocin)9	Yes (Kurazono et al., 2000)	Yes (Yamamoto et al., 2001)
	malX	Pathogenicity-associated island marker (from strain CFT073)	Yes (Johnson et al., 2001a, 2003b)	No (Johnson et al., 2002a)
	fli	Flagellin	N/a	(Lane et al., 2005)
	ukoE-K	Unknown	Yes (Sorsa et al., 2007)	N/a

Note: The list is not comprehensive even for recognized markers, and many as-yet-unknown markers remain to be characterized. Conversely, not all of the listed traits necessarily contribute to virulence; some are only epidemiologically linked with virulence, and/or confer phenotypes that are suspected of promoting virulence. Additionally, some of these traits also are prominent among intestinal pathogenic *E. coli*, e.g., cytolethal distending toxin, certain Dr-binding adhesins, and EAST1. Misc., miscellaneous.
Source: Modified from Johnson and Russo (2005).
[a] Statistically associated with clinical isolates, or with specific host characteristics; or highly prevalent in a specific extraintestinal infection syndrome.
[b] Based on animal model infection studies, not necessarily using isogenic strains or complemented mutants.
[c] Certain adhesins and toxins also function as invasins, e.g., type 1 fimbriae, certain Dr-binding adhesins, and CNF1 (Khan et al., 2002; Mulvey et al., 2000; Selvarangan et al., 2001).

variety of clinical syndromes occur in this location, including acute peritonitis secondary to fecal contamination, spontaneous bacterial peritonitis, dialysis-associated peritonitis, diverticulitis, appendicitis, intraperitoneal or visceral abscesses (hepatic, pancreatic, splenic), infected pancreatic pseudo-cysts, septic cholangitis and/or cholecystitis, and pelvic inflammatory disease. *E. coli* can be isolated either alone or, as often occurs, with other facultative and/or anaerobic members of the intestinal flora.

Pulmonary Infection

E. coli is not usually regarded as a significant cause of pneumonia. Indeed, enteric Gram-negative bacilli account for only 2–5% of community-acquired pneumonia episodes, in part because in healthy hosts they colonize the oropharynx only transiently and in only a minority of individuals. In contrast, oral colonization with *E. coli* and other Gram-negative bacilli increases with severity of illness and antibiotic use. As a result, Gram-negative bacilli are a substantially more common cause of pneumonia among residents of long-term-care institutions (Muder, 1998) and are the most frequent cause (60–70%) of hospital-acquired pneumonia, particularly in postoperative patients and in the intensive care unit (Craven et al., 1990; Emori and Gaynes, 1993; Fluit et al., 2001; Center for Disease Control NNIS System, 1996). Although significant institutional variation occurs, *E. coli* is generally the third or fourth most commonly isolated enteric Gram-negative bacillus in nosocomial pneumonia, accounting for 5–8% of episodes in both U.S. and European-based studies (Cook et al., 1998; Fluit et al., 2001; Horan et al., 1988; Center for Disease Control NNIS System, 1996).

Surgical Site Infection

E. coli is the fourth most common organism implicated in surgical site infections. It accounts for 8% of the total 300,000 to 800,000 surgical site infections that occur annually in the United States (Center for Disease Control NNIS System, 1996).

Meningitis

E. coli is one of the two leading causes of neonatal meningitis (along with group B *Streptococcus*), causing 20–40% of an estimated 400 cases annually in the United States (De Louvois, 1994; Murphy, 2000). Other than in neonates, *E. coli* meningitis occurs predominantly in the setting of disruption of the meninges due to surgery or trauma, or in the presence of cirrhosis where presumably the meninges are seeded from poorly cleared portal-source episodes of bacteremia (Pauwels et al., 1997).

Additional Infections

E. coli is capable of causing infection in nearly every organ and anatomical site. Other extraintestinal infections that can be caused by *E. coli* include: infections of ulcers due to pressure or ischemia (particularly in patients with diabetes or other causes of neurovascular compromise), cellulitis, burn wound infections, osteomyelitis (via contiguous spread or hematogenously; particularly of vertebral bodies), orthopedic device-associated infection, and myositis/fasciitis (Elliott et al., 2000; Grayson et al., 1994; Revathi et al., 1998; Saccente, 1998; Sapico, 1999; Johnson and Russo, 2002a). *E. coli* occasionally causes complicated sinusitis and rarely causes endocarditis, vascular graft infection, endophthalmitis, or brain abscesses.

Bacteremia-Sepsis

E. coli bacteremia can result secondarily from any of the above primary sites of infection, from percutaneous intravascular devices, or from the increased intestinal mucosal permeability that occurs in neonates and accompanies neutropenia, chemotherapy-induced mucositis, trauma, and burns. In studies from all continents, *E. coli* accounts for 17–37% of clinically significant blood isolates, with isolates originating in the community versus hospital being approximately equal (Bernard et al., 2001; Elhanan et al., 1995; Fluit et al., 2001; Gosbell et al., 2000; Gransden et al., 1990; Ismail et al., 1997; McBean and Rajamani, 2001; McGregor and Colligan, 1993; Olesen et al., 1998; Rayner and Willcox, 1988; Sader et al., 2002; Siegman-Igra et al., 2002; Uslan et al., 2007). Isolation of *E. coli* from a blood culture is almost always clinically significant, and is typically accompanied by sepsis syndrome, severe sepsis (sepsis-induced dysfunction of at least one organ or system), or septic shock (American College of Chest Physicians, 1992).

SIGNIFICANCE AS PUBLIC HEALTH PROBLEM

The medical and economic impacts of extraintestinal *E. coli* infections are evident from a review of the following specific syndromes (Table 48.2). It is important to note, however, that data reported

TABLE 48.2 Estimated frequency and associated annual costs in the treatment of selected extraintestinal infection syndromes due to ExPEC in United States

Infection syndrome	Estimated frequency of cases	Estimated direct costs (U.S. dollars)
Uncomplicated cystitis in premenopausal women	6–8 million	1 billion
Uncomplicated pyelonephritis	250,000	175 million
Catheter-associated UTI	130,000–525,000	47–350 million
Pneumonia	14,100–23,400	80–133 million
Surgical site infection	24,000–64,000	94–252 million
Sepsis	127,500	1.1–5.9 billion

Source: Modified from Russo and Johnson (2003).

below have been generated primarily from studies based in the United States and Europe. The extent to which these data can be extrapolated to other countries is unknown. Clearly, costs will be dependent on health-care system. Additional data, in particular from developing countries, would be desirable.

Urinary Tract Infection

UTI is a common infection in ambulatory patients, accounting for 1% of ambulatory care visits in the United States, and second only to lower respiratory tract infection among the infections responsible for hospitalization (Hooton and Stamm, 1997; Stamm and Hooton, 1993). From both clinical and economic points of view, UTI is best considered by clinical syndrome within the context of specific hosts. *E. coli* is the single most prevalent pathogen for all UTI syndrome–host group combinations. *E. coli* causes 85–95% of episodes of uncomplicated cystitis in premenopausal women (Hooton and Stamm, 1997; Stamm and Hooton, 1993). The estimated total number of cases of uncomplicated cystitis is 6–8 million/year in the United States and 130–175 million globally. In the United States, uncomplicated cystitis is responsible for an estimated $1 billion of direct health-care costs annually (Harding and Ronald, 1994; Patton et al., 1991; Schappert, 1994). Furthermore, each episode results in a mean of two restricted activity days and six symptom days (Foxman and Frerichs, 1985). Because of this, since women now constitute nearly 50% of the work force, cystitis results in considerable additional indirect costs. *E. coli* are the cause of over 90% cases of uncomplicated pyelonephritis in premenopausal women (Talan et al., 2000). An estimated 250,000 cases of pyelonephritis occur each year in the United States, 100,000 of which require hospitalization (McCarthy, 1980; Stamm et al., 1989). Based on population ratios (U.S. population 301 million, global population 6.6 billion), this would translate into an estimated 5.5 million cases worldwide per annum. In the United States, the mean direct cost per cure is approximately $700 (Talan et al., 2000). Therefore, in the United States alone, the estimated *E. coli*-associated costs for pyelonephritis are $175 million/year. An estimated 1–1.5 million episodes of catheter-associated UTI (Fluit et al., 2001) occur annually in the United States, with an associated treatment cost of $363–676 per episode (Saint, 2000; Stamm et al., 1991; Tambyah et al., 2002). *E. coli* accounts for 13–35% of the episodes. Thus, the estimated direct health-care cost in the United States associated with catheter-associated UTI due to *E. coli* is $47–350 million/year.

Abdominal Infection

Specific data are not available for intraabdominal and pelvic infections regarding overall infection rates, the proportion of episodes in which *E. coli* is isolated, or associated costs. However, considering the frequency of these infections, the common participation of *E. coli*, and the multiple interventions and prolonged hospital stays often necessary for successful management, the cost of intraabdominal/pelvic infections due to *E. coli* is undoubtedly substantial.

Pulmonary Infection

Nosocomial pneumonia prolongs hospitalization by an estimated mean of 5.9 days and adds an estimated $5000 in costs per episode (Jarvis, 1996; Wenzel, 1989). Therefore, the total annual associated cost of nosocomial pneumonia in the United States is estimated to be $1.5 billion/year, with estimated *E. coli*-associated costs of $75–120 million/year.

Surgical Site Infection

Approximately 34 million surgical procedures are performed annually in the United States. As a result of these procedures, 300,000–800,000 surgical site infections occur every year (Vital and Health Statistics, 1998). Surgical site infection is associated with a 2–2.5-fold increase in the 6-month mortality rate (Kirkland et al., 1999; Poulsen et al., 1995). Surgical site infection results

in a mean increase of 10.2 days of hospitalization and an added cost of $4000–5000 per patient (Kirkland et al., 1999; Zoutman et al., 1998). Therefore, the total estimated associated costs of surgical site infection in the United States is $1.2–4.0 billion/year, with the estimated *E. coli*-associated portion being $94–252 million/year.

Meningitis

The number of cases of *E. coli* meningitis may be increasing due to the increased use of ampicillin designed to reduce the vertical transmission of group B S*treptococcu*s. Although this strategy has been effective in decreasing the prevalence of group B streptococcal infections, a concomitant increase in infections due to *E. coli* (85% were ampicillin resistant) has been observed (Stoll et al., 2002). Case-fatality rates range from 25–40%, and 33–50% of survivors develop neurological sequelae (De Louvois, 1994; Franco et al., 1992; Unhanand et al., 1993). No cost data are available for these infections, but the prolonged hospitalizations that they commonly entail and the extensive supportive and rehabilitative care that often is needed even after the infection is cured doubtlessly results in substantial direct costs despite the modest number of cases.

Bacteremia-Sepsis

Septicemia was the tenth ranked cause of mortality in the United States in 2000 and was responsible for 1.3% of deaths overall (Minino and Smith, 2001). A study, based on U.S. data, estimated that 751,000 cases of severe sepsis occurred in 1995. With the observed 28.6% associated mortality rate (Angus et al., 2001), this translates into an estimated 215,000 deaths. Among the 15 leading causes of death in the United States since 1950, the largest increase in death rate has been due to septicemia, increasing 38-fold (i.e., from 0.3 in 1950,to 11.5 in 2000, per 100,000 U.S. standard population) (Minino and Smith, 2001; Murphy, 2000). Estimated hospitalizations rates for septicemia in Medicare beneficiaries have also increased dramatically, from 90,965 in 1986 to 219,350 in 1997 (a 241% increase) (McBean and Rajamani, 2001). The incidence of severe sepsis and its associated mortality has been projected to increase in the coming years by 1.5% per annum (Angus et al., 2001). Although associated mortality overestimates true attributable mortality, in the context of sepsis this difference may be less than one might predict. The associated mortality for severe sepsis in patients with and without underlying comorbidity was 31.8% and 25%, respectively (Angus et al., 2001). Since the latter value derives from hosts without comorbid conditions that could confound the association of sepsis with mortality, it probably approximates the true attributable mortality due to sepsis. These data thus strongly suggests that most of the mortality associated with severe sepsis is actually due to sepsis itself and not to comorbidities.

In 1997, the approximately 219,350 hospitalizations for septicemia were estimated to cost Medicare $1.8 billion in hospitalization costs alone (McBean and Rajamani, 2001). The true cost is acknowledged to be significantly higher, since neither prehospital and posthospital costs, nor costs for physician services in hospital, were included. In 1997, a total of 773,530 cases of severe sepsis were estimated to occur nationwide (Angus et al., 2001). Therefore, extrapolation of estimated Medicare costs for septicemia would yield a conservative estimate of $6.5 billion/year. Considerably higher estimates have been provided with the average cost per case of severe sepsis calculated to be $22,100 (1995 dollars) (Angus et al., 2001) or $44,600 (2001 dollars) (Weycker et al., 2003). These figures project to an annual United States cost for all-cause severe sepsis of $16.7–34.5 billion.

By using the conservative estimate that *E. coli* causes 17% of the cases of severe sepsis (Bernard et al., 2001; Fluit et al., 2001; McBean and Rajamani, 2001), severe sepsis due to *E. coli* would be associated with an estimated 40,000 deaths in 2001, and an estimated *E. coli*-associated direct health-care costs of $1.1–2.8 billion/year in the United States alone. From a global perspective, the World Health Organization's report regarding the leading infectious causes of death worldwide in 1999 is informative (World health Organization, 2000). Although two of the infections listed (i.e., acute respiratory tract infection and acquired immunodeficiency syndrome) in some instances cause sepsis, sepsis per se did not appear on the list. Differentiating sepsis-associated mortality from mortality caused by an infection at a defined anatomical location may be difficult, if not impossible. Nonetheless, it is important to acknowledge sepsis as a distinct, infectious clinical entity. A sepsis-specific therapy has been approved in the United States (Bernard et al., 2001), and additional sepsis-specific therapies are in development. Therefore, regardless of whether sepsis is primary or secondary, its prevalence, associated mortality, and economic consequences warrant individual recognition. If the U.S. data on sepsis-associated mortality are extrapolated worldwide, sepsis-associated mortality would supplant acute lower respiratory infections (3,963,000 estimated deaths per annum) as the number one infectious cause of death (4,950,000 estimated deaths per annum). Sepsis-associated mortality due to *E. coli* (using the

conservative estimate of *E. coli* causing 17% of sepsis cases (Bernard et al., 2001; Fluit et al., 2001; McBean and Rajamani, 2001)) would be ranked seventh overall (868,000 estimated deaths per annum). This calculation assumes that sepsis-associated mortality is uniform among all pathogens. This may not be the case, since some studies have suggested a higher sepsis-associated mortality with *Pseudomonas* and/or *Candida* than with other pathogens. Nonetheless, these figures leave little doubt that the global burden of *E. coli* sepsis-associated deaths is substantial.

SHORT HISTORY OF THE DISEASE

ExPEC, or their evolutionary precursor, have likely been part of the colonic flora of humans since the dawn of humankind. Likewise, infections due to ExPEC almost certainly have an equally long history. In the past, ExPEC have typically been highly susceptible to antibiotics, hence readily eradicated with antibiotic therapy. Unfortunately, this situation has changed as of late. Antimicrobial resistance among *E. coli* strains has increased (see "Treatment"). Furthermore, the incidence of serious extraintestinal infection due to *E. coli* increases with age (Angus et al., 2001; Jackson et al., 2005; McBean and Rajamani, 2001). As the proportion of elderly patients increases in the United States and other developed countries, so likely will the number of extraintestinal *E. coli* infections. The combination of increasing numbers and increasing antimicrobial resistance predictably will make the future management of extraintestinal *E. coli* infections more challenging and costlier than ever.

TREATMENT

In general, the frequency of resistance precludes empirical use of ampicillin, even in community-acquired infections. The prevalence of resistance to first-generation cephalosporins and trimethoprim-sulfamethoxazole is increasing among community-acquired strains in the United States (currently 10–40%) and is even higher outside North America. Until recently, trimethoprim-sulfamethoxazole was the drug of choice for the treatment of uncomplicated cystitis in many locales. Although continued empirical use of trimethoprim-sulfamethoxazole will predictably result in ever-diminishing cure rates, a wholesale switch to alternative agents (e.g., fluoroquinolones) will just as predictably accelerate the widespread emergence of resistance to these antimicrobial classes, as is already occurring in many areas. Resistance to fluoroquinolones has been steadily increasing over the last decade, with 2002–2005 prevalence values ranging from 5–20% in North America and even higher in other regions. The prevalence of resistance is higher in settings with extensive use of fluoroquinolone prophylaxis (e.g., in patients with leukemia, transplants, and cirrhosis), and among isolates from long-term-care facilities and hospitals. Among fluoroquinolone-resistant strains, a significant prevalence of coresistance (30–40%) to amoxicillin/clavulanic acid and piperacillin has been reported. The prevalence of coresistance to more advanced cephalosporins (second-, third-, and fourth-generation), monobactams (e.g., aztreonam), piperacillin-tazobactam, and the non-amikacin aminoglycosides is increasing but still generally $<10\%$. Carbapenems (e.g., imipenem) and amikacin are the most predictably active agents, but recently resistance has been described against these agents as well (Bogaerts et al., 2007; Lartigue et al., 2007). Although clinical experience is limited, tigecycline and polymyxin B (an agent of last resort due to potential toxicities) are highly active in vitro (Stein and Craig, 2006).

PROTECTIVE IMMUNE RESPONSE

ExPEC are typical extracellular bacterial pathogens. These strains are inherently resistant to innate host defense factors such as complement, cationic antimicrobial peptides, and phagocytosis in the absence of opsonization. Given the extracellular lifestyle of ExPEC, the development of bactericidal antibodies should lead to protective immunity (Ahmed et al., 2002). However, despite the peaceful coexistence of ExPEC strains with humans (and other mammals and birds) on the intestinal ($+/-$ the vaginal and oropharyngeal) mucosal surfaces, the host is unable to develop a protective immune response as a result of colonization. In fact, the host is susceptible not only to an initial infection at an extraintestinal site, but also to recurrent infections from both homologous and heterologous strains (Russo et al., 1995; Olesen et al., 1998; Maslow et al., 1994; Brauner et al., 1994). This suggests that the development of a protective immune response is not always a consequence of natural ExPEC infection. We hypothesize that ExPEC have evolved mechanisms to avoid and/or subvert an acquired protective immune response from the host. To successfully develop a vaccine to protect against ExPEC, an understanding is required of (1) the mechanisms by which these strains escape the

host's acquired immune response, and (2) optimal immunization approaches.

Despite the host's apparent inability to develop a protective immune response to natural infection, we hypothesize that a successful immunization strategy can be developed that will confer protection against ExPEC. An immunologic correlate for protection against ExPEC infection (e.g., threshold antibody titer) has not been established. Further, individuals with deficiencies in humoral or cell-mediated immunity do not seem to have an increased incidence of ExPEC-mediated infections such as UTI. However, abundant experimental evidence supports that humoral immunity is important in conferring protection against ExPEC infection. In animal models, passive or active immunization against capsule, O-specific antigen, and iron-regulated outer membrane proteins (OMPs) have afforded protection against systemic infection (Kaijser and Ahlstedt, 1977; Salles et al., 1989; Bolin and Jensen, 1987), and immunization with capsule, O-antigen, and P and type 1 fimbriae, and the siderophore receptor IroN are protective against UTI from ExPEC strains expressing these virulence factors (Kaijser et al., 1978, 1983; Langermann et al., 1997, 2000; O'Hanley et al., 1991; Pecha et al., 1989; Russo et al., 2003b). Further, in cynomologus monkeys, more rapid clearance of *E. coli* from the urinary tract correlated with anti-*E. coli* serum IgM and urine secretory IgA and IgG (Hopkins and Uehling, 1995). Taken together, these data support that generation of an appropriate systemic and perhaps a mucosal (e.g., against cystitis) acquired immune response will prevent infections due to ExPEC.

ExPEC VACCINES

At present, no human ExPEC vaccines are licensed in the United States. A number of whole-cell vaccines that contain ExPEC and a variety of other pathogens that cause UTI have been studied and are available for use in Europe for the prevention of UTI. These include Urovac (SolcoBasel, Basel, Switzerland), Uro-Vaxom (OM Pharma, Myerlin, Switzerland), Urvakol (Institute of Microbiology, Czech Republic), and Urostim (National Center for Infectious and Parasitic Diseases, Bulgaria). However, the data that support the use of these vaccines are limited and/or far from convincing, and many studies lack scientific rigor. Therefore, we will discuss whole-cell vaccines under "ExPEC Vaccine Candidates" (Russo and Johnson, 2006).

ExPEC VACCINE CANDIDATES

Surface Polysaccharides

Development of a successful vaccine designed to protect against infections due to ExPEC presents several challenges (Russo and Johnson, 2006). First, although surface polysaccharides such as capsule have formed the basis for several successful vaccines directed against extracellular pathogens such as *Haemophilus influenzae* type b, *Streptococcus pneumoniae*, and certain serotypes of *Neisseria meningitidis* (Smit et al., 1977; Lepow et al., 1986; Centers for Disease Control and Prevention., 1991), this approach is less practical for ExPEC. More than 80 capsular serotypes exist for *E. coli* strains (Jann and Jann, 1990; Orskov et al., 1977). Further, for the O-antigen moiety of LPS, >150 major variants, some with multiple subtypes, have been described in *E. coli* (Whitfield and Valvano, 1993). Although only a fraction of these capsular and O-antigen variants are encountered among ExPEC, surface polysaccharides from ExPEC isolates nonetheless exhibit considerable antigenic diversity. Further, certain capsular polysaccharides (e.g., K1, K5) are poorly immunogenic, which may be due to their antigenic similarities to host tissues (Roberts, 1995). These considerations would be predicted to make the development of an ExPEC vaccine based on surface polysaccharides extremely challenging (Whitfield and Valvano, 1993). Despite this, the development of a polyvalent conjugated vaccine based on a combination of the most common capsular and O-antigen serotypes is still a consideration.

Adhesins

Assessment of surface-exposed protein moieties as putative vaccine candidates has also been pursued. Adhesins are a logical choice because of their surface exposure and potential role in pathogenesis. Antibodies directed against these elements have the promise to enhance bactericidal activity mediated by complement or by professional phagocytes via opsonization, and/or to inhibit bacterial binding to host structures, a potentially critical step in the pathogenesis of infection. P fimbriae, which via their PapG adhesin molecule recognize glycolipids that contain a Galα(1-4)Gal moiety, are associated with the 70–90% of ExPEC isolates that cause pyelonephritis and in 30–50% of those that cause cystitis. Systemic immunization with purified P fimbriae (Pecha et al., 1989; O'Hanley et al., 1991) and synthetic peptides corresponding to the protective epitope of the P fimbria major structural subunit (Schmidt et al., 1988)

conferred protection in a murine pyelonephritis model. Likewise, immunization with purified P fimbriae or with purified PapDG protein complex conferred protection in a nonhuman primate model (Roberts et al., 1984, 2004), and passive immunization with anti-PapG conferred protection to chickens in an air sac infection model (Kariyawasam et al., 2004b). Human studies to assess the efficacy of a vaccine against P fimbriae or its components thereof have not been performed. FimH, the adhesin for the mannose binding type 1 pilus that has been shown to mediate binding to uroepithelial cells via uroplakin receptors, is a critical determinant in the pathogenesis of cystitis in mice, and is expressed in >90% of *E. coli* strains. Systemic immunization with recombinant FimH and its chaperone FimC was protective in a murine cystitis model (Langermann et al., 1997) and prevented cystitis in three of the four cynomolgus monkeys (Langermann et al., 2000). A human phase 2 trial has been undertaken, but published data are not available. If the FimH-FimC vaccine is successful in preventing cystitis, it has the potential to prevent bacteremia originating from this site. However, most cases of ExPEC bacteremia from a urinary tract origin occur in the setting of concomitant renal infection. The impact of a FimH-FimC vaccine on pyelonephritis is unclear. Further, the utility of this vaccine will probably not extend to the many other types of infection caused by extraintestinal *E. coli* outside of the urinary tract (Vandemaele et al., 2005; Kariyawasam et al., 2004b), since its protective effect appears to result from inhibition of bladder-specific adherence mediated by type 1 pilus (Langermann et al., 1997).

Immunization with purified Dr fimbriae reduced mortality after challenge with a homologous strain in a chronic UTI model, using C3H/HeJ mice, but bacterial titers in the urinary tract were not affected (Wroblewska-Seniuk et al., 2005). Although Dr fimbriae and related adhesins are associated with ExPEC isolates that cause UTI in children and pregnant women, overall their prevalence in surveys of ExPEC isolates is generally <10% (Gordon et al., 2005; Johnson et al., 2005c; Sannes et al., 2004), making them a less than ideal vaccine candidate, particularly as a "stand alone" immunogen. S and F1C fimbriae are more prevalent among ExPEC isolates, but have not been assessed as vaccine candidates.

Outer Membrane Proteins

OMPs are also potential vaccines candidates. Several iron-regulated OMPs have been assessed to date. This group of proteins is also logical given that (1) many are surface exposed; (2) iron acquisition is a requisite for pathogenesis, since free iron is largely unavailable in animal hosts; (3) a variety of iron-regulated and non-iron-regulated OMPs have been shown to exhibit increased expression in vivo in mice (Snyder et al., 2004); (4) unlike adhesins, which display considerable antigenic variability (Weissman et al., 2006), OMPs assessed as putative vaccine candidates demonstrate a high degree of conservation (Durant et al., 2007).

One of the most extensively studied iron-regulated OMPs has been the siderophore receptor IroN. Expression of IroN is increased in human blood, ascites, and urine (Russo et al., 1999; Hagan and Mobley, 2007), contributes to invasion of uroepithelial cells in vitro (Feldmann et al., 2007), and contributes to virulence in a mouse UTI model (Russo et al., 2002), in the avian air sac infection model (Dozois et al., 2003), and in the rat neonatal meningitis model (Negre et al., 2004). Systemic immunization with denatured IroN conferred protection against renal but not bladder infection in a mouse UTI model (Russo et al., 2002). A recent study demonstrated that both active and passive systemic immunization with IroN conferred protection against ExPEC challenge in a lethal sepsis model (Durant et al., 2007). The prevalence of IroN in human ExPEC isolates ranged from 39–83% (mean 50%, 461/919), depending on the site of infection (Johnson et al., 2001c, 2000a, 2002a, 2001d; Bauer et al., 2002b; Russo et al., 1999; Hagan and Mobley, 2007).

Limited published studies have pursued other OMPs as potential vaccine candidates. Several conserved OMPs have been shown to be expressed during UTI, leading the authors to conclude that such antigens could form the basis of an ExPEC vaccine (Hagan and Mobley, 2007). Through the use of a "reverse vaccinology" approach, FyuA and the antigens C0393, C4424, and C3389, but not ChuA, were shown to confer protection in a lethal sepsis model (Durant et al., 2007). Passive immunization with rabbit antisera, raised against iron-regulated OMPs in *E. coli* (O78/K80/H9), protected turkeys from bacteremia and death in an air sac inoculation model (Bolin and Jensen, 1987; Kariyawasam et al., 2004b). Active nasal immunization with purified aerobactin receptor IutA or passive immunization with anti-IgY raised against IutA protected chickens after challenge with the homologous strain and both the homologous and heterologous strains, respectively, in an air sac infection model (Kariyawasam et al., 2002, 2004b). A number of ExPEC iron-regulated OMPs have been demonstrated to be urovirulence factors (e.g., IreA, Iha) but have not yet been assessed as potential vaccine candidates (Johnson et al., 2005b; Russo et al., 2001).

OmpT, a non-iron-regulated OMP, is highly prevalent among ExPEC isolates, but has not yet been assessed experimentally as either a urovirulence factor or a potential vaccine candidate (Gordon et al., 2005; Johnson et al., 2005c; Sannes et al., 2004). No human studies have been performed assessing OMPs as vaccine candidates. However, OMPs possess their own challenges, which include difficulties in purification and in maintaining the proper conformational structure. Further, in ExPEC strains, although some OMPs are widely prevalent, others (e.g., IreA) are less so (Russo et al., 2001). Moreover, nearly all ExPEC strains possess capsule and O-antigen, which may impede antibody binding to OMP antigens. Lastly, given the variable prevalence of many OMPs in ExPEC, it is unlikely that a single OMP will be able to confer broad protection, thus necessitating the need for a polyvalent vaccine.

Lipid A/Core Saccharides of LPS

Because of the relative antigenic conservation of lipid A and the core saccharides of LPS, not only among the different *E. coli* strains but also among *Enterobacteriaceae* in general, there has been significant interest in the role of antibodies directed against these moieties in protecting against a variety of infections. The demonstration that passive administration of polyclonal antisera developed against an O-antigen-deficient *E. coli* strain (J5) could significantly decrease mortality against Gram-negative bacteremia (35/91 treated patients had *E. coli* bacteremia) generated tremendous excitement (Ziegler et al., 1982). It was hypothesized that the protective effect of J5 antisera was due to antibodies directed against core saccharides or lipid A, which neutralized the biologic activity of lipid A or increased bacterial clearance. Disappointingly, however, subsequent studies, which treated patients with Gram-negative sepsis with human monoclonal antibodies directed against lipid A, did not support the initial findings (Greenman et al., 1991; Ziegler et al., 1991). It has been subsequently demonstrated that J5 antiserum contains antibodies directed against ≥3 OMPs (e.g., OmpA, anti-murein lipoprotein, and peptidoglycan-associated lipoprotein), which suggested that the protective effect initially seen with polyclonal J5 antiserum (Ziegler et al., 1982) may actually have been due to antibodies directed against these alternative targets, rather than LPS per se (Hellman et al., 1997). Other investigators are continuing to pursue the development of a subunit vaccine composed of detoxified J5 LPS complexed to *N. meningitidis* group B OMPs (Cross et al., 2003).

Toxins

Alpha-hemolysin (HlyA) has been shown to be highly conserved (O'Hanley et al., 1993). In a mouse model of pyelonephritis, systemic immunization with purified HlyA was associated with decreased renal damage, but did not affect the clearance of *E. coli* (O'Hanley et al., 1991), and in another study both active and passive immunization with antisera raised against HlyA protected mice (Linggood and Ingram, 1982). Other toxins that are variably present in ExPEC isolates (Gordon et al., 2005; Johnson et al., 2005c; Sannes et al., 2004), such as cytotoxic necrotizing factor-1 (Rippere-Lampe et al., 2001b) and secreted autotransporter toxin (Guyer et al., 2002), have been shown to contribute to uropathogenesis, but have not been assessed as potential vaccine candidates (Guyer et al., 2002).

Whole-Cell Vaccines

Four standardized whole-cell vaccine formulations have been tested for their efficacy in preventing UTIs.

1. Urovac (SolcoBasel, Basel, Switzerland) consists of 10 heat-killed uropathogens (*E. coli*, $N = 6$; *P. mirabilis*, $N = 1$; *M. morganii*, $N = 1$; *K. pneumoniae*, $N = 1$; *E. faecalis*, $N = 1$: 1×10^8 cfu of each strain per dose). Urovac conferred protection in mouse, rat, and cynomolgus monkey UTI models when administered intramuscularly (IM) or via the intravaginal route (Kruze et al., 1992; Uehling et al., 1991, 1994). In an open comparative study of 400 women who had a UTI, there was a significant decrease in recurrent UTI in women treated with Urovac IM. However 47% had reactions that were attributed to endotoxin (Grischke and Ruttgers, 1987). As a result, subsequent studies explored intravaginal administration to minimize adverse reactions and maximize a mucosal immune response. A double-blind, placebo controlled, phase 2 clinical trial in 54 women demonstrated that six intravaginal immunizations with Urovac (0, 1, 2, 6, 10, 14 weeks), but not three intravaginal immunizations (0, 1, 2), increased the time to reinfection compared to placebo (Uehling et al., 2003). This protective effect was not associated with an increase in antibody levels against the uropathogens included in Urovac. Therefore, it is unclear whether the protection observed was due to an acquired immune response or an immunostimulatory effect on the host's innate defense response that may require regular booster

doses. A small (n = 24–26 per group), recent study demonstrated that women with recurrent UTI that underwent "primary" intravaginal immunization (0, 1, 2 weeks) and "primary" immunization with boosters (0, 1, 2, 6, 10, 14 weeks) were significantly more likely to remain free of recurrent *E. coli* infection, but not UTIs by any bacteria, compared to placebo (Gautam and Khera, 2007). This protective effect was not associated with differences in *E. coli* IgA and IgG antibodies in urine and vaginal fluid samples.

2. OM-89 or Uro-Vaxom (OM Pharma, Myerlin, Switzerland) is a lyophilized extract from 18 *E. coli* strains and is administered via the oral route. The proposed mechanism of OM-89 is induction of antibody response to antigens, both present and not present in the vaccine (Huber et al., 2000). A meta-analysis of five placebo-controlled double blind studies (1 capsule/day for 90 days with a 6-month study duration) supported that oral therapy with OM-89 was associated with a decrease in recurrent UTI compared to placebo (Bauer et al., 2002a). The same conclusion was reached in a recent multicenter, double-blind study conducted in 453 women over 12 months (1 capsule/day for months 1–3, no treatment in months 4–6, 1 capsule/day for the first 10 days of months 7–9) (Bauer et al., 2005).
3. Urvakol (Institute of Microbiology, Czech Republic) (Koukalova et al., 1999a, 1999b), which contains inactivated whole cells of *E. coli*, *P. mirabilis*, *P. aeruginosa*, and *E. faecalis*, and 4.Urostim (National Center for Infectious and Parasitic Diseases, Bulgaria) (Marinova et al., 2005, Nenkov et al., 1995), which contains lyophilized lysates of *E. coli*, *P. mirabilis*, *K. pneumoniae*, and *E. faecalis*, are also administered orally. These vaccine formulations have been studied both in animals and in human clinical trials. Published data are limited but suggest that these formulations have a nonspecific immunostimulatory effect on both innate and acquired immunity. It is unclear how the immunostimulatory properties of OM-89, Urvakol, and Urostim are more effective than those bestowed by the daily bacterial load from ingested food or from the endogenous colonic flora, which contains the uropathogens destined to cause UTI.

Other nonstandardized whole-cell formulations have been assessed in a variety of animal infection models. Vaginal immunization with a formalin-killed *E. coli* strain (O6, P fimbriae, type 1 pilus positive) conferred protection against cystitis to cynomolgus monkeys after challenge with the homologous strain (Uehling et al., 1987). Systemic immunization with formalin killed *E. coli* (O4, P fimbriae, type 1 pilus, hemolysin positive) afforded some protection against renal damage, but not bacterial clearance (Roberts et al., 1995). Immunization of chickens, via spray droplets, with attenuated *E. coli* constructs with deletions in either *galE*, *purA*, or *aroA* resulted in an appropriate immune response and conferred protection against pulmonary challenge with the wild-type homologous parent (O78), but not against a heterologous *E. coli* strain (O2) (Kariyawasam et al., 2004a). Thus, although the available data regarding whole-cell *E. coli* vaccines to date is far from convincing and many studies lack scientific rigor, based on successes with other pathogens (e.g., *B. pertussis*) the concept should not be discarded.

Genetically-Engineered Whole-Cell Vaccines

Our laboratory has generated data, which lay the foundation for the logical development of a killed, whole-cell *E. coli* vaccine (Russo et al., 2007a). We demonstrated that nasal immunization with a formalin-killed ExPEC derivative deficient in capsule and O-antigen results in (1) a significantly greater overall humoral response compared to its wild-type derivative (which demonstrates that capsule and/or the O-antigen impede the development of an optimal humoral immune response) and (2) a significantly greater immune response against noncapsular and O-antigen epitopes. We also demonstrated that a similar amount of antibodies that recognize surface epitopes on CP923 (capsule and O-antigen minus) is generated after immunization with live and formalin-killed CP923, suggesting that antigen presentation, surface architecture, and conformational epitopes are relatively conserved with formalin treatment. These antibodies also bound to a subset of heterologous ExPEC strains and enhanced neutrophil-mediated bactericidal activity against both the homologous and a heterologous strain. Taken together, these studies support the concept that formalin-killed genetically engineered ExPEC derivatives are whole-cell vaccine candidates to prevent infections due to ExPEC. We envision the potential for additional improvement of the humoral immune response. First, since the genetics of capsule and O-antigen production in ExPEC are well-described (Russo, 2002), construction of additional capsule and O-antigen-deficient derivatives should be straightforward. Our data support that a molecular epidemiologic approach, possibly incorporating virulence gene profiling and multilocus sequence typing, has the potential to identify prototypic strains from relatedness groups

for use in a polyvalent vaccine containing multiple formalin-killed capsule and O-antigen-deficient constructs. The goal for such a vaccine would be to generate a polyclonal antibody response against surface-exposed epitopes in 90–100% of ExPEC isolates. Second, we hypothesize that ExPEC factors other than capsule and O-antigen may adversely modulate the host's acquired immune response or that a dominant antigen may narrow the immune response. If/when identified, disruption of the corresponding genes may further improve the host's antibody response. Third, adjuvants have the potential to enhance the immune response. Fourth, although lipidA toxicity should be less of an issue with mucosal immunization, if necessary, constructs can be generated in which the bioactive properties of lipidA have been minimized (Somerville et al., 1996). Lastly, if certain epitopes/proteins are shown in future studies to be critical in conferring protection against ExPEC infection, they can be overexpressed in the genetically engineered background that results in the optimal antibody response.

PROSPECTS FOR THE FUTURE

Although the development of an effective vaccine against ExPEC will be challenging, continued efforts in this area will likely lead to success (Russo and Johnson, 2006). Pursuit of this goal will be driven in part by the need for a human vaccine, but also by vaccine development against *E. coli* strains that cause infections in domesticated animals, which are responsible for a variety of infectious syndromes that result in a significant economic burden. Animal and human isolates of *E. coli* share common virulence factors, global genomic similarities, and in some cases are indistinguishable (Johnson et al., 2001b, 2005d, 2007; Moulin-Schouleur et al., 2007). In humans, the first target population will probably be women who suffer from recurrent UTIs. However, given the overall number of ExPEC infections and the fact that ExPEC is a leading cause of severe sepsis, with sepsis ranked as the tenth overall cause of death in the United States, we envision a broader population benefiting from an efficacious ExPEC vaccine. The high rate of *E. coli* bacteremia (3× higher than *S. pneumoniae*) in the elderly identifies them as one such population (Jackson et al., 2005). Two major approaches are likely to be pursued.

The first will be the continued identification and evaluation of ExPEC vaccine candidates (e.g., adhesins, iron-regulated and constitutively expressed OMPs, and perhaps lipid A/core saccharides of LPS). Because surface polysaccharides (e.g., capsule, O-antigen) exhibit antigenic heterogeneity, limited immunogenicity, and poor immunological memory, if not protein conjugated, at present they seem to be less viable candidates. Likewise, because adhesins possess significant antigenic variability, development of a broadly efficacious ExPEC vaccine based solely on adhesin antigens will also be challenging. At present, a number of studies support the use of OMPs as potential ExPEC vaccine candidates. The OMPs assessed to date are relatively conserved and have been shown to confer protection in several animal infection models. A potential problem may be that nearly all ExPEC strains possess capsule and O-antigen, and these surface polysaccharides may impede antibody binding to OMP antigens. Due to the variable prevalence of virulence factors in ExPEC strains, and the diversity of virulence factor profiles observed in different clonal groups of ExPEC, we predict that a polyvalent vaccine will be necessary to confer broad protection. Besides eliciting bactericidal antibodies (i.e., those that enhance complement-mediated bactericidal activity and/or bactericidal activity mediated by professional phagocytes via opsonization) against a variety of antigenic targets, a polyvalent vaccine also has the potential to inhibit the function of multiple virulence factors (e.g., adhesins, iron-acquisition proteins) necessary in the pathogenesis of ExPEC infection, thereby maximizing its efficacy. A potential limitation of this approach is the effort/money needed to identify and assess multiple vaccine candidates. Further, purification of proteins, especially OMPs, in an antigenically appropriate form may be challenging.

An alternative and more novel paradigm would be the continued development of a whole-cell vaccine. Immunization with whole *E. coli* has certain potential advantages. First, given that commensal *E. coli* and ExPEC are part of the normal human flora, mucosal immunization with whole organisms will likely be safe. Second, utilization of whole organisms has the potential for the development of bactericidal antibodies to multiple antigenic targets. Third, whole organisms may possess natural adjuvants (Jeannin et al., 2002, 2003). Lastly, immunization with whole organisms has the potential for development of bactericidal antibodies directed against conformational and linear epitopes. However, this approach also has potential limitations. Nasal immunization with killed, whole ExPEC strains is likely to generate antibodies directed against antigens present in commensal *E. coli* strains that constitute part of our normal intestinal flora. Whether this has the potential to modify the carriage of commensal *E. coli*, and if so, whether this might adversely affect the host, is unknown. Although nasal immunization can generate both a mucosal and a systemic response,

an adjuvant may be needed to generate an immune response of sufficient magnitude to confer protection (Couch, 2004). There is strong evidence implicating the use of heat-labile *E. coli* enterotoxin as an adjuvant (for nasal immunization with an inactivated influenza vaccine) in the development of Bell's palsy (Mutsch et al., 2004). Therefore, prior to consideration of nasal immunization with an ExPEC vaccine formulation in humans, it will be necessary to develop a safe mucosal adjuvant. Lastly, given the antigenic complexity of a killed ExPEC vaccine and the possibility of biologically active components, there will undoubtedly be increased scrutiny by regulatory bodies regarding safety issues.

In summary, development of a polyvalent subunit vaccine or a genetically engineered killed whole-cell vaccine will be challenging. However, achieving this goal is important because of the medical–economic burden attributable to infections due to ExPEC.

KEY ISSUES

- An efficacious ExPEC vaccine would prevent disease and may be cost effective in women with recurrent UTIs and probably other high-risk groups for ExPEC infection, such as the elderly.
- ExPEC surface polysaccharides possess significant antigenic heterogeneity, making their use as vaccine targets challenging.
- ExPEC adhesins (e.g., P fimbriae and type 1 pilus), iron-regulated OMPs (e.g., IroN), and lipid A/core saccharides of LPS are immunogenic, and when used as immunogens confer protection in various animal infection models.
- Human phase 1 studies have been completed for vaccines based on the type 1 pilus adhesin (FimH and its chaperone protein FimC) and on detoxified J5 LPS (lipid A/core saccharides) complexed to *N. meningitidis* group B OMPs; however, no phase 2/3 data have been published.
- A variety of whole-cell vaccine formulations, administered via the vaginal or oral route for the prevention of recurrent UTI, have been assessed in animal models and human clinical trials in Europe. These hold some promise but require further evaluation.
- One option for a successful ExPEC vaccine will be the development of a polyvalent subunit vaccine composed of some combination of adhesins, OMPs, and perhaps detoxified lipid A/core saccharides of LPS.
- An alternative approach will be the construction of a whole-cell vaccine that contains multiple strains of killed, genetically engineered derivatives of pathogenic wild-type ExPEC in which factors that impede an optimal host immune response (e.g., capsule, O-antigen) have been inactivated and critical antigenic determinants are overexpressed.
- Development of either a polyvalent subunit vaccine or a genetically engineered killed whole-cell vaccine will be challenging. However, achieving this goal is important because of the medical–economic burden attributable to infections due to ExPEC.

OUTLINE

ABSTRACT

Along with other sexually transmitted diseases, gonorrhoeae has an enormous impact on global human health, as the World Health Organization estimates that 62 million new gonococcal infections occur annually. Syndromes range from uncomplicated cervicitis in women and urethritis in men to upper tract infection and pelvic inflammatory disease in women with consequent reproductive tract damage, and rarer cases of invasive disease; asymptomatic infections are also common in women. Ocular infections that threaten eyesight can occur in infants born to infected women. Untreated gonorrhea also facilitates the spread of HIV-AIDS. Although the causative

agent, *Neisseria gonorrhoeae*, is usually sensitive to modern antibiotic treatments, the spread of antibiotic resistance is causing concern that these options may become limited. Most major gonococcal surface antigens are hypervariable and their expression is subject to phase variation, but considerable advances have been made in elucidating the molecular mechanisms that govern these, and in comprehending gonococcal pathogenesis. Conserved antigens of current interest include NspA and the transferrin-binding proteins, but comparison with *Neisseria meningitidis* suggests that others might exist. The systemic and genital tract immune response to uncomplicated gonorrhea is generally weak and poorly understood, and repeated infections are common. While *N. gonorrhoeae* deploys multiple mechanisms to evade destruction by host immune defenses, the concept is emerging that it also avoids inducing adaptive immunity and manipulates host responses to its own advantage. A previous attempt to develop vaccines based on pilus antigen proved ineffective, and efforts to create a porin-based vaccine have stalled. Experimental studies are hampered by the lack of good animal models as gonorrhea is an exclusively human infection. Concerted, new, and sustained effort is required to identify suitable gonococcal antigenic targets, define the parameters of immune protection against gonococcal infections in vivo, comprehend the mechanisms of both male and female genital tract immune defense against infection, and devise novel immunization strategies for eliciting immune protection in the male and female genital tracts. Sociopolitical barriers to the deployment of the resources required to accomplish these goals need to be overcome.

INTRODUCTION

Gonorrhea is an ubiquitous, worldwide sexually transmitted disease (STD) that is most common in developing nations and it disproportionately afflicts underprivileged and urban populations. It is also widely acknowledged that gonorrhea is underreported, and its true incidence is probably much greater than the official numbers. While about 90% of men typically display symptoms within a few days of infection, in women symptoms are more nonspecific and at least 30–50% (possibly more) of infected women are asymptomatic or go unrecognized (Hook and Handsfield, 1999). Moreover, women bear the brunt of morbidity as untreated cervicitis can progress to upper tract infection and pelvic inflammatory disease (PID), leading to subsequent tubal scarring, infertility, and risk for ectopic pregnancy. Eye infections can be acquired by babies born to infected women, or in adults by the direct transfer of infected material, in both cases leading to corneal scarring and blindness. Though an infrequent complication of genital infection, disseminated gonococcal infection is a systemic bacteremic condition most often involving the skin or joints, leading to septic dermatitis, arthritis, or other manifestations. Untreated gonorrhea is a risk factor for the acquisition of HIV, although the mechanisms underlying this are incompletely understood.

Since the beginning of the antibiotic era, the gonococcus (*Neisseria gonorrhoeae*) has regularly developed resistance to antibiotics used for treatment, including penicillin, tetracycline, and most recently the fluoroquinolone, ciprofloxacin. Although anecdotal evidence suggests that some cases of uncomplicated gonorrhea may be self-limiting and clear spontaneously after a few months, it can also persist for years. Furthermore, it does not leave a state of effective specific immunity, but can be acquired repeatedly with no apparent diminution in probability, severity, or duration. This has led to the speculation that *N. gonorrhoeae* interacts with the human immune system in a manner that is little understood, but that results in failure to generate an adaptive immune response.

Gonorrhea therefore represents a challenging problem in infectious disease, both from the public health and clinical standpoint, and scientifically. Great strides have been made in comprehending the molecular biology of *N. gonorrhoeae* (its genome has been completely sequenced), and in elucidating its pathogenic mechanisms and colonization of the human male and female genital tracts (Edwards and Apicella, 2004). Comprehension of the immune response against the gonococcus and how this can be manipulated to generate protective immunity to gonorrhea are, however, limited, and efforts over many years to develop an effective vaccine have not yet been successful.

HISTORICAL ASPECTS OF GONORRHEA

While gonorrhea is likely an ancient human affliction and apparent references to it can be seen in the Bible and other ancient writings, it was not until the 18th century that it was recognized as a distinct disease from syphilis; credit for this is given to Benjamin Bell (1749–1806), a surgeon in Edinburgh, Scotland (Benedek, 2005). The causative agent, now known as *N. gonorrhoeae*, was first recognized microscopically in specimens of pus by Albert Neisser (1855–1916) at the University of Breslau in 1879, and confirmed by Arpad Bokai (1856–1919) at the University of

Budapest in 1880. Thus, the gonococcus was among the earliest bacteria to be associated with human disease. However, controversy persisted for several years because it proved impossible to infect animals such as rabbits or dogs, and brave efforts on the part of investigators to infect themselves or other volunteers with cultures were initially unsuccessful. Indeed the difficulty of culturing the gonococcus and of distinguishing it morphologically from other micrococci undoubtedly contributed to this until the gram stain was developed (1884) and better culture media were devised.

The British lawyer James Boswell (1740–1795), better known as the biographer of Samuel Johnson, left copious personal papers describing 12–19 episodes of gonorrhea over the course of some 30 years (Ober, 1970). These reveal, besides his profligate lifestyle, that the infections subsided (presumably cleared) after several months or more, but left no evident state of immunity against repeated infection—or recrudescence. The advent of sulfonamides in 1936, followed by penicillin in 1943, provided effective and rapid therapy, but antibiotic resistance soon emerged. In the United States, gonorrhea rates peaked in 1975 at >460 reported cases per 100,000 population, and thereafter declined substantially. However, in recent years there has been concern that the trend has leveled out or may even be increasing again in both the United States and Western Europe. The worldwide incidence, estimated at 62 million cases per year (WHO, 2001), however, reveals that gonorrhea represents a major international health issue for which there is a huge unmet need to provide treatment and effective preventative measures.

ETIOLOGIC AGENT: *NEISSERIA GONORRHOEAE*

Classification

N. gonorrhoeae is one of two pathogenic species of the genus *Neisseria*, the other being *Neisseria meningitidis* (Sparling, 1999). *Neisseria* is classified in the family Neisseriaceae within the phylum Proteobacteria (β subgroup) of the Eubacteria (Janda and Gaydos, 2007). *N. gonorrhoeae* typically appears as an aerobic gram-negative diplococcus that lacks a polysaccharide capsule (Fig. 49.1). It is nutritionally demanding, requiring enriched media such as chocolate agar or modified Thayer-Martin agar for growth. In the past, diagnosis has usually depended on microscopy and culture (Janda and Gaydos, 2007), but in developed nations nucleic acid amplification tests have been found somewhat more sensitive and easier to use (Peeling et al., 2006), and have become the preferred method for diagnosis of urogenital infection.

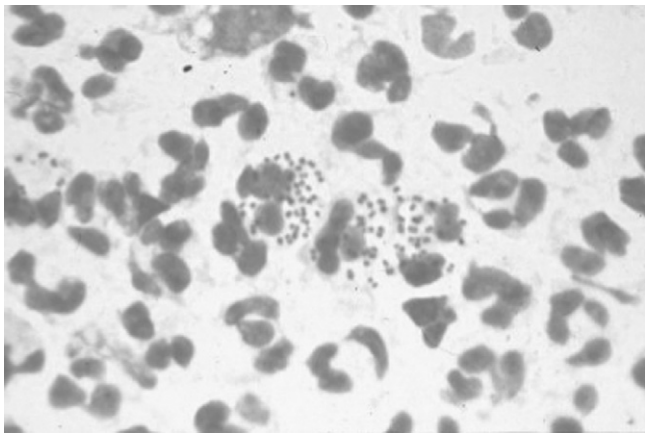

FIGURE 49.1 *N. gonorrhoeae* in a gram-stained smear of exudate from a case of gonorrhea. Note the presence of gram-negative diplococci within neutrophil leukocytes.

Antigens Encoded by N. *gonorrhoeae*

The antigens of *N. gonorrhoeae* are complex and highly variable, but unlike the closely related *N. meningitidis* (see Chapter 53) it does not possess a polysaccharide capsule. Most of the major surface components are subject to phase variation in which their expression can be up- or down-regulated spontaneously or modified in response to environmental signals. These factors have complicated both serological classification of *N. gonorrhoeae* (and hence its utility for epidemiological tracing) and analysis of the immune response to infection. *N. gonorrhoeae* is also naturally transformable, thus horizontal transfer of genes and the proteins, including antigens, encoded by them can readily occur. The major surface antigens are listed in Table 49.1, and are discussed below.

Lipooligosaccharide (LOS)

N. gonorrhoeae possesses a lipooligosaccharide (LOS) anchored in the outer membrane through lipid A, with short, triple-branched, and variable glycan chains (Apicella et al., 1987; Burch et al., 1997). These depend on glycosyltransferases some of which are subject to off–on expression through phase variation determined by a slip–strand mispairing mechanism resulting from poly-G tracts in the coding sequences of the genes (Yang and Gotschlich, 1996). However, some of the oligosaccharides mimic host glycolipid epitopes (Mandrell et al., 1988). In addition, LOS can be sialylated by means of a gonococcal sialyltransferase

TABLE 49.1 Major antigens of *Neisseria gonorrhoeae*

Antigen	Functions and properties[a]	Comments[a]
LOS	Outer membrane integrity; adhesin; host cell interactions	Abs bactericidal (if LOS not sialylated); T-independent Ag; glycan chains variable
Porin	Major OMP; anion exchange channel; host cell interactions	Constitutive; 2 main serovars plus several subtypes; Abs bactericidal if LOS not sialylated and in absence of Ab to Rmp
Opa proteins	Host cell interactions; immunosuppressive	Expression phase variable; >50 types
Rmp	Protects porin	Highly immunogenic, induces blocking Ab
Pili	Adhesin; host cell interactions	Expression phase variable; highly heterogeneous; type-specific Abs inhibit homologous pilus adherence
H.8	Conserved lipoprotein epitope	Present in *Neisseria meningitidis* and other neisseriae
NspA	Conserved small OMP; function unknown	Abs conformation dependent, bactericidal; present in *N. meningitidis*
Tbp	Iron uptake (binds human transferrin)	Abs inhibit iron uptake and adherence, bactericidal
IgA1 protease	Cleaves human IgA1 and lysosomal LAMP1; inhibits S-IgA function; promotes intracellular survival	Constitutive; few antigenic variants; Abs inhibit enzyme activity

[a]See text for explanations and further discussion.

for which the host supplies the substrate, cytidine monophosphate-*N*-acetylneuraminic acid (Mandrell et al., 1990; Smith et al., 1995). Some, though not all, of the glycan subunits are immunogenic, and antibodies to them can induce complement-dependent bacteriolysis. However, sialic acid residues on LOS interfere with this bactericidal activity by facilitating the binding of the complement regulatory factor H (Ram et al., 1998). Other LOS glycan structures enhance resistance to complement by binding the regulatory protein, C4b-binding protein (Ram et al., 2007).

Gonococcal LOS is highly endotoxic, probably through interaction with Toll-like receptor (TLR) 4 and CD14, and contributes significantly to the inflammatory response induced by gonococcal infection and the resulting damage to tissues such as the fallopian tube (Gregg et al., 1981). However, LOS is not considered a prime candidate for a vaccine antigen unless its toxicity can be reduced or eliminated. In addition, carbohydrate antigens are usually T-independent unless coupled to proteins. Moreover, sialylation of LOS inhibits the bactericidal activity of complement-fixing antibodies against it (Estabrook et al., 1997).

Porin

Porin (P.I) is the major outer membrane protein (OMP) constituting ~30% of all gonococcal surface protein. Only one porin is present, designated PorB (in contrast to *N. meningitidis* which has two porins, PorA and PorB). Gonococcal porin is the basis of a serovar classification determined by means of a panel of monoclonal antibodies (Sarafian and Knapp, 1989). Two major porin types exist, P.I-A and P.I-B, each having numerous subtypes. Porin is a homotrimeric molecule, which forms a pore in the outer membrane, and probably functions as an ion channel. As a major surface protein that is constitutively expressed in all strains and one of the least variable, it has been proposed as a vaccine antigen (see below). This is supported by findings that antibodies against it mediate in vitro complement-dependent bacteriolytic and opsonic activities (Virji et al., 1986, 1987). Within the gonococcal outer membrane, porin is closely associated with both LOS and another protein designated Rmp (reduction-modifiable protein) or P.III, and conventional biochemical purification usually results in preparations of porin that are contaminated with Rmp. When these are used to immunize animals, antibodies induced by Rmp may block complement-dependent bacteriolysis mediated by antibodies to porin (Rice et al., 1986). Thus efforts at developing vaccines based on porin have required procedures that eliminate Rmp yet preserve the native conformation of porin (Wetzler et al., 1992). Sialylation of adjacent LOS molecules also interferes with the bactericidal activity of antibodies to porin (Elkins et al., 1992).

Porin has been found to stimulate human T and B lymphocytes (Wetzler et al., 1996; Mackinnon et al., 1999) and interact with TLR2 (Massari et al., 2002; Singleton et al., 2005). Thus, it is likely to be of significance for the interactions of gonococci with the human immune system (Massari et al., 2003).

Opacity (Opa) Proteins

The Opa proteins (P.II) represent a large family of polymorphic OMPs found in *N. gonorrhoeae*; they were named because their expression governs the appearance (opacity) of the colonies on agar plates. Approximately

50–60 proteins and genes have been described, and each isolate appears to possess about 10–12 *opa* genes. Opa protein expression is controlled by a slip–strand mispairing mechanism arising from the presence of a variable number of a pentanucleotide (CTCTT) repeats in the signal sequences of the *opa* genes. An individual gonococcus can simultaneously express up to 3 or 4 Opa proteins, which can be switched off or on again spontaneously. Opa switching has been observed in vivo, both in humans and in colonized mice (Jerse et al., 1994; Jerse, 1999), but it does not appear to be driven by selective pressure arising from the host's specific immune responses.

Whereas a few gonococcal Opa proteins have been found to bind to heparan sulfate proteoglycans, the majority bind in a species-specific manner to certain human cell surface receptors of the carcinoembryonic antigen-related cell adhesion molecule (CEACAM) family (Popp et al., 1999; Virji, 2000). This interaction probably facilitates gonococcal colonization and invasion of epithelial cells, which express CEACAM1, CEACAM5, and CEACAM6 on their apical surfaces. Recognition of CEACAM1, the only member of the family that is expressed on T cells, by Opa-expressing gonococci results in the suppression of T-helper cell activity by signaling through an ITIM (immunoreceptor tyrosine-based inhibition motif) present on the intracellular tail of CEACAM1 (Boulton and Gray-Owen, 2002). Similar effects have been reported in human B cells (Pantelic et al., 2005). This is postulated to represent one mechanism by which *N. gonorrhoeae* suppresses the development of specific immunity in the host, and it has therefore been suggested that, for example, outer membrane vesicles used as a vaccine candidate should be depleted of CEACAM1-binding Opa proteins (Lee et al., 2007). However, CEACAM3, an activating receptor having an intracellular ITAM (immunoreceptor tyrosine-based activating motif), has been proposed as an adaptation that allows human neutrophils to phagocytose and kill Opa-expressing gonococci (Sarantis and Gray-Owen, 2007).

Pili

Gonococcal type IV pili are surface filamentous structures that mediate initial host cell contact, and are considered to be important virulence factors essential for human infection (Swanson et al., 1987). Pilus expression is subject to phase variation. Structurally, pili consist of numerous pilin subunits, which are generated when "silent" non-expressed genes in several *pilS* loci are recombined into the *pilE* expression locus (Segal et al., 1985; Hamrick et al., 2001; Criss et al., 2005). This results in an extremely large number of highly variable pilin sequences, yet the conserved regions of pilin are shrouded in the core of the assembled pilus (Parge et al., 1995), and there is little or no antibody response to the conserved residues (Forest et al., 1996; Hansen et al., 2007). Phosphorylation and glycosylation add to the structural heterogeneity (Hegge et al., 2004). PilC has been identified as the adhesin moiety at the pilus tip (Rudel et al., 1995) that interacts with CD46 on epithelial cells (Källström et al., 1997), although the identification of CD46 as the pilus receptor has been questioned (Tobiason and Seifert, 2001). CD46 is a complement regulatory protein (membrane cofactor protein) that serves as a receptor for several other human pathogens, including measles virus and *Streptococcus pyogenes*, and its ligation results in immunosuppressive effects (Riley-Vargas et al., 2004). Ligation of CD46 on human $CD4^+$ T cells leads to the development of T-regulatory cells and the production of the immunosuppressive cytokine, IL-10 (Kemper et al., 2003). Indeed piliated gonococci have been shown to induce IL-10 secretion by human T cells (Plant and Jonsson, 2006).

Several studies have shown that antibodies to gonococcal pili can block adherence and mediate opsonization (Rothbard et al., 1985; Virji and Heckels, 1985), although the protective epitopes are highly variable. However, as the pilus type of infecting gonococci changes rapidly, well before any immune response can be mounted (Swanson et al., 1987; Seifert et al., 1994) it is unlikely that an immune response could be effective against such a moving target.

H.8 Lipoprotein

H.8 is a conserved antigenic determinant found on *N. gonorrhoeae* and *N. meningitidis* and some commensal neisseriae, and defined by a monoclonal antibody (Cannon et al., 1984). Further investigation revealed that at least two proteins contain the repeated epitope, AAEAP, one being a lipoprotein with an azurin-like sequence (Kawula et al., 1987). Its role in gonococcal pathogenesis is unknown, although antibodies against it have been found in the sera of convalescent patients (Black et al., 1985).

NspA

A search for conserved proteins in meningococci using a panel of monoclonal antibodies against outer membrane preparations identified one such protein that was present in all strains of *N. meningitidis*, designated NspA (Martin et al., 1997). Interest was stimulated by the finding that the defining monoclonal antibody exerted complement-dependent bacteriolysis and conferred passive

protection against challenge. NspA was later identified also in *N. gonorrhoeae* with few amino acid variations (Plante et al., 1999), and antibodies against it were found in sera of infected patients (Hedges and Russell, unpublished observations). However, NspA is a small OMP (~16 kDa) and its crystallographic structure reveals it to be mostly inserted in the membrane with only three small surface-exposed loops (Vandeputte-Rutten et al., 2003). While bactericidal antibodies recognize the L3 loop, this is a conformational epitope whose structural integrity depends on the association of NspA with the lipid membrane and detergent-solubilized NspA is not recognized (Cadieux et al., 1999; Hou et al., 2003). Thus, it has proven difficult to generate protective antibodies that recognize native NspA on the gonococcal surface, although efforts to exploit it as a potential vaccine antigen against meningococci have continued (Martin et al., 2000). The biological function of NspA remains unknown. NspA deletion mutants of *N. meningitidis* grow satisfactorily in culture media and are virulent in an infant rat bacteremia model (Moe et al., 2001), but as it is constitutively expressed in all clinical isolates presumably it has an important role for the growth of the bacteria in the natural human host.

Transferrin-Binding Protein

Like most other pathogenic bacteria, *N. gonorrhoeae* has evolved several mechanisms to acquire iron from the host in which it occurs only in protein-bound form (Cornelissen and Sparling, 1994; Schryvers and Stojiljkovic, 1999). Indeed, pathogenic neisseriae utilize a ferric iron-uptake regulator (Fur) mechanism to sense low environmental iron concentrations and regulate the expression of many genes in response to such conditions in vivo (Grifantini et al., 2003). Among the proteins that are up-regulated in low iron conditions are the transferrin-binding proteins, TbpA and TbpB (Cornelissen et al., 1997, 2000; Ronpirin et al., 2001), which have been found to be essential for virulence in a human challenge model (Cornelissen et al., 1998). Moreover, Tbps are constitutively expressed, not subject to phase variation, and are relatively well conserved (Cornelissen et al., 2000; Agarwal et al., 2005). Surface-exposed loops of TbpA have been defined (Yost-Daljev and Cornelissen, 2004). The specificity of gonococcal Tbps for human transferrin might contribute to the unique host specificity of *N. gonorrhoeae* for humans. However, as with most other gonococcal antigens, natural uncomplicated infection does not lead to the development of potent antibody responses against Tbp (Price et al., 2004). These considerations make gonococcal Tbps potential vaccine candidates. Intranasal immunization of mice with gonococcal TbpA and TbpB conjugated to cholera toxin (CT) B subunit induces circulating and vaginal antibodies that exert bactericidal activity against heterologous strains (Price et al., 2005). In a further development of this approach, functional domains from TbpA and TbpB were genetically fused to the A2 subunit of CT and co-expressed with CT B subunit to create chimeric immunogens. Intranasal immunization of mice with these constructs also induced serum bactericidal and vaginal growth-inhibiting antibodies (Price et al., 2007).

N. gonorrhoeae also produces analogous lactoferrin-binding proteins (LbpA and LbpB) that are able to sequester iron from human lactoferrin, the iron-binding protein found in secretions (Blanton et al., 1990). However, only about half of all clinical isolates express Lbp, and it therefore does not appear to be an essential virulence factor, although it can partly substitute for Tbp in the male challenge model (Anderson et al., 2003).

IgA1 Protease

Both *N. gonorrhoeae* and *N. meningitidis* produce an IgA1 protease that cleaves human IgA1 (not IgA2) at a Pro–Ser or Pro–Thr bond in the hinge region (Kilian and Russell, 2005). This enzyme is constitutively expressed in all clinical isolates, and is believed to serve as a virulence factor. However, definitive proof of this assertion has been difficult to obtain, because of the unique specificity of IgA1 proteases for human (and other anthropoid ape) IgA1, thereby making conventional animal models inapplicable. Because an IgA1 protease-deletion mutant was found to colonize isolated fallopian tube explants to the same extent as wild-type gonococci it was originally suggested that IgA1 protease is not an essential virulence factor (Cooper et al., 1984). However, this conclusion is undermined by the absence of the relevant enzyme substrate, IgA1 anti-gonococcal antibodies. Vaginal washes from infected women contain gonococcal IgA1 protease that can cleave IgA1 in vitro (Blake et al., 1979), but we were unable to identify the characteristic cleavage fragments of IgA1 in genital secretions from infected women (Hedges et al., 1998a), possibly due to the presence of IgA1 protease-inhibiting antibodies (Lomholt et al., 1995a). Gonococcal IgA1 protease also cleaves the lysosomal protein LAMP-1, thereby enhancing intracellular survival (Hauck and Meyer, 1997; Lin et al., 1997), although degradation of LAMP-1 alone appears to be insufficient to promote gonococcal survival within phagosomes (Binker et al., 2007). In contrast to other bacterial pathogens, there is relatively little antigenic variation in neisserial IgA1 proteases

(Lomholt et al., 1995b), thus they too remain a potential target antigen for inclusion in a gonococcal vaccine.

AniA

AniA (originally called Pan1) is the major anaerobically induced OMP of *N. gonorrhoeae* that possesses nitrite reductase activity (Clark *et al.*, 1987). Antibodies to AniA have been detected in patients with both uncomplicated and complicated gonorrhea as well as disseminated gonococcal infection (Clark *et al.*, 1988), indicating that it is expressed in vivo. AniA expression has been linked to enhanced resistance to complement-mediated killing of gonococci (Cardinale and Clark, 2000), suggesting that it might be a vaccine candidate, but AniA appears to be antigenically heterogeneous and no specific studies of its potential as a vaccine antigen have been reported.

OmpA-Like Protein

A 23 kDa gonococcal OMP homologous to OmpA of *Escherichia coli* has been described and shown to have a significant role in adherence to and invasion of human cervical and endometrial carcinoma cells (Serino *et al*., 2007). This protein is also required for intracellular survival of *N. gonorrhoeae* within macrophages following its uptake, and a deletion mutant shows diminished recovery in the murine vaginal infection model. Thus gonococcal OmpA appears to be a virulence factor, but its potential as a vaccine antigen has not been reported.

Other Potential Antigens: Lessons from Meningococcal Vaccine Development

Considerable effort has been devoted in recent years to the development of new and improved vaccines against *N. meningitidis*, because capsular polysaccharide vaccines are of limited value or unavailable in the case of serogroup B. Given the relatedness of the two species, the search for meningococcal protein-based vaccine candidates may also suggest useful avenues of exploration for gonococcal vaccine development. Neisserial outer membrane vesicles containing surface protein antigens and depleted of reactogenic components such as LOS, or incorporating mutant LOS of diminished reactogenicity, show considerable promise (Bakke et al., 2001; Fisseha et al., 2005). Genome mining has identified several meningococcal genome-derived neisserial antigens (GNA), including GNA33 (Adu-Bobie et al., 2004), GNA1870, GNA1946, GNA2132 (Jacobsson et al., 2006), and also NadA (Comanducci et al., 2004). A universal meningococcal vaccine has been developed from a cocktail of such antigens (Giuliani et al., 2006). As the genome of at least one strain of *N. gonorrhoeae* has been sequenced, genome mining should be a feasible approach in this case also.

PROTECTIVE IMMUNE RESPONSE

It is a well-known clinical observation that gonorrhea can be contracted repeatedly, and despite multiple exposures no state of effective immunity is conferred after recovery (Noble et al., 1977). A study in commercial sex workers in Nairobi, Kenya, suggested that multiple exposures diminished the probability of reinfection with the homologous serovar of *N. gonorrhoeae*, implying the development of partial serovar-specific immunity (Plummer et al., 1989), but this finding was not repeated elsewhere (Fox et al., 1999) although few persons are at comparable risk for infection as those who took part in the former study. Numerous studies have assessed antibody responses in both serum and the local genital secretions. However, these efforts have been complicated by several factors, including the extraordinary antigenic variability of the gonococcus, which makes it difficult to select target antigenic preparations against which to measure antibody responses. In addition, longitudinal and prospective studies that would allow the measurement of antibody levels before, during, and after an infection have been difficult to conduct among persons at highest risk for infection, such as the clientele of STD clinics. The sensitive nature of the disease has also obviated accurate record keeping, such that previous episodes of infection cannot always be reliably documented. Moreover, as cervical infection in women may frequently be asymptomatic, cases often go undetected for prolonged periods and it is not always possible to determine when an infection was acquired in a positive-testing individual. All of the above factors have contributed to difficulty in defining correlates of protective immunity to gonorrhea. Indeed, the prevailing paradigm holds that whereas the host might generate an adaptive immune response to *N. gonorrhoeae*, its extraordinary capacity to vary its surface antigens and to resist complement-mediated lysis enables the gonococcus to evade the impact of the host's specific immune responses against it. However, an emerging view is that *N. gonorrhoeae* also avoids inducing effective immune responses in the first place. Most studies on the immune response to gonorrhea have examined subjects with a spectrum of disease conditions, adding to the complexity of interpretation, or

have focused on uncomplicated lower tract infections, i.e., gonococcal cervicitis and urethritis. Rigorous, comparative, and quantitative studies of immune responses to different states of gonococcal infection, i.e., asymptomatic, uncomplicated, salpingitis or PID in women or epididymitis in men, and disseminated infection, have not been conducted.

Antibody

A large number of studies have documented the presence of antibodies to *N. gonorrhoeae* in the serum and local genital secretions of both men and women infected with gonorrhea (Kearns et al., 1973a, 1973b; O'Reilly et al., 1976; Tapchaisri and Sirisinha, 1976; Tramont, 1977; McMillan et al., 1979a, 1979c, 1979b; Tramont et al., 1980; Ison et al., 1986; Tramont, 1992; Price et al., 2004). However, some anti-gonococcal antibodies probably induced by cross-reactive antigens of *N. meningitidis* or commensal neisseriae can also be detected in individuals who have never been exposed to *N. gonorrhoeae*. We applied quantitative methods to the analysis of IgM, IgG, and IgA antibodies serum and secretions of subjects at enrollment and treatment and at recall approximately 2 and 4 weeks later, in comparison with age- and gender-matched control subjects presenting at the same clinic but proven microbiologically not to be currently infected with *N. gonorrhoeae* (Hedges et al., 1998b, 1998a, 1999). To reduce the impact of antigenic variability, antibodies were assayed against a standard laboratory strain and against each patient's homologous isolate. Although modest levels of antibodies were detected in serum and secretions, and more to the homologous isolate, in general antibodies were not much higher in infected than in currently uninfected subjects. Antibody levels mostly declined at recall visits, and no correlation was found with known history of prior infection. We concluded that despite the typical generation of an acute inflammatory reaction in symptomatic patients, the adaptive humoral immune response, both local and systemic, to uncomplicated gonorrhea is minimal.

As discussed above, several studies have shown that serum antibodies (predominantly IgG) to various gonococcal antigens, including LOS, porin, and pili, can induce complement- or neutrophil-mediated killing of gonococci in vitro. Whether these conditions are always met in vivo is questionable, because *N. gonorrhoeae* at least in uncomplicated disease remains largely a superficial mucosal infection that colonizes and invades the genital mucosal epithelium. It has been proposed that the ratio: [(anti-porin IgG + anti-LOS IgG)/anti-Rmp IgG] predicts the bactericidal activity of human serum and hence immunity to gonococci (Rice et al., 1994). However, this hypothesis has not been rigorously tested, and while it is plausible that complement-mediated bacteriolysis plays an important role in invasive gonococcal infection (as it does in meningococcal disease), the extent to which it is essential for immune defense within the lumen and mucosa of the genital tract is open to question. Gonococci are able to survive partially within neutrophils (Shafer and Rest, 1989; Jerse and Rest, 1997; Simons et al., 2005), and as noted above possess several mechanisms for avoiding destruction by complement. Furthermore, the immune defense mechanisms in the genital tract, especially that of the male, are not well understood (Russell and Mestecky, 2002). Although secretory IgA (S-IgA) is found in both male and female secretions and has been shown to be locally produced and transported especially in the cervix of the female tract (Kutteh, 1999) or in the penile epithelial glands of Littré in the male (Anderson and Pudney, 1999), IgG, probably largely of systemic origin, is the predominant Ig isotype in both male and female tracts. Although antibody-mediated inhibition of gonococcal attachment to epithelium has been demonstrated (Tramont, 1977), and is a known function for S-IgA antibodies in general (Russell and Kilian, 2005), the function of IgG antibodies in the genital tract is less clear. Whether all complement components are present in genital secretions at sufficiently high concentration to form a functional bacteriolytic system is unclear. Furthermore, IgA antibodies or their $F(ab')_2$ fragments generated by the action of IgA1 proteases have been shown to interfere with IgG antibody-mediated complement activation (Griffiss and Goroff, 1983; Russell et al., 1989; Jarvis and Griffiss, 1991; Hamadeh et al., 1995). Thus, although complement-mediated bacteriolysis is considered to be a major mechanism of defense against systemic meningococcal disease and possibly also in disseminated gonococcal infection, it is debatable whether it holds the same significance for local mucosal gonococcal infections.

Cell-Mediated Immunity

Cellular immune responses in gonorrhea have been even less well investigated, probably because the clinical picture of the disease does not suggest the involvement of significant cell-mediated immunity (CMI) or delayed-type hypersensitivity reactions to *N. gonorrhoeae*. Lymphocyte proliferation and leukocyte migration-inhibition assays have revealed that patients with gonorrhea display CMI to gonococcal extracts, usually to a greater degree than control subjects (Kraus et al., 1970; Esquanazi and Streitfeld, 1973; Grimble and McIllmurray, 1973; Kearns et al., 1973b; Wyle et al., 1977; Landolfo et al., 1981). Peripheral blood T cells from patients with gonorrhea proliferate in response

to gonococcal porin, and a significant proportion of these cells are Th2 cells that express $\alpha4\beta7$ integrin, the receptor for the mucosal addressin MAdCAM-1 (Simpson et al., 1999). Neisserial porins enhance the expression of the costimulatory ligand B7-2 (CD86) on murine B cells, thereby enhancing T cell stimulation, and they also stimulate responses in neutrophils (Bjerknes et al., 1995; Wetzler et al., 1996; Mackinnon et al., 1999; Simpson et al., 1999). Further studies are necessary to investigate the cellular and regulatory aspects of the immune response in gonorrhea. As antibody responses require the participation of T cells and antigen-presenting cells, it is possible that the paucity of both antibody and cytokine responses in gonorrhea might be due to inadequate activation of these cell types, or their modulation by gonococcal factors.

Inflammatory cytokines IL-1β, IL-6, IL-8, and TNF-α have been found in the urine and plasma of men experimentally infected with *N. gonorrhoeae* (Ramsey et al., 1995), and exposure of epithelial cells in culture to *N. gonorrhoeae* induces the synthesis of IL-1β and TNF-α, probably through the NF-κB pathway (Naumann et al., 1997). Some women with gonorrhea, especially those with concomitant infections due to *Chlamydia trachomatis* or *Trichomonas vaginalis*, showed high circulating levels of inflammatory cytokines but not in the genital secretions (Hedges et al., 1998b). There is little published information on the cytokine response to naturally acquired gonorrhea in men; we found that the cytokine response in men with gonococcal urethritis was weak, although IL-8, which is normally present in semen (Pate et al., 2001), was elevated (Hedges and Russell, unpublished observations).

EPIDEMIOLOGY

Significance as a Public Health Problem

Gonorrhea has worldwide distribution, and WHO estimates that 62 million new infections occur annually, most of these occurring in sub-Saharan Africa and South and Southeast Asia (Fig. 49.2). Although by the 1990s it had been almost eliminated from Western

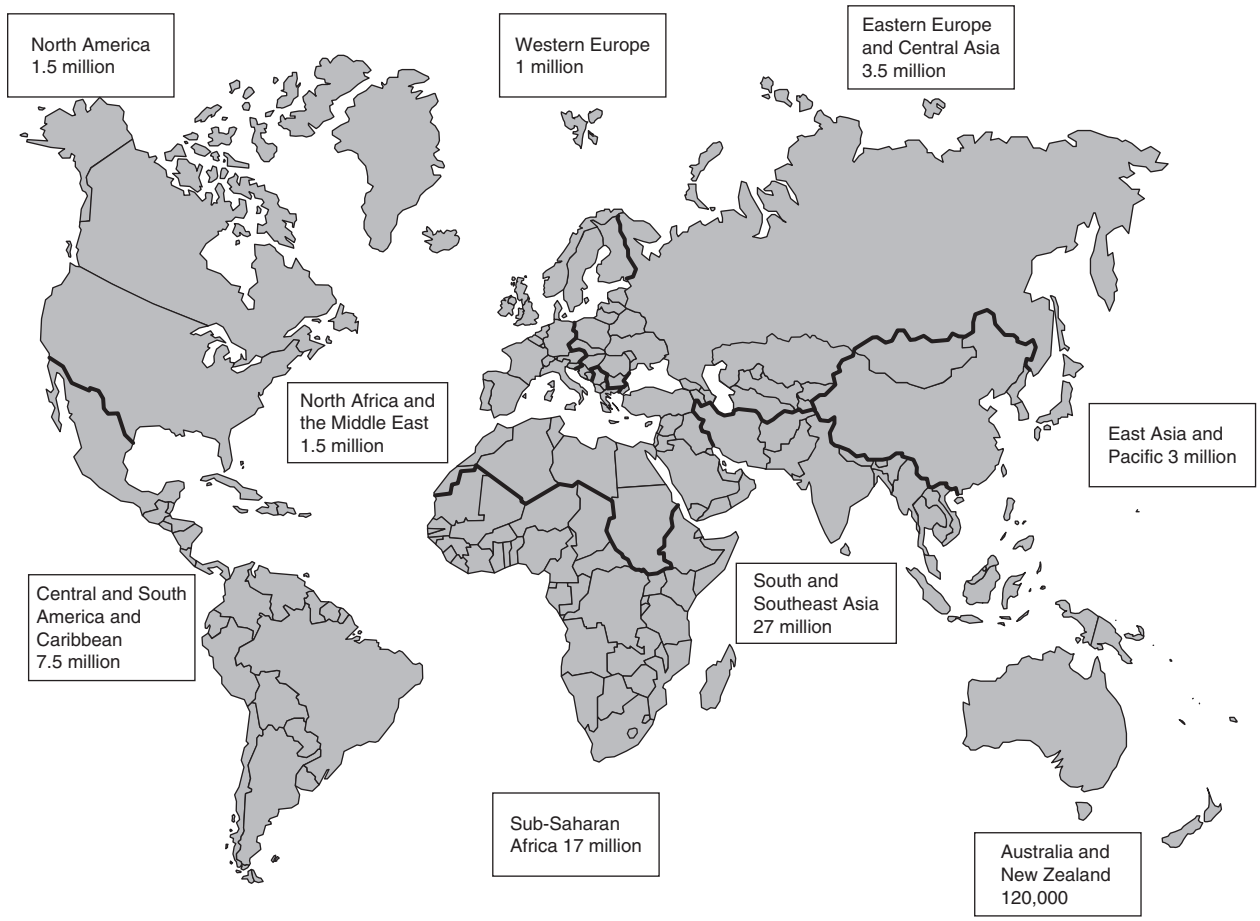

FIGURE 49.2 Worldwide distribution of gonorrhea according to WHO estimates for 1999 (WHO, 2001).

Europe (<20 cases per 100,000 population, even fewer in Sweden at 2.4 cases per 100,000 in 1996) (WHO, 2001), recent increases are thought to have resulted from increased migration from the former Soviet Union and Eastern European countries where rates remained higher. Among Western nations, the United States has the highest rate at >327,000 reported cases in 2006 (>100 cases per 100,000 population) making it the second-most-frequent, notifiable infectious disease (CDC, 2007), but the majority of cases occur in the Southeastern states and among African-Americans. In all communities, gonorrhea occurs overwhelmingly among the sexually active age-groups, i.e., 15–50 years of age. With an estimated incidence of >60 million new infections annually, it is clear that gonorrhea represents a major international health issue that is inadequately addressed.

Potential as a Biothreat Agent

N. gonorrhoeae is not considered to constitute any threat as a potential agent for biowarfare or terrorism. It is far too sensitive to environmental conditions other than enriched growth media, including dehydration and non-physiological temperatures, to survive for longer than a few minutes outside of the human body.

CLINICAL DISEASE

The clinical spectrum of gonococcal infections comprises asymptomatic mucosal infection of any site potentially exposed in the course of sexual contact, through symptomatic local infections, and upper genital tract and systemic complications (Hook and Handsfield, 1999). Thus, sexually exposed persons may acquire gonococcal infection not only at urogenital sites but also at the pharynx or rectum where infections are more often asymptomatic than not. Asymptomatic and unidentified infections at all mucosal sites are associated with increased risk for complications of infection (see below) and they contribute substantially to the persistence of *N. gonorrhoeae* in communities. Persons who are unaware of their infections lack the cues provided by signs and symptoms to seek health care and may thus unknowingly transmit the organism to others.

In men, the most common clinical manifestation of gonorrhea is symptomatic urethritis that typically presents with urethral discharge and dysuria about 3–5 days following exposure to an infected sex partner. The discharge of classical gonococcal urethritis is most often grossly purulent and on gram-stained smears large numbers of polymorphonuclear leukocytes are present, some of which contain ingested organisms seen as gram-negative diplococci (Fig. 49.1). In a small proportion of infected males, the spread of urethral infection to the epididymis and testis leads to acute gonococcal epididymitis.

The description of the clinical spectrum of disease in women is more complex. Gonococcal infection is one of many potential causes of vaginal discharge and the most common symptoms, vaginal discharge or dysuria, are present in about 50% of infected persons. On speculum-guided pelvic examination, some women with gonococcal cervicitis may have purulent endocervical discharge. In addition to the uterine cervix, other common sites of gonococcal infection in women include the urethra and Bartholin's glands. In 15–40% of infected women, untreated infection may ascend to cause complicated upper genital tract infection involving the endometrium and fallopian tubes, even giving rise to peritonitis. This clinical syndrome is often referred to as PID and the scarring resulting from upper genital tract infections in turn substantially increases the risk of infertility and ectopic pregnancy, as well as chronic pelvic pain and increased risk of repeat episodes of PID.

In addition to local genital infections, a small proportion (approximately 1%) of untreated infections may spread hematogenously to cause disseminated gonococcal infection, a bacteremic illness which is most often manifest as a septic dermatitis or asymmetric septic arthritis. Rarely, gonococcal bacteremia may infect heart valves to cause endocarditis or even, very rarely, meningitis.

TREATMENT

Uncomplicated gonococcal infections can be readily cured by the administration of single-dose antibiotics, while persons with complicated infections are treated longer, typically for 10–14 days. In the United States, gonorrhea treatment is guided by the Centers for Disease Control and Prevention's STD Treatment Guidelines (CDC, 2006), an evidence-based document which is periodically revised to represent current best practices for treatment of most STDs other than HIV-AIDS.

Since the availability of sulfa drugs heralded the beginning of the modern antibiotic age, however, *N. gonorrhoeae* has regularly become resistant to the drugs used to treat it. Gonococci develop antibiotic resistance either through the selection of chromosomal mutations conferring resistance to drugs,

as has occurred for penicillins, tetracyclines, macrolides, spectinomycin, and fluoroquinolone antibiotics, or through acquisition of plasmids containing antibiotic-resistant genes, as has occurred for both penicillins and tetracyclines to date. Until recently the regular availability of new antibiotics has allowed the recommendation of alternative therapies as gonococcal antibiotic resistance has emerged. In recent years, however, increasingly widespread resistance to fluoroquinolone antibiotics such as ciprofloxacin has left third-generation cephalosporin antibiotics (e.g., ceftriaxone or cefixime) as the primary drugs recommended for treatment of gonorrhea with few alternative therapies. It is reasonable to expect that *N. gonorrhoeae* will eventually become resistant to cephalosporin and related beta-lactam drugs, and the question is "when" rather than "whether" this will happen. This in turn emphasizes the importance of efforts to develop vaccines to prevent gonorrhea.

PATHOGENESIS

The pathogenic process of gonococcal infections has been extensively reviewed by Edwards and Apicella (2004) who discuss at length the differences between infections of the male and female tracts. These authors proposed a model of the infectious process incorporating the following features. In males, following exposure to an infected sex partner, initial attachment of gonococci to urethral epithelial cells depends on pili, and is succeeded by endocytosis involving Opa proteins, LOS, and porin. A quiescent phase lasts for up to 40 h after infection during which gonococci cannot be cultivated, probably because they are residing within epithelial cells. As the organism grows, LOS is largely responsible for eliciting the acute inflammatory response that ensues after a few days, including the production of cytokines such as TNFα, IL-1β, IL-6, and IL-8 and the recruitment of neutrophils, giving rise to the symptoms of infection. Opa proteins are also involved in the interaction of gonococci with neutrophils and their non-opsonic phagocytic uptake by these cells. Indeed, it has been proposed that Opa-CEACAM3 interactions are responsible for neutrophil activation and subsequent intracellular killing of gonococci. However, at least some gonococci are able to survive within neutrophils. Endocytosis by urethral epithelial cells appears to result from the interactions between LOS and the asialoglycoprotein receptor. However, sialylation of LOS impairs both invasion of epithelial cells and phagocytic uptake by neutrophils.

Although gonococci transmitted from men to women are mostly sialylated and sialylation can occur within the female tact, infection of cervical epithelial cells does not appear to be affected by sialylation. Indeed it is speculated that desialylation by host neuraminidases facilitates the transmittal from women to men (Edwards and Apicella, 2004). Although cell lines derived from female tract epithelium can release inflammatory cytokines when cultured with gonococci in vitro, this is not necessarily what happens in vivo, and female infections are frequently asymptomatic, i.e., they display no evidence of an inflammatory response. However, production of complement components by cervical epithelium results in deposition of C3b on the gonococcal surface by alternative pathway activation and the rapid inactivation of this to C3bi, which allows invasion of the epithelial cells through their expression of complement receptor 3. Pili and porin are also involved, but probably not Opa proteins. Progression to upper tract infection, which can occur in 45% of women with untreated gonococcal cervicitis, is facilitated by hormonal changes and menstruation is known to enhance the onset of PID or disseminated infection. Gonococci adhere to non-ciliated cells in the fallopian tubes, and this leads to loss of ciliated cells possibly through the production of inflammatory cytokines. Disseminated infections have been associated particularly with gonococci that express porin type P.IA, which binds complement factor H leading to inhibition of alternative pathway activity and enhancing resistance to complement-mediated lysis.

The immune response to infection has been discussed above.

VACCINES

History

In the early 1900s crude whole-cell vaccines were often applied as a treatment for gonorrhea that was believed to work by enhancing opsonization (Eyre and Stewart, 1909)—then much in vogue following its demonstration by Wright and Douglas (1903). Subsequent efforts to develop prophylactic vaccines have, however, been frustrated by the difficulty of creating suitable animal models of the disease. Small animal models (rabbits, mice) were attempted in the 1930s and 1940s [reviewed in Arko (1989)]; later more extensive work was done using chimpanzees (Lucas et al., 1971) and subcutaneous chamber models in various laboratory animals (Arko, 1972). While skin chamber models, particularly in guinea pigs, allowed characterization of some aspects of pathology and the definition of various "immunotypes" (Chandler

et al., 1976; Wong et al., 1979), they, like most other species, have proved to be inadequate models of human genital infection. Furthermore, susceptibility to guinea pig complement did not accord with resistance to human complement (Arko, 1989). The establishment of gonococcal urethritis in male chimpanzees and transfer of the infection to females afforded a model more closely resembling the human disease (Brown et al., 1972), but several practical, economic, and now ethical issues have impeded the widespread use of primate models to study gonococcal pathogenesis and immunity. Interestingly, it was found that parenteral immunization with formaldehyde-fixed gonococci induced substantially greater protective immunity than prior experimental infection (Arko et al., 1976). However, a vaccine made from lysed gonococci proved to be ineffective when tested in humans (Greenberg et al., 1974).

Several groups have developed human challenge models to study various aspects of virulence and immune response in humans (Swanson et al., 1987; Cohen and Cannon, 1999; Schmidt et al., 2001). However, for ethical reasons (i.e., the far higher risk for upper genital tract complications and sequelae in women) these are limited to males only. Moreover, as infections are terminated by antibiotic treatment on development of symptoms or after 1 week, only short-term effects can be studied. Nevertheless, such models may provide a preliminary test of vaccine efficacy. Meanwhile, a mouse vaginal challenge model has been successfully resurrected and shown to be reproducible (Jerse, 1999), although it inevitably suffers the shortcomings of all rodent models in not replicating all facets of the human disease, it can be used to test initial vaccine potential (Plante et al., 2000).

Because of demonstrations in vitro that antibodies to pili could block gonococcal attachment to epithelial cells, which were supported by findings in subcutaneous chamber models, a major effort was mounted to develop a gonococcal pilus vaccine (Tramont et al., 1981; Siegel et al., 1982). This vaccine was successful in eliciting genital antibody responses to homologous pili (McChesney et al., 1982), but in a large-scale field trial it proved completely ineffective (Boslego et al., 1991). Given what is now known about gonococcal pilus structure and the molecular basis of its antigenic hypervariability, this outcome viewed in hindsight is not surprising and there is little current interest in pursuing pilus-based gonococcal vaccines.

The finding that some monoclonal antibodies were bactericidal against a range of gonococci of different porin serovar spurred the development of a porin-based vaccine (Heckels et al., 1989; Elkins et al., 1992). Because of the association of porin with LOS and Rmp, recombinant porin was renatured and incorporated into liposomes that induced antibodies capable of binding to the gonococcal surface and causing bacteriolysis (Elkins et al., 1994). An alternative formulation was prepared from gonococci engineered to delete expression of Rmp (Wetzler et al., 1992). Such preparations are highly immunogenic, probably on account of the adjuvant effect of porin (Lowell et al., 1988). A gonococcal porin vaccine was prepared by Wyeth-Lederle Vaccines (Matsuka et al., 1998), but it does not appear to have been tested as yet in clinical trials.

Current Licensed Vaccines

There are no currently licensed vaccines against gonorrhea.

Vaccines in Development

Although a few candidate vaccine antigens continue to be investigated in laboratories (Table 49.2), none since the gonococcal pilus vaccine has progressed to clinical trial, and pursuit of a porin-based vaccine appears to have stalled. The current sociopolitical and funding scenario in the United States is not conducive to the development of gonococcal vaccines. No dedicated charitable foundations exist to support research into STDs (other than HIV-AIDS), and major pharmaceutical manufacturers seem averse to embarking on new vaccine programs. Studies on gonococcal pathogenesis and immunity, the discovery of gonococcal antigens, and efforts to develop vaccines have been discussed above.

TABLE 49.2 Gonococcal antigens under investigation as potential vaccine candidates

Antigen	Status[a]
Porin	Liposomal formulations developed; immunogenicity and protective potential shown in animals and in vitro; clinical trials pending?
NspA	Immunogenicity and protective potential shown in animals and in vitro (meningococcal vaccines)
Tbp	Immunogenicity shown in animals; protective potential of Ab shown in vitro
LOS	Not known; potential for coupling constitutive oligosaccharides to protein carriers, or using anti-idiotypic or peptide mimics

[a]See text for discussion.

POSTEXPOSURE IMMUNOPROPHYLAXIS

Postexposure immunoprophylaxis, either passive or active, has not been considered for gonorrhea as treatment with appropriate antibiotics is usually effective. Moreover, the short incubation period before the development of symptoms (at least in males), would probably not allow time for the development of an active immune response *de novo*, and inadequate understanding of the correlates of immune protection does not afford a basis for passive administration of preformed antibodies. Early efforts to use therapeutic immunization to treat gonorrhea (see above), although apparently partially successful, did not include adequate controls, and they were supplanted by the advent of chemotherapy.

PROSPECTS FOR THE FUTURE

Efforts at developing vaccines against gonorrhea have fluctuated over several decades as enthusiasm has grown and receded, according to measures of success in comprehending gonococcal pathogenesis and immunity or, conversely, the perceived difficulty, as the complexity of these issues has emerged. Undoubtedly, an important factor is the sociopolitical priority accorded to a disease that is all too often regarded as a matter of morality with strong religious overtones. At the same time it is clear that *N. gonorrhoeae* presents significant scientific challenges because it is an extremely well-adapted and successful human pathogen that exploits weaknesses in not only the human reproductive tract and immune system but also in our behavior. The unfortunate outcome of the pilus vaccine initiative probably had a knock-on effect in undermining the effort to develop a porin-based vaccine, which has not yet proceeded to even a Phase I clinical trial. Whether or not it might be ultimately successful in progressing toward a workable vaccine, a thoughtfully planned trial could yield an abundance of valuable information about human genital tract immune responses.

The hypervariability of most of the major surface antigens of *N. gonorrhoeae* probably means that LOS, pilus, and Opa proteins are not viable candidates for vaccine antigens. Even a "cocktail" vaccine consisting of multiple components selected to represent the spectrum of commonly encountered gonococcal antigens seems an unlikely prospect at present, and might make the cost of such a vaccine too high for use in underdeveloped nations where it is most needed. Progress has stalled over the identification of novel, conserved gonococcal antigens, yet the genome-mining approaches recently pursued for the identification of novel antigens in *N. meningitidis* could surely also be applied to *N. gonorrhoeae*. In addition, major efforts to develop new meningococcal vaccines based on conserved protein antigens or native outer membrane vesicles containing the non-capsular surface components could usefully suggest similar approaches to a gonococcal vaccine.

An important aspect is an improved understanding of immunity to infection in the male and female genital tracts (Russell and Mestecky, 2002). The focus of reproductive immunology has hitherto been on the remarkable mechanisms involved in permitting the engraftment of a semi-allogeneic fetus in the uterine wall without resulting in immunological rejection. The mechanisms of immune response against and delivery of immune effectors to infectious agents have been much less explored, even in the female tract, and almost not at all in the male tract. Yet, recent successes in developing vaccines against human papillomaviruses and herpes simplex virus type II, both of which are genital infections, indicate that it should be possible to develop vaccines against other genital tract pathogens. It has been known for some time that the genital tract (both male and female) is an effector site of the so-called "common mucosal immune system" (Russell and Mestecky, 2002), in the sense that mucosal immune responses induced at remote inductive sites elsewhere can result in the development of S-IgA antibody responses in the genital secretions. Neither the male nor female tracts, however, contain such inductive tissues as typified by intestinal Peyer's patches or Waldeyer's ring in the upper respiratory tract. In these mucosa-associated lymphoid tissues (MALT) organized lymphoid follicles are overlain by a specialized follicle-associated epithelium which samples the luminal contents and passes antigenic materials to the underlying immune-responsive cells. The MALT structures appear to be necessary to disseminate the responding B and T cells to remote mucosal effector sites. For reasons that have been incompletely elucidated, but probably involve the selective expression of chemokines as well as mucosal addressins and homing receptors on the cells involved, mucosal IgA responses induced in the upper respiratory MALT (tonsils in humans, nasal lymphoid tissue in rodents) have a strong propensity to be expressed in the genital tract (Wu et al., 2000; Gallichan et al., 2001). In addition, antigen-presenting dendritic cells have been identified within and underneath the genital tract epithelium, where they likely function to induce local immune responses (Hussain and Lehner,

1995). Investigation and exploitation of these immune response mechanisms for the protection of the genital tract against pathogens need to be vigorously pursued.

A major new advance in immunology in the past few years has been the discovery of a third subset of helper T cells designated "Th17" on account of their ability to produce IL-17 (Weaver et al., 2007). Th17 cells span the divide between innate and adaptive immunity, and by producing IL-17 as well as other downstream factors, elicit inflammatory responses including the mobilization of neutrophils and defensins. While on one hand this results in inflammatory and autoimmune damage—which has been the main focus of interest in Th17 responses so far—it is becoming clear that the Th17 axis of immunity plays an important role in defense against bacterial pathogens (Happel et al., 2003; Yu et al., 2007), including those of mucosal surfaces, and especially those involving an acute inflammatory response. Yet, investigators in microbial pathogenesis and infectious diseases have been slow to pursue this development. Whether *N. gonorrhoeae* is among the numerous bacterial pathogens that elicit Th17 responses remains to be determined, but initial evidence suggests that it might do so (Feinen et al., 2008). If that is correct, then new paradigms in gonococcal pathogenesis and immunity might emerge.

KEY ISSUES

- Sustained effort is required to identify novel, conserved gonococcal antigens as targets for protective immunity.
- The mechanisms and surrogate measures of protective immunity to gonococcal infection in the genital tract should be defined.
- An improved understanding is needed of immune defense mechanisms, their induction and delivery, within both male and female genital tracts.
- Immunization strategies should be devised for the generation of protective immune responses within the genital tract.
- Efforts should be directed to generate and maintain stable, long-term political and financial commitment to the development of vaccines against STDs (other than HIV-AIDS).

OUTLINE

ABSTRACT

Helicobacter pylori (*H. pylori)* is possibly the most widespread human pathogen worldwide. Since it was initially suggested in 1983 by Marshall and Warren to be implicated in gastritis and peptic ulcer disease, *H. pylori* has also been implicated in gastric carcinoma and was classified as a class I carcinogen. During the last two decades, a significant body of research has revealed the multiple processes that this Gram-negative bacterium activates to cause gastroduodenal disease in humans. Most infections are acquired early in life and may persist for the entire life of the individual. While infected individuals mount an inflammatory response, which becomes chronic, along with a detectable adaptive immune response, these responses are ineffective in clearing the infection. *H. pylori* has unique features that allow it to reside within the harsh conditions of the gastric environment and also to evade the host immune response. Although only a fraction of infected individuals develop the significant clinical diseases associated with this infection, it is important to eradicate *H. pylori* from humans. Current therapies based on proton pump inhibitors and antimicrobials are effective but fail at times due to poor compliance and the development of antibiotic resistance by *H. pylori*. Therefore, an effective vaccine is clearly needed. This chapter reviews the association of *H. pylori* with human disease, the best-characterized virulence factors, the host response, and vaccine development efforts to date. Although major advances have been made in our understanding of how *H. pylori* interacts with humans, this bacterium keeps on surprising investigators and there are still many unanswered questions that need to be addressed in order to develop an effective vaccine.

INTRODUCTION

Helicobacter pylori (*H. pylori*) is perhaps the most common human pathogen, and has the unique ability to colonize the human gastric mucosa. The clinical importance of this bacterium has become recognized relatively recently. Before the discovery of *H. pylori*, the stomach was not generally considered a niche that pathogens could infect because it is an inhospitable environment where the gastric juice and low pH are able to digest most things and clearly possesses a strong bactericidal action.

SHORT HISTORY OF THE DISEASE

In the 19th century, there were some initial reports of spiral-shaped bacteria in the stomach of dogs and humans, but their characterization and relevance to disease were not determined until almost 100 years later. There is evidence that *H. pylori* has been infecting humans for thousands of years, since pre-Columbian mummies and mummified human feces at least 3000 years old have been found to harbor *H. pylori* (Allison et al., 1999). Also, a study by Blaser and colleagues suggested that human infection by *H. pylori* may have occurred at least 11,000 years ago based on the finding of Asian strains of *H. pylori* in Amerindian populations in remote regions of the Amazon (Ghose et al., 2002). They interpreted their findings to suggest that the ancestors of present-day Amerindians were infected with *H. pylori* when they migrated from Asia and crossed the Bering Strait 11,000 years ago to colonize the Americas.

These gastric bacteria were isolated and cultured by two investigators in Perth, Western Australia, Barry Marshall and J. Warren, who detected the curved bacilli in the stomachs of patients with chronic gastritis and peptic ulceration (Marshall et al., 1984; Marshall and Warren, 1984). Isolation and growth of the bacteria was not a straightforward undertaking since the bacteria were slow to grow. When these investigators initially suggested that gastritis and ulcers might be associated with infection with these bacteria, the scientific community met their proposal with significant skepticism. To address this skepticism, Marshall and another volunteer acted as guinea pigs to try to fulfill Koch's postulates. They self-administered broth cultures of the bacteria. Both volunteers developed gastritis, underwent endoscopy, and provided biopsies from which the bacteria were reisolated. Following the reports of this team of Australians, who initially referred to this bacteria as *Campylobacter pyloridis*, others were also able to culture *H. pylori* from gastric biopsies of patients with gastritis. These studies triggered substantial interest in determining the involvement of this bacterium in other gastric diseases. The association of the infection with this bacterium and ulcers was deduced later from epidemiological studies and was strengthened by observations that antimicrobial therapy had a curative effect on ulcers.

A decade after the seminal studies of Warren and Marshall, the World Health Organization International Agency for Research in Cancer classified *H. pylori* as a class I carcinogen, after epidemiological and statistical studies linked the infection with a higher risk of gastric malignancy. In 2005, Warren and Marshall became the recipients of the Nobel Prize in Physiology or Medicine for their discovery of *H. pylori* and its role in gastritis and peptic ulcer disease.

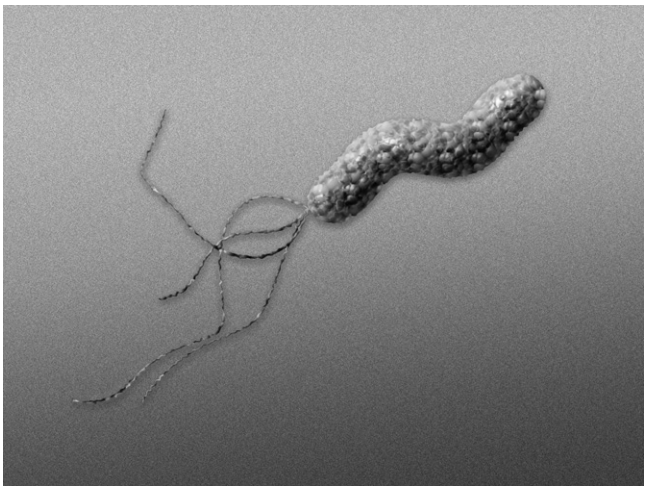

FIGURE 50.1 The flagellated, spiral-shaped bacteria, *Helicobacter pylori*.

Since the studies of Marshall and Warren, significant advances have been made in our understanding of how this human pathogen interacts with its host. This chapter will review historical aspects of the diseases associated with *H. pylori* infection, characteristics of the bacterium, the host response, virulence mechanisms, how the disease is treated, and what preventive measures are in development.

ETIOLOGIC AGENTS

The *Helicobacter* genus was introduced in 1989 with *pylori* as the first species classified. Members of the genus *Helicobacter* are Gram-negative, spiral-shaped, microaerophilic bacteria that are often characterized by sheathed flagella (Fig. 50.1). There are at least 20 characterized species of the genus *Helicobacter*, with several species capable of colonizing the stomach of humans and other animals (Table 50.1). The best recognized and characterized of these species is *H. pylori*. There is also one species, *Helicobacter hepaticus*, which infects the human liver. The shape of this microorganism and its motility, made possible by flagella, are crucial characteristics that facilitate penetration and colonization of the mucosal environment. The mucous covering the epithelial lining of the stomach provides a protective niche for *Helicobacter* from hydrochloric acid in the lumen of the stomach, while the epithelium protects the bacteria from immune responses. Upon making its way through the mucosal layer, *H. pylori* utilize some of their surface proteins as adhesins to attach to membrane-associated receptors on gastric epithelial cells.

TABLE 50.1 Species of the *Helicobacter* genus known to infect humans or animals and the tissue infected

Species	Host	Tissue colonized
Helicobacter pylori	Human	Stomach
Helicobacter acinonychis	Feline	Stomach
Helicobacter hellmanni	Human, feline, canine	Stomach
Helicobacter felis	Feline, canine	Stomach
Helicobacter bizzozeronii	Feline, canine	Stomach
Helicobacter salomonis	Feline, canine	Stomach
Helicobacter pullorum	Poultry	Intestine, liver
Helicobacter rodentium	Rodent	Liver, intestine, gallbladder
Helicobacter fennelliae	Canine	Intestine
Helicobacter trogontum	Rodent	Intestine
Helicobacter hepaticus	Rodent	Liver
Helicobacter muridarum	Rodent	Intestine
Helicobacter canis	Canine, feline	Intestine, liver
Helicobacter bilis	Rodent	Liver
Helicobacter cinaedi	Human, primate	Intestine
Helicobacter pametensis	Poultry	Stomach
Helicobacter mastomyrinus	Rodent	Intestine, liver
Helicobacter cholecystus	Rodent	Gallbladder, liver
Helicobacter mustelae	Ferret	Stomach

VIRULENCE FACTORS

Adhesins

In order to colonize the unwelcoming niche of the stomach and to induce pathogenesis, *H. pylori* expresses a variety of virulence factors. Adherence factors are considered virulence factors because these adhesins are necessary for colonization and maintenance of infection (Evans, Jr. and Evans, 2000). Multiple adhesins have been identified for *H. pylori*, but the ones responsible for pathogenic events are still being investigated. Several well-known adhesins are BabA, SabA, AlpAB, HopZ, HpaA, and urease. BabA and SabA bind to fucosylated and sialylated ABO blood group antigens, respectively (Fig. 50.2). There are clearly multiple adhesins and receptors for *H. pylori* because only half of the strains in the US have detectable BabA (Hennig et al., 2004). While the attachment of *H. pylori* using BabA as an adhesin does not appear to induce signaling or immune responses from host cells, SabA appears to be required for activation of neutrophils and the resulting oxidative burst by binding to sialylated neutrophil receptors (Unemo et al., 2005). Although the AlpAB receptor is unknown,

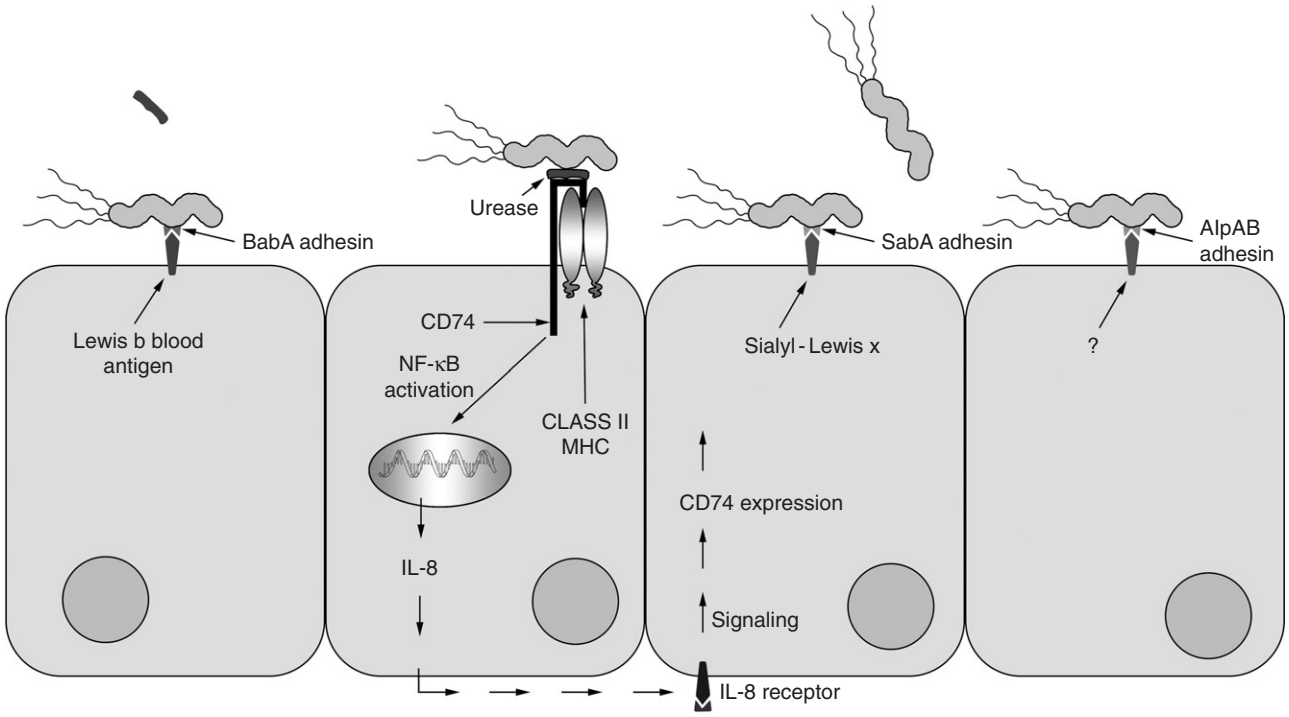

FIGURE 50.2 *H. pylori* adhesins, BabA, SabA, AlpAB, and urease binding to their respective receptors, Lewis b blood antigen, sialyl Lewis x, unknown, and CD74 and class II MHC. Engaging CD74 results in NF-κB signaling and IL-8 production, which further increases CD74 expression.

it may be even more important as an adhesin because studies with knockout strains dramatically reduced adherence of the bacteria to some cells (Odenbreit et al., 2002). In addition, AlpAB$^+$ strains activate signaling processes in epithelial cells that influence inflammatory cytokine production (Lu et al., 2007). For instance, deletion of AlpAB reduced interleukin (IL)-6 induction in gastric epithelial cells, whereas IL-8 induction was reduced by deletion of AlpAB in East Asian but not in Western strains of *H. pylori*. These observations suggested that AlpAB may induce gastric injury by mediating adherence to gastric epithelial cells and by modulating proinflammatory intracellular signaling cascades. HopZ, another adhesin being investigated, also showed decreased adherence when a knockout strain was utilized (Peck et al., 1999), but not as dramatically as the AlpAB knockout strain. The HpaA protein is another outer membrane protein (MP) that was shown to be an important adhesin in a mouse model (Carlsohn et al., 2006). *H. pylori* urease can also act as an adhesin (Fan et al., 2000). Urease present on the bacterial surface due to bacterial lysis or release (Bode et al., 1993; Rokita et al., 2000) binds to class II MHC molecules on host cells, and may induce their apoptosis (Fan et al., 2000). Since there have been multiple *H. pylori* adhesins described, bacterial adhesion is clearly a complex mechanism with multiple outcomes depending on the host cell receptor engaged.

cag Pathogenicity Island

One of the best-recognized *H. pylori* virulence factors is the *cag* pathogenicity island. This pathogenicity island is made up of 31 genes, which encode for a type IV secretion system. The system is composed of a needle-like organelle that pierces the host cell membrane and injects bacterial factors into the host cells. The most-recognized protein translocated into host cells by the type IV secretion system is the cytotoxin associated gen A (CagA) virulence factor, which is injected into the cytoplasm of host gastric epithelial cells after attachment to these cells (Odenbreit et al., 2000). CagA does not appear to have homologs in other *Helicobacter* or other bacterial species. While several genes within the island are known to be antigenic, CagA is the most virulent, and is known to undergo tyrosine phosphorylation by the Src family kinases once inside the host cell. CagA has differing numbers of tyrosine phosphorylation motifs (EPIYA motifs), which determine the virulence of the *H. pylori* strain and host cell response to it. The amount of EPIYA motifs is directly

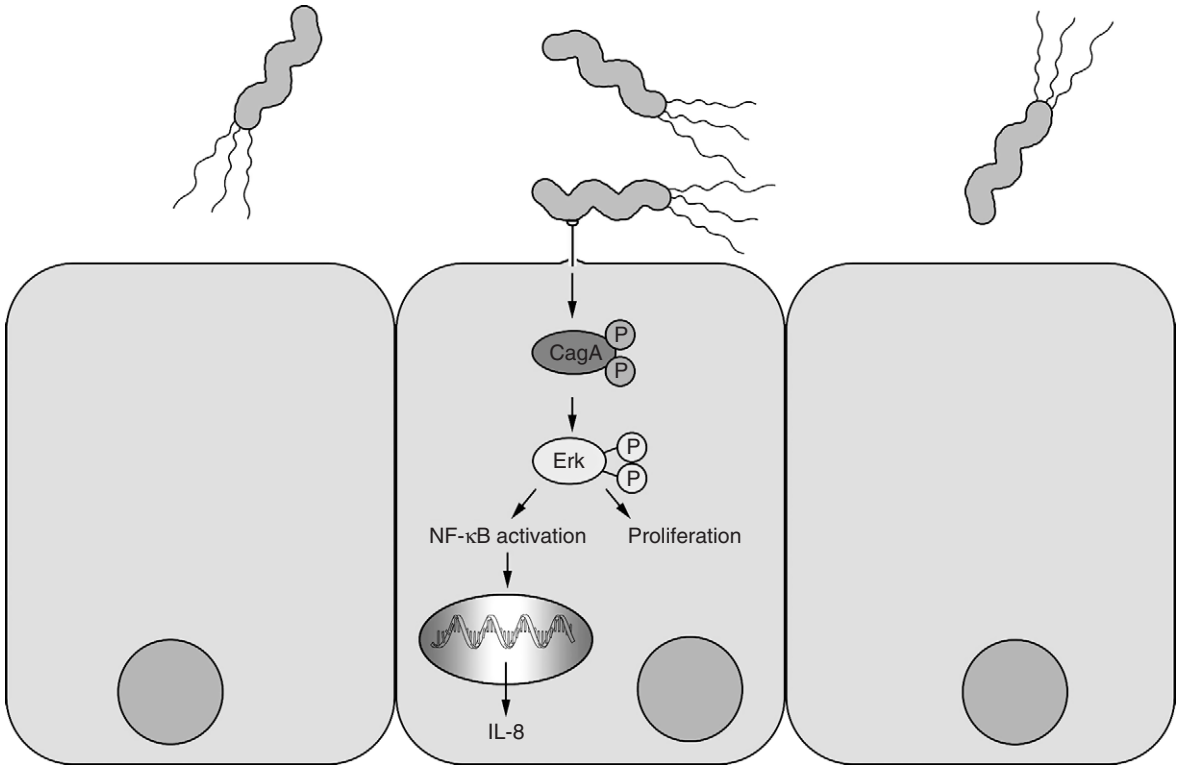

FIGURE 50.3 *H. pylori* infects CagA into a host gastric epithelial cell. After phosphorylation, ERK 1/2 signaling is induced, which leads to NF-κB activation and proinflammatory cytokine production, or changes in cell-cycle events.

related to the levels of phosphorylation and cytoskeletal rearrangement seen in epithelial cells (Figueiredo et al., 2005). Phosphorylated CagA interacts with a tyrosine phosphatase, SHP-2. Upon tyrosine phosphorylation, host cell signaling is activated, such as ERK1/2 signaling, which is responsible for changes in epithelial cell morphology and cell cycle events (Higashi et al., 2004). Through ERK1/2 signaling, NF-κB may also be activated, and upregulation of proinflammatory cytokines may also ensue (Brandt et al., 2005; Fig. 50.3). The activation of the Ras/MEK/ERK pathway occurs following the interaction of CagA with Grb2. Because CagA interacts with important signaling mediators in the host cells, it is considered responsible for changes in cell morphology, adhesion, and turnover. The CagA virulence factor has also been suggested to be associated with the induction of *H. pylori* gastric cancer (Al Marhoon et al., 2004; Chiba, 2004). Interestingly, in Asian and South American countries where 90% of strains are CagA positive, gastric cancer is more prevalent. Western countries have a higher incidence of cag^- strains, which are more likely to lead to ulcers or asymptomatic outcomes of infection. CagA found in Eastern strains has also been proposed to be more virulent and undergo more tyrosine phosphorylation than CagA from Western strains (Azuma, 2004). A recent study showed that CagA physically interacts with E-cadherin independently of CagA tyrosine phosphorylation and induces aberrant expression of an intestinal-differentiation marker (Murata-Kamiya et al., 2007). These studies suggest that CagA may play a role in the transdifferentiation of gastric mucosa to an intestinal type, a premalignant transdifferentiation that gives rise to intestinal-type gastric adenocarcinoma.

Other bacterial components proposed to be injected into host cells through the type IV secretion system are bacterial cell wall components such as peptidoglycan. One study indicates that an intracellular sensor for peptidoglycan, Nod1, which initiates NF-κB signaling and upregulation of proinflammatory immune responses (Viala et al., 2004) recognizes *H. pylori* peptidoglycan injected via the type IV secretion system. This is one of several mechanisms whereby NF-κB signaling is initiated by *H. pylori*, and the response seen during infection is likely due to several events since other bacterial factors mentioned below also induce NF-κB activation.

VacA

The vacuolating toxin (VacA), is expressed by about half of all *H. pylori* strains. Like CagA, VacA appears to be unique to *H. pylori* since no other species have a homolog. There is substantial allelic diversity for VacA between strains of *H. pylori*, which contributes to the degree of virulence it projects. VacA has two possible signal regions, s1 or s2. It also may have one of two midregions, m1 or m2, that represents the binding domain. VacA is an 88 kDa protein composed of two subunits of 33 and 55 kDa. The 55 kDa segment is utilized during attachment to the host cell, while the smaller segment forms the pore. The diversity has led to many subtypes being named, some of which can be traced geographically. Diversity between subtypes determines the degree of vacuolation and ability to form pores (Cover and Blanke, 2005). VacA s1/m1 strains are considered more virulent and are more associated with gastric cancer (Miehlke et al., 2000). The presence of *vacA* and *cagA* genes have led to the division of *H. pylori* strains into two broad families, type I and type II. Type I strains produce both VacA and CagA, while type II strains lack their expression. Type I strains are regarded as being more pathogenic and with the greater potential to cause disease.

VacA has effects on many cell types, including gastric epithelial cells, antigen-presenting cells, mast cells, and lymphocytes, which makes it an important virulence factor. This toxin is secreted by *H. pylori*, and it binds to the plasma membrane of host cells where it forms anion-selective channels in the plasma membrane of the cells. This process results in the release of nutrients from the cell, and the bacteria may use these for survival (Szabo et al., 1999). As the anion concentration becomes higher inside the cell through these pores, proton pumping also increases, as does an influx of weak bases. The weak bases are protonated and trapped inside, causing osmotic swelling and the formation of a vacuole (Cover and Blanke, 2005). VacA can also disrupt mitochondrial membrane potential and affect cellular ATP concentrations, which disrupt the cell cycle progression and lead to apoptosis (Cover et al., 2003; Kimura et al., 1999). Another significant way in which VacA contributes to pathogenesis is by inhibiting T cell activation and proliferation. When mixed with T cell lines, VacA inhibited IL-2 production and downregulated surface expression of their IL-2 receptors, which are required for T cell proliferation and viability (Cover and Blanke, 2005). Multiple signaling pathways of T cell activation are also affected by VacA exposure, which is one mechanism *H. pylori* may use to evade immune responses.

Urease

Another major virulence factor of *H. pylori* is urease, which is expressed by all strains. Urease is composed of two subunits, α, which is approximately 24 kDa, and β, which is approximately 68 kDa. *H. pylori* produces a large amount of urease, representing 5–10% of the total protein content of the bacterium. This enzyme is essential for the survival and pathogenesis of the bacteria. Perhaps the most important role urease plays is to hydrolyze urea into CO_2 and NH_3, which aids in buffering the area immediately around the bacteria from the acidic conditions it may encounter in the stomach. Urease is crucial for *H. pylori* colonization, as shown by studies where urease-negative strains were not able to colonize in multiple animal studies (Karita et al., 1995; Tsuda et al., 1994). The inability of urease-negative strains to colonize was initially assumed to be due to their inability to buffer their niche. However, similar studies under hypochloridic conditions also led to the same results where urease-negative mutants of *H. pylori* could not colonize in an animal model. These observations suggested a role for urease beyond its enzymatic function. Although much urease is located intracellularly, there is some present on the bacterial surface (Phadnis et al., 1996; Rokita et al., 2000). *H. pylori* surface-associated urease can act as an adhesin for the bacteria, which induces the production of inflammatory cytokines from both gastric epithelial cells and macrophages (Harris et al., 1998; Tanahashi et al., 2000), along with their apoptosis (Fan et al., 2000). While the mechanism of action associated with these responses elevated by urease is not entirely clear, the induction of apoptosis may result as a consequence of binding to class II MHC (Fan et al., 1998). Other studies from this group also suggest that the urease B subunit binds to CD74, or the class II MHC-associated invariant chain (Ii), and induces IL-8 production by gastric epithelial cells (Beswick et al., 2006). Both of these responses are important in the overall pathogenesis seen during *H. pylori* infection.

In addition to urease A and B, there are several other proteins involved in the urease system that are crucial to the success of the buffering system ensuring bacterial survival. The UreI protein of *H. pylori* is an integral MP that functions as a proton-gated urea channel (Weeks et al., 2000). It regulates cytoplasmic urease activity by controlling permeability to urea, which is essential for maintaining a pH where the bacteria can survive (Rektorschek et al., 2000). The importance of UreI in maintaining pH makes it crucial for survival of *H. pylori*, and its necessity has been shown in studies where UreI knockout strains failed to colonize in

animal models (Mollenhauer-Rektorschek et al., 2002; Skouloubris et al., 1998). The other urease system proteins, UreE–H, are accessory proteins required for assembly of active urease enzyme.

OipA

Another important disease-associated virulence factor of *H. pylori* is the outer inflammatory protein, or OipA. OipA is part of a family of 32 outer-MPs characterized as part of the *H. pylori* genome. This protein has been suggested to induce proinflammatory responses from gastric epithelial cell lines. In one study with *H. pylori* clinical isolates, isolates expressing OipA, but not the *cag* pathogenicity island, were able to induce IL-8 production from gastric epithelial cell lines at three times the level of strains that did not express either (Yamaoka et al., 2000). Isolates from Japan all expressed OipA, while isolates from the United States did not, and thus it is thought that the presence of OipA may make Japanese strains more virulent. When the signaling induced by cagPAI was compared to OipA, OipA was found to induce phosphorylation of Stat1, while the cagPAI induced NF-κB activation (Yamaoka et al., 2004). Both of these signaling pathways contribute to induction of IL-8 production, but act in conjunction with one another to fully activate the IL-8 promoter.

Other Virulence Factors

Lipopolysaccharide expressed by *H. pylori* is a very weak immunogen compared to that of other Gram-negative bacteria, although it has been shown to induce proinflammatory cytokines (Bliss et al., 1998). Other bacterial factors that may play a role in the induction of immune responses are neutrophil-activating protein (NAP) and heat shock protein 60 (Hsp 60) (Bai et al., 2003; Yamaguchi et al., 1998). Hsp 60 has been shown to induce proinflammatory cytokines by macrophages and gastric epithelial cells (Gobert et al., 2004; Takenaka et al., 2004), which appears to be mediated by Toll-like receptors (TLRs).

THE IMMUNE RESPONSE TO *H. PYLORI*

As reviewed in detail below, epidemiological studies have shown that about 50% of the world's population is infected by *H. pylori* and most infections are asymptomatic, making the infection lifelong without an effective bacterial elimination (McColl, 1996; Rhen et al., 2003; Svennerholm and Quiding-Jarbrink, 2003). Since the bacteria induce an immune response, the persistence of the infection suggests that the response is not effective in elimination of the infection. Furthermore, multiple lines of evidence suggest that the immune response contributes to the pathogenesis associated with the infection. As a result, the immune response induced by *Helicobacter pylori* is a theme of continuous study that has stimulated multiple questions.

The inability of the host response to clear *H. pylori* infection could reflect downregulatory mechanisms that are acting to ensure immune responses without simultaneous harmful inflammation as a mechanism to protect the host. As a result, the chronic immune response induced may not be sufficiently robust or not directed against protective antigens (Svennerholm and Quiding-Jarbrink, 2003) and could thus provide a colonization advantage for the bacteria by providing enhanced availability of adhesion places. Another mechanism where *H. pylori* can downregulate the immune response is through the VacA protein, as described in the previous section. This cytotoxin can interfere with the processing and presentation of antigens by antigen-presenting cells (APCs; Molinari et al., 1998), and also inhibiting T cell activation through interference of the calcineurin-associated IL-2 signaling pathway (Gebert et al., 2003).

Multiple studies have provided data supporting the role of some bacterial components in triggering cellular as well as humoral immune responses, while suppressing other responses. These observations have led to models that help explain how the bacteria can persist in the gastric environment generating a noneffective immune response that, together with the host factors, can determine the severity of the disease.

The Humoral Response

The noninfected human stomach is relatively free of inflammatory cells, whereas *H. pylori* infection results in dense infiltration of mononuclear cells triggering an immune response. Most individuals infected with the bacteria develop specific antibodies, which are found in serum and in gastric aspirates or extracts of stomach. Thus, high titers of IgG and IgA antibodies against MP, flagellin, urease, LPS, and HpaA have been reported in patients infected with *H. pylori* (Mattsson et al., 1998a). However, those titers do not differ between asymptomatic patients and patients with duodenal ulcer (Mattsson et al., 1998b). Studies performed with biopsies from the antral region of the stomach of noninfected and *H. pylori*-infected patients of IgM- and IgA-producing cells showed frequencies of 40- to 50-fold higher in infected subjects.

However, IgG-producing cell numbers are the same for noninfected and infected *H. pylori* subjects. Those results suggest that the infection induces a large recruitment of immune cells into the gastric mucosa, particularly IgA-producing cells.

The T-Cell Response

H. pylori infection also induces the recruitment of $CD4^+$ and $CD8^+$ T cells into the gastric mucosa, but there appears to be preferential activation of $CD4^+$ cells rather than $CD8^+$ cells (Lundgren et al., 2003). Circulating $CD8^+$ cells produce IFN-γ when they are stimulated with *H. pylori* antigens. Thus, the presence of this subset of T cells in the infected mucosa suggests that cytotoxic T cell activity can be elicited by *H. pylori* (Fan et al., 1994; Quiding-Jarbrink et al., 2001). Other subsets of T cells whose frequencies have also been reported to be increased in the antral lamina propria of subjects infected with *H. pylori* are $CD45RO^+$ memory T cells as well as activated $CD69^+$ and $CD25^+$ T cells (Stromberg et al., 2003a, 2003b).

Several studies have noted that the T helper cell response to *H. pylori* is polarized, since $CD4^+$ T cells in the gastric mucosa of infected individuals produce IL-12 and IFN-γ, whereas IL-4 production by these T cells is absent (Bamford et al., 1998; Haeberle et al., 1997). While there is a demonstrated infiltration of T cells in the gastric mucosa and most of those are $CD4^+$ T cells with markers of activation, various studies have tried to address the inefficiency of the host response in clearing the infection. Different studies have demonstrated that *H. pylori* infection can decrease T cell response as well as induce T cell anergy (Lundgren et al., 2003; Stromberg et al., 2003a). For example, memory T cells isolated from peripheral blood from infected people responded less to stimulation with *H. pylori* antigens than cells isolated from noninfected subjects (Karttunen et al., 1990; Lundgren et al., 2003; Quiding-Jarbrink et al., 2001). These results suggested the presence of regulatory T (T-reg) cells $CD4^+$ $CD25^+$ in the peripheral blood of *H. pylori* infected individuals. This notion was supported by observations that a higher responsiveness was obtained after depletion of *H. pylori*-T-reg specific cells (Baecher-Allan et al., 2001; Lundgren et al., 2003). Hence, these studies may help explain the inability of the host response to eliminate the infection due to the activation of T-reg cells. Such cells may simultaneously reduce mucosal damage mediated by T cells as well as reduce specific T cell responses that can be effective in protection against the infection.

The Gastric Epithelium as an Active Player in the Mucosal Response

In terms of providing protection, the gastric epithelium has typically been regarded as a physical barrier; however, multiple studies have provided evidence to suggest that the gastric epithelium plays a key role in the inflammatory and immune responses induced by *H. pylori*. The epithelium is the only cell phenotype in the gastric mucosa that is in direct contact with the pathogen. This feature places the epithelium in a strategic situation to interact with *H. pylori* and with the immune elements in the lamina propria. There is strong evidence to suggest that the gastric epithelium is an active player in the response while performing functions associated with antigen-presenting cells (Barrera et al., 2001; Ye et al., 1997), in addition to its well-documented ability to produce cytokines that trigger the recruitment of inflammatory cells into the gastric lamina propria (Beswick et al., 2005a; Fig. 50.4).

The production of IL-8 in response to *H. pylori* infection is one of the first epithelial responses. This chemokine acts as a chemoattractant inducing the migration of immunological components into the gastric mucosa from the periphery, particularly polymorphonuclear cells that contribute to epithelial damage (Yoshikawa and Naito, 2001) as well as macrophages. Macrophages produce nitric oxide in response to *H. pylori* urease leading to induction of additional inflammatory mediators (Gobert et al., 2002). As reviewed above, one of the major mechanisms of IL-8 induction by epithelial cells is through the injection of CagA by the type IV secretion system (Fischer et al., 2001; Henderson and Nataro, 2001; Sansonetti, 2002). This system releases CagA into the epithelial cell cytosol inducing cell proliferation and IL-8 production (Mimuro et al., 2002). Our group has recently described the interaction of *H. pylori* with CD74 on gastric epithelial cells leading to the production of IL-8, via NF-κB activation (Beswick, et al., 2005a). Interestingly, IL-8 induced by *H. pylori*, in addition to its effect in the recruitment of inflammatory cells, also acts in an autocrine manner, since gastric epithelial cells express the receptors for IL-8, and induces further expression of CD74 (Beswick et al., 2005b). Some of the interactions of the epithelium with *H. pylori* can be detrimental to the integrity of the epithelium. For instance, it has been shown that *H. pylori* use class II MHC as receptors on gastric epithelial cells and this interaction leads to apoptosis (Fan et al., 2000). This interaction is mediated via *H. pylori* urease. It has also been reported that cag genes may upregulate Fas ligand (FasL) expression leading T cells to undergo apoptosis (Wang et al., 2000).

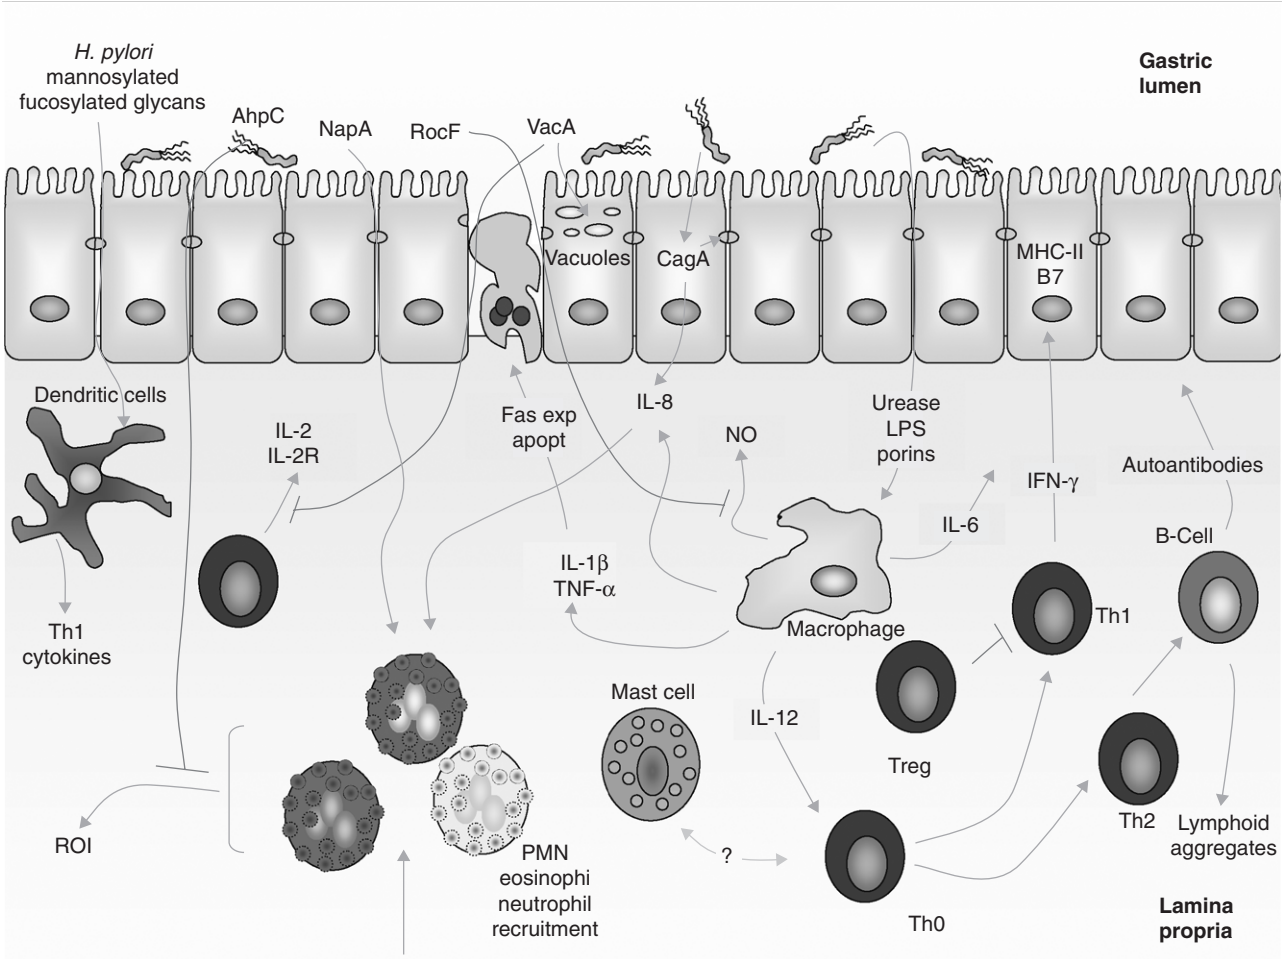

FIGURE 50.4 Immune response induced by *H. pylori*.

The Innate Response to *H. pylori*

Other potential interactions that lead to production of proinflammatory cytokines are the interactions of *H. pylori* with TLR expressed by epithelial cells. It has been reported that gastric epithelial cells express TLR4, TLR5, and TLR9 (Ishihara et al., 2004; Schmausser et al., 2004; Schmausser et al., 2005; Smith et al., 2003) that interact with LPS, flagellin, and CpG motifs, correspondingly. The expression of those receptors by epithelial cells is of importance in innate immunity against *H. pylori*.

The infected gastric mucosa contains a significant macrophage population that produce nitric oxide and IL-12 that help drive a T helper 1 response responsible for the production of IFN-γ, and little or no IL-4 and IL-5 (D'Elios et al., 1997). As alluded to earlier, the predominant Th1 response induced by *H. pylori* is not effective in controlling the infection and may have adverse effects on the host (D'Elios et al., 1997; Fan et al., 1994; Lindholm et al., 1998). Macrophages also produce other cytokines in response to *H. pylori* and these include IL-1β, IL-6, monocyte chemotactic protein 1 (MCP-1), IL-8, and TNF-α (Bliss et al., 1998). In addition to macrophages, another innate cell population that has been shown to respond to *H. pylori* with the production of cytokines includes dendritic cells that produce IL-6, IL-8, IL-10, and IL-12, and have increased expression of CD80, CD83, CD86, and HLA-DR as a result of their stimulation with *H. pylori* (Galgani et al., 2004). Thus, together with the well-documented cytokine response by the epithelium, it is not surprising that immunochemical reports show that the staining levels for most cytokines (IL-8, IL-6, TNF-α, TGF-β) are substantially increased in asymptomatic or gastric ulcer *H. pylori* positive patients when compared to basal levels expressed by noninfected individuals (Lindholm et al., 1998).

As may be expected due to the nature of the cytokines produced in response to *H. pylori*, this innate

response to *H. pylori* may have a direct effect in the subsequent adaptive response through the enhancement of processing and presentation of antigen by host cells, mainly gastric epithelial cells, and in influencing the polarity of T helper cells. The expression of class II MHC as well as other molecules, such as cathepsins, CD74 and CD86, important in the regulation of antigen processing and presentation, is increased by gastric epithelial cells in the infected mucosa (Barrera et al., 2001, 2005;Ye et al., 1997). Paradoxically, this increase in expression of class II MHC molecules and CD74 can contribute to the colonization as mentioned above.

Mast cells represent another cell phenotype that is present within the *Helicobacter*-infected gastric mucosa of humans and mice (Nakajima et al., 1997). Mast cells are also present in the gastric mucosa during nonsteroidal anti-inflammatory drug induced gastritis. While these cells represent an innate defense component and may kill bacteria through the release of proteases and other mediators, a recent study showed that they can mediate bacterial clearance in vaccinated mice, and were suggested to do so via a cross talk with $CD4^+$ T cells (Velin et al., 2005).

Autoimmunity Associated with *H. pylori* Infection

Due to the fact that almost every individual has autoreactive T cells, it has been suggested that pathogens can induce activation and proliferation of those autoreactive clones, thereby triggering autoimmune diseases. This predisposition, together with the molecular similarity between some bacterial antigens and autoantigen epitopes, provides the basis of molecular mimicry (Albert and Inman, 1999; Murali-Krishna et al., 1998; Scherer et al., 1993). Molecular mimicry may also play an important role in upregulating the immune response to *H. pylori*.

Autoimmune Gastritis

There are several known *H. pylori* antigens that have cross-reactivity with host components. Perhaps the best known is the expression of Lewis antigens by *H. pylori* LPS. This antigen is similar to that expressed by human cells, including gastric epithelial cells (Appelmelk et al., 1996). Thus, in experiments using *H. pylori* infected mice it was observed that they developed antibodies against LPS, Lewis X, and Lewis Y antigen. Interestingly, these mice also developed antibodies to H^+, K^+-ATPase, which is a major target autoantigen in chronic *H. pylori* gastritis with corpus atrophy (Appelmelk et al., 1998; Claeys et al., 1998). In humans, serum antibodies recognize native and recombinant H^+, K^+-ATPase lacking Lewis antigens (Claeys et al., 1998); hence, human anti-H^+, K^+-ATPase antibodies associated with *H. pylori* do not involve Lewis antigen mimicry as it is the case in infected mice (Alderuccio et al., 2002). Due to this cross-reactivity between bacterial antigens and some mucosal components, *H. pylori* may play a role in the development of autoimmune gastritis (AIG). AIG is an organ-specific disease that can result in pernicious anemia. This type of gastritis involves the corpus and fundus, but not the autrum. It is characterized by the presence of autoantibodies to H^+, K^+-ATPase, high levels of gastrin in serum, diminutions in acid secretion, and pepsinogen I/II ratio (Faller et al., 1997, 1998; Toh et al., 1992).

Thrombocytopenic Purpura and Atherosclerosis

Other autoimmune diseases outside of digestive tract that have been associated with *H. pylori* infection include thrombocytopenic purpura and atherosclerosis (Gasbarrini et al., 2003). In immune thrombocytopenic purpura (ITP) cross mimicry between *H. pylori* and platelet antigens has been suggested (Michel et al., 2002). Platelet-associated immunoglobulin G from patients with ITP has been shown to cross-react with CagA, but the titers of these antibodies decreased after *H. pylori* eradication (Takahashi et al., 2004). Others studies have also demonstrated a positive correlation between the eradication of *H. pylori* and platelet counts (Hashino et al., 2003; Hino et al., 2003; Michel et al., 2002; Veneri et al., 2002). Epidemiological and clinical reports have identified an association between chronic infections with *H. pylori* and coronary heart disease (Aceti et al., 1996; Mendall et al., 1994; Ossei-Gerning et al., 1997; Patel et al., 1995) promoting acute cardiovascular events by provoking atherosclerotic plaque instability or rupture (Aceti et al., 1996). The bacteria may provoke a systemic inflammatory response, with an increase in plasma fibrinogen and other markers of inflammation such as C reactive protein, white cell counts, serum albumin, and plasma viscosity, which are implicated in the plaque instability or rupture (Mehta and Li, 1999; Mendall et al., 1996; Patel et al., 1994). In addition, it has been suggested that *H. pylori* HSP60-like subunits and antibodies against these antigens can mediate cytotoxicity on stressed endothelial cells that could trigger atherogenesis and plaque instability (Birnie et al., 1998; Mayr et al., 2000). More recently, the presence of *H. pylori* DNA has been demonstrated in a considerable number of atherosclerotic plaques, which supports the hypothesis that the bacteria can have a direct role in the development of atherosclerosis and the plaque instability or

rupture (Ameriso et al., 2001; Farsak et al., 2000). Other reports have shown that anti-CagA antibodies cross-react with vascular wall antigens, providing another hypothetical pathogenic link between *H. pylori* and atherosclerosis (Franceschi et al., 2002).

Evasion of the Host Immune Response by *H. pylori*

In order to maintain persistent infection, *H. pylori* has developed strategies to evade the host response. Some of these mechanisms involve innate immunity while others involve adaptive immunity.

The immune response to *H. pylori* is composed of Th1 and Th2-cells types, but the cytokines profiles are polarized to a Th1 response. Some studies suggest that the Th1 response is dysfunctional and may play a role in the pathogenesis of infection. One way *H. pylori* may evade immune responses is by utilizing mannosylated and fucosylated glycans on the bacterial surface to bind to DC-SING on dendritic cells. This binding induces the release of Th1-type cytokines by dendritic cells. Thus, the interaction between *H. pylori* and dendritic cells may influence antigen presentation and cytokines secretion by these cells. The bacteria use this interaction to trigger ineffective immune responses that permit its persistence and the development of gastric inflammation and injury (Appelmelk et al., 2003).

Another mechanism used by *H. pylori* to elude the immune response is by limiting the effect of proinflammatory molecules. Thus, *H. pylori* has a gene, *rocF*, that encodes a functional arginase to compete with host enzyme iNOS, which limits the production of nitric oxide (Gobert et al., 2002). There are also other enzymes encoded by *H. pylori* that contribute to immunological evasion such as alkylhydroperoxide reductase (AhpC), which catalyzes the reduction of organic peroxides to alcohols, and neutrophil-activating protein, NapA, which encodes an iron-binding neotrophil-activating protein. These two proteins have an essential role in controlling hydroperoxides and reactive oxygen, which thereby decreases essential immune responses (Ding et al., 2004).

Host defense can also be avoided by *H. pylori* during the innate immunity mediated by TLRs. It has developed strategies to evade activation through TLR; thus, its LPS has low immunogenic activity due to lipid A core modification. Through this modification in the LPS it allows the bacteria to avoid signaling via TLR4 (Ogawa et al., 2003). Another modification is with the flagellin protein. Whereas flagellins secreted by Gram-negative pathogens can activate TLR5-mediated proinflammatory responses, *H. pylori* flagellin is not secreted and consequently is noninflammatory (Gewirtz et al., 2004). Another TLR that *H. pylori* can circumvent is TLR9 because the *H. pylori* DNA is highly methylated (Takata et al., 2002); recognition and response by TLR9 is limited . Yet another way *H. pylori* avoids response by a component of the innate immune response is by producing polyamines, which induce macrophages apoptosis (Chaturvedi et al., 2004).

H. pylori can further avoid elements of the immune response by utilizing a mechanism called antigen variation. This involves the gene *cagY*, which is a surface protein of *H. pylori* that contains a number of amino acid repeat patterns in the amino terminus and the midregion. This pattern can be explained by the high number of DNA repeats that facilitate sequence variation through intragenomic recombination. This system provides a mechanism for rapid changes in amino acid composition when the epitopes of CagY is exposed. Studies have shown there is both strain-specific protein variation, as well as absent or minimal host response to CagY proteins. Several other *H. pylori* surface proteins, such as BabA and BabB, contain repetitive DNA sequences as well, suggesting that CagY immune evasion may be a model for a common mechanism in *H. pylori* immune response evasion (Aras et al., 2003b). A mechanism similar to this is described for the gene *cagA*. The bacteria can regulate the number of tyrosine phosphorylation motifs present with CagA in order to modify the degree of disruption in host cells. This can be in response to selective pressures, and thereby the bacteria may regulate the inflammatory immune response and persist for long term (Aras et al., 2003b, 2003a).

Not only does *H. pylori* make use of various immune avoidance strategies, but it is also able to subvert elements of the host immune response for its own advantage. The use of immunologically relevant molecules such as class II MHC and CD74 as receptors to facilitate its binding and to promote biological responses by gastric epithelial cells are clear examples of subversion.

PD-L1 (also known as B7-H1 or CD279) is one of the two ligands that bind to the programmed cell death receptor, PD-1, on activated T cells and it functions to control the induction and maintenance of peripheral T cell tolerance. The other ligand is known as PD-L2 or B7-DC. PD-L1 is constitutively expressed on cells of hematopoietic origin such as T cells, B cells, DCs, macrophages, mesenchymal stem cells. PD-L1 expression on nonhematopoietic cell types suggests that PD-L1 protects tissues from autoimmune attack. A series of recent studies suggest that microbes that cause chronic infection take advantage of the interaction between PD-1 and its ligands to evade host

immune effector mechanisms. We recently showed that *H. pylori* infection leads to upregulated expression of PD-L1 on human gastric epithelial cell lines (Das et al., 2006). In those studies anti-PD-L1 antibody enhanced T cell proliferation and IL-2 production. PD-L1 is upregulated in gastric biopsies from people infected with *H. pylori* compared with samples from uninfected people, suggesting that *H. pylori* enhances the expression of PD-L1 on the epithelium to facilitate its persistence in the host.

EPIDEMIOLOGY

Initial Infection

The acquisition of *H. pylori* infection usually occurs in childhood, and could persist for decades in some infected subjects. The route of transmission appears to be person to person, and there is also evidence of waterborne transmission. Animals do not seem to be a source of infection, since *H. pylori* is strictly a human pathogen. Evidence of intrafamilial transmission has been reported (Bamford et al., 1993; Kivi et al., 2003) where parents, specially the mother, may play an important role in the transmission of the infection. Poor hygiene is a predisposing factor to infection, with oral–oral and fecal–oral transmission as the most probable modes of transmission. The fecal–oral transmission could be a result of direct contact with the infected person or through contaminated water or food. The oral–oral route has been supported by the PCR detection of *H. pylori* DNA in saliva and dental plaque. However, the presence of DNA does not indicate viability of the bacteria. Waterborne transmission has been reported in Colombia, Peru, China, and Japan (Goodman et al., 1996; Karita et al., 2003; Klein et al., 1991; Zhang et al., 1996). Waterborne factors identified in Colombian children included swimming streams and pools, and drinking water from streams. The study in Peru concluded that the water supply was exposed to bacterial contamination. The study conducted by Karita et al. in Japan demonstrated that there is a strong relationship between serological prevalence of *H. pylori* and a history of drinking well water.

Disease Association

As alluded to earlier in this chapter, *H. pylori* has been identified as the causal agent for chronic gastritis, and duodenal and gastric ulcers, and is associated with the development of gastric cancer, but little is known about what determines one disease or the other. The outcome of the infection may involve a combination of the bacterial infection, as well as environmental factors. A high percentage of the duodenal and gastric ulcers are reported to be attributable to *H. pylori*, around 95% and 70%, respectively. Multiple virulence genes have been studied for disease association, and these genes include the *cag* pathogenicity island, BabA, OipA, and VacA. Although these genes have been associated with a higher risk of developing gastric pathologies, none of them can be specifically associated with a particular disease. However, a recent report suggests that the presence of *jhp0917-0918* gene from *H. pylori* is correlated to an increased risk of duodenal ulcer. This gene is present in 42% of duodenal ulcers compared with 21% of gastritis. Its presence was also associated with increased IL-8 production and was a marker of protection for gastric cancer (Lu et al., 2005).

The association between gastric cancer and *H. pylori* has been demonstrated by many different studies (Forman et al., 1991; Parsonnet et al., 1991; Watanabe et al., 1998). Some of the evidence comes from studies of serum samples from patients with gastric cancer and control subjects free of cancer, where a significant association was found between the infection by *H. pylori* and gastric cancer (Talley et al., 1991). Further evidence suggests that 70% of distal gastric cancers are attributable to *H. pylori* (Ekstrom et al., 2001) when IgG anti-*H. pylori* and immunoblot to detect antibodies against CagA are combined. Since gastric carcinogenesis is a complex, multistep, and multifactorial process, it is important to remember that the association between *H. pylori* and gastric cancer is modified by environmental factors such as tobacco smoking, alcohol drinking, and deficiency of dietary antioxidants (Lunet and Barros, 2003).

The prevalence of the infection varies between countries, but there are two patterns for developed and developing countries. For developed countries, the prevalence of infection increases with age where the seropositivity detected in the Eurogast study was between 35% in the 25–34 years age group and 62% in the 55–64 years age group (1993). In addition, a study from Germany showed an overall prevalence of 40% in participants between 18 and 79 years (Rothenbacher and Brenner, 2003). However, the frequency of the infection is decreasing in many developed countries. For example, a report from the Netherlands in children and young adolescents showed that from 1978 to 1993 *H. pylori* prevalence declined from 19% to 9% in children up to 8 years of age and from 23% to 11% in adolescents (Roosendaal et al., 1997).

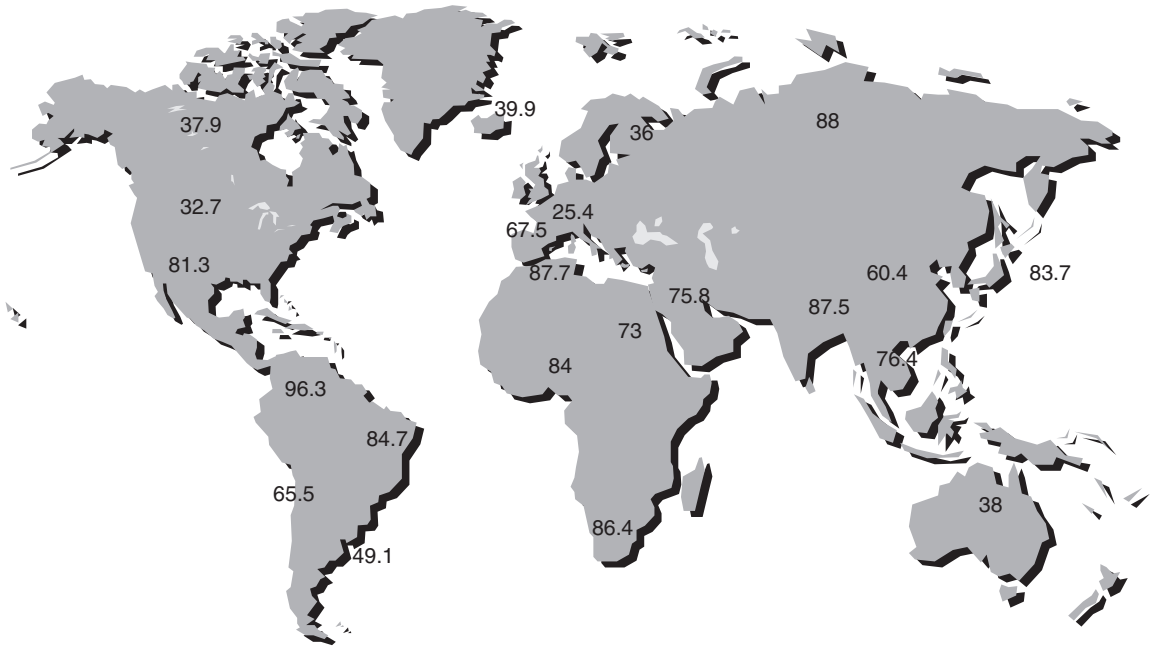

FIGURE 50.5 Prevalence of *Helicobacter pylori* infection around the world per 100,000 population (Lunet and Barros, 2003).

In contrast, the data in developing countries suggests that increasing age is a predisposing factor for infection since the prevalence of infection for the developing countries is more than 50% by 5 years and by 20 years the infection rate exceeds 90% (Bardhan, 1997; Fig. 50.5). Possibly, the age when *H. pylori* is acquired could be considered a risk factor in the serious diseases associated with the infection, since that will determine the length of the chronic inflammation. The prevalence of *H. pylori* varies between the different countries. In a study from Brazil the prevalence in adults was 82% compared with 65% in adults from Guatemala (Dowsett et al., 1999; Oliveira et al., 1994).

Pathogen versus Commensal

Lately, the prevalence of the infection by *H. pylori* has been decreasing in developed countries as a consequence of the improvement in the hygienic conditions and also due to the widespread use of antibiotic therapy for the eradication of *H. pylori* (Parsonnet, 1995; Rothenbacher and Brenner, 2003). The reduction in the prevalence of the infection is accompanied by a diminished rate of the gastric pathologies associated with *H. pylori* including gastritis and gastric cancer. However, the incidence of esophageal adenocarcinoma has been increasing in the United States, Canada, and South Australia and in six European countries (Scotland, Denmark, Iceland, Finland, Sweden, and Norway) (Vizcaino et al., 1998). The absence of *H. pylori* infection has been associated with an increased risk of development of esophageal adenocarcinoma in different case-controlled studies (de Martel et al., 2005; Ye et al., 2004). A possible explanation, provided by Blaser and colleagues, to the apparent protection conferred by *H. pylori* infection in esophageal adenocarcinoma may reside within the delicate balance between the microbe and the host (Blaser, 2005). Blaser proposes a cross talk between the microbe and the host where they could be sending signals to each other. For example, during the infection the acidity of the stomach can increase and *H. pylori*, in turn, signals the host to reduce the stress on the bacteria, using CagA as a signaling molecule, that induces an inflammatory immune response affecting the acid-producing cells and in consequence lowering the pH (Blaser, 2005). In that way, the bacterium downregulates some process in the host preventing the damage of the gastric mucosa and thus keeping their habitat. On the other hand, it is well known that CagA-positive strains increase the risk of gastric cancer, but these strains also modulate the acid production in the stomach, and this balance could be really important in the pathogenesis of the esophageal diseases (Blaser, 2005). Avoiding anti-*H. pylori* treatment is still not an option besides the possible deleterious effects in the esophagus because it is well known that the eradication reduces the risk of gastric cancer significantly.

CLINICAL DISEASE

Diseases Associated with *H. pylori* Infection

Gastritis

The symptoms associated with acute infection with *H. pylori* include nausea and abdominal pain that may persist for several days. These are the same symptoms reported by the volunteers in Marshall et al. (1985) study. In this study, the gastric mucosa was found to be inflamed within 1 week after exposure. A hallmark feature of infection with *H. pylori* is a pronounced inflammatory response, and the inability of the host to clear the infection results in a persistent infection with associated chronic inflammation. Chronic gastritis is elicited by pathogenic products of *H. pylori*, as will be reviewed below, together with the host response to the infection. In addition to a panel of proinflammatory chemokines elicited by the bacteria, the host mounts a polarized T helper cell response. Studies of infected antral biopsies have shown IL-12, IFN-γ, and TNF-α, but not IL-4 mRNA, or protein expression (Bamford et al., 1998; Haeberle et al., 1997). Various independent studies suggest that this polarization in the T cell response contributes to the severity of the associated diseases. As reviewed earlier, chronic gastritis is also thought to include an autoimmune component because several studies have revealed that patients with AIG were infected with *H. pylori*. This chronic inflammation contributes to an increased risk for ulceration and cancer. In fact, infection with *H. pylori* is recognized as a major contributor to chronic gastritis and peptic ulcer formation, and is strongly associated with gastric carcinoma and mucosa-associated lymphoid tissue (MALT) lymphoma (Correa, 1995; Solnick and Tompkins, 1992; Talley et al., 1991). While all individuals infected with *H. pylori* have histological gastritis, only a fraction of the infected persons develop gastric ulcers, duodenal ulcers, gastric cancer, or MALT lymphoma.

Peptic and Duodenal Ulcers

Before *H. pylori* was implicated in peptic ulceration, most ulcers were attributed to nonsteroidal anti-inflammatory drugs (NSAIDs), alcohol consumption, or were labeled as of unknown causes. Among the lay population, ulcers were generally attributed to spicy foodstuffs or stress. Today, the two most recognized etiologic causes responsible for peptic ulcers are chronic infection with *H. pylori* and NSAIDs. Infection with *H. pylori* is found in 90% of patients with duodenal ulcers and between 70% and 90% of patients with gastric ulcers (Cohen, 2000). Patients in the United States who are infected with *H. pylori* have a 3.5 times increased risk of developing peptic ulcer disease than uninfected persons (Nomura et al., 1994). While peptic ulcer was at one time a relatively common disease in the United States, its incidence has been decreasing during the last 30 years, and is currently estimated to be about 10% or 3.7 million new cases each year. According to the National Institutes of Diabetes and Digestive and Kidney Diseases (NIDDK, http://www.niddk.nih.gov/), the prevalence of peptic ulcers in the United States is 5 million people with 6500 fatalities on an annual basis. This decrease in peptic ulcer incidence has paralleled a decrease in the prevalence of *H. pylori* infection in the US population. The etiologic role of *H. pylori* in peptic ulcer has been confirmed by studies where antimicrobial treatment of infected individuals promoted ulcer healing and a decrease in the rate of ulcer recurrence (Graham et al., 1992).

Gastric Cancer

Gastric carcinoma remains among the most common forms of cancer worldwide. Interestingly, gastric cancer was the leading cause of cancer mortality in the United States until the late 1950s, but like the incidence of peptic ulcers, the prevalence of gastric cancer has also been declining in parallel with a decline in the infection with *H. pylori*. The incidence of gastric cancer in the general US population by 2001 was 7.1 per 100,000; it was about twice as frequent in minority populations (www.CDC.gov). In 2003, there were 22,400 new cases of gastric cancer diagnosed in the United States and 12,100 related deaths (Jemal et al., 2003). Until the early 1980s, gastric cancer was the leading cause of cancer-related deaths worldwide and now is second only to lung cancer. Given the strength of the evidence supporting an association between adenocarcinomas of the gastric mucosa and *H. pylori* infection, *H. pylori* became classified as a class I carcinogen by the International Agency for Research on Cancer in affiliation with the World Health Organization (1993). Thus, it became the first bacterial agent to be classified as a carcinogen. While animal models to study the linkage of infection with *H. pylori* and the associated diseases were initially difficult to establish, a study in Mongolian gerbils showed that *H. pylori* infection could result in gastric adenocarcinoma (Watanabe et al., 1998). A recent study examining molecular mechanisms to explain the linkage between *H. pylori* infection and cancer showed, using Mongolian gerbils, that the CagA virulence factor from *H. pylori* induced dysregulation of β-catenin-dependent pathways (Franco et al., 2005). As pointed out by the authors of the study, activation of β-catenin leads to

transcriptional upregulation of genes implicated in cancer development.

The prevalence rates of *H. pylori* seropositivity and the incidence of gastric cancer are highly associated within several populations from various countries (1993). For instance, seropositivity may be as high as 80–100% in some age groups in some countries or in minorities with lower incomes in the United States (Blaser and Parsonnet, 1994; Correa, 1995). These groups have the highest risk of developing gastric cancer and/or gastric ulcer.

Since only a fraction (<1%) of the infected individuals eventually develop gastric carcinoma, other factors are thought to contribute to carcinoma development. In addition to virulence of *H. pylori*, other components include the host response, genetic susceptibility, duration of chronic inflammation, and environmental factors. The process whereby infection with *H. pylori* is associated with gastric carcinoma is believed to be a multistep process initiated by chronic gastritis, followed by chronic atrophic gastritis, intestinal metaplasia, and dysplasia (Correa, 1995).

Gastric MALT Lymphoma

H. pylori has also been implicated in the onset of MALT lymphoma. This association has been supported by multiple studies. For instance, while the normal stomach lacks organized lymphoid tissue, one study showed that most patients with gastric MALT lymphoma were also infected with *H. pylori* (Wotherspoon et al., 1991). Studies using animal models have also linked the infection with other *Helicobacter* species with the development of MALT lymphoma. Infection of ferrets with *H. mustelae* or mice with *H. felis* reproduced MALT development, which could be treated with antimicrobials. In addition, several studies in humans have demonstrated that clearance with antimicrobials also resulted in regression of gastric MALT lymphoma in patients who remained in remission (Isaacson et al., 1999; Wotherspoon et al., 1993). MALT lymphoma is found in a small fraction of patients infected with *H. pylori* with an estimated incidence of 1 per 80,000. Chronic antigenic stimulation with *H. pylori* may be responsible for the development of MALT lymphoma associated with this infection. The cells in MALT lymphoma are largely B cells whose surface immunoglobulin recognize autoantigens rather than *H. pylori* antigens (Hussell et al., 1993), which suggests that they originate from autoreactive B cells.

Thus, *H. pylori*-associated pathogenesis encompasses a range of diseases that affect people worldwide. There are significant global and domestic problems resulting from these diseases, which lead to considerable morbidity, mortality, and societal costs.

Treatment

The most common treatment of *H. pylori* symptomatic infection involves three drugs that include two antimicrobials such as amoxicillin and clarithromycin. The other drug is a proton pump inhibitor (PPI), such as omeprazole (Losec) and ezomeprazole (Nexium). This represents the first-line therapy that is administered twice a day and ranges from 7 days outside the United States to 10 or 14 days within the United States (Bytzer and O'morain, 2005; McLoughlin et al., 2005). This triple therapy has had a success rate above 80%. The eradication of *H. pylori* is recommended as the most cost-effective treatment of gastric and duodenal ulcers. Failures in the treatment have been attributed to inadequate patient compliance and the development of antibiotic resistance. Because of the increase in antibiotic resistance, there have been efforts to study the efficacy of quadruple therapy that includes bismuth in addition to the two antibiotics and a PPI. This is considered a second-line treatment (McLoughlin et al., 2005). However, these regimens are associated with side effects such as abdominal pain or nausea, poor compliance due to the high number of tablets to be taken daily, and high cost. The emergence of antibiotic resistant strains makes eradication difficult to achieve. Furthermore, reinfection is frequent in areas with high level of transmission, making antibiotic therapy ineffective in the global control of the infection.

Due to the increase in antibiotic resistance and the associated treatment failure, some studies have considered alternative agents such as phytomedicines, probiotics, and antioxidants to treat *H. pylori* infection. While the use of these agents in vitro or in animal models has provided promising results, the few reported in vivo human trials have shown these agents to be largely ineffective.

PATHOGENESIS

The evidence accumulated through multiple studies suggests that pathogenesis of *H. pylori* infection is the result of both bacterial factors and the host immune response. An added factor into the equation is the contribution of environmental factors to the pathogenesis associated with the infection. Different combinations of these factors determine disease outcome of the infection. *H. pylori* vary in the expression of virulence factors, and the variation affects the

intensity of the host immune responses. Chronic infection is common, as the bacteria evade some host responses, and the host fails to respond effectively to eradicate the bacteria.

There are two main phenotypes exhibited with patients who develop disease due to *H. pylori* infection. When high acid secretion and chronic inflammation are seen, more commonly in the antrum of the stomach, gastric or duodenal ulcers normally result. In the case of gastritis of the corpus, decreased acid secretion, and gastric atrophy, gastric cancer is more likely (El Omar et al., 1997). Another difference often seen between these two phenotypes is the density of bacteria. In ulcer patients, high amounts of colonized bacteria have often been observed, whereas in the case of hyposecretion of gastric acid, much lower bacterial density is noted.

Inflammation

Perhaps the most important response for both phenotypes is inflammation. Both antigen specific and nonspecific responses contribute to inflammation during infection. These responses contribute to fighting infection, but are also responsible for mucosal damage. Adhesion of *H. pylori* to the host epithelium, or bacterial factors such as urease or the *cag* pathogenicity island, induce signaling that upregulates proinflammatory cytokines and chemokines such as IL-8 and GRO-α. Although the *cag* pathogenicity island is the most recognized factor inducing inflammatory responses, there are several other interactions known to upregulate these responses. We have recently discovered that through *H. pylori* attachment to CD74, or cross-linking CD74 on gastric epithelial cells, NF-κB activation occurs, leading to IL-8 production (Beswick et al., 2005a). Blocking this interaction with monoclonal antibodies resulted in a substantial decrease in the amount of IL-8 produced in response to *H. pylori.* Other bacterial factors that induce inflammatory responses are HSP60, which was shown to induce IL-8 through TLR pathways (Takenaka et al., 2004), and urease, which induced responses from both gastric epithelial cells and peripheral blood mononuclear cells (Tanahashi et al., 2000).

The cytokine responses, in turn, recruit other immune cells to the site of infection. IL-8 is one of the initial responses that recruit neutrophils to the site of infection. Neutrophils are then activated by *H. pylori* or its soluble products, and proceed to release reactive oxygen species (ROS) and more IL-8 (Shimoyama et al., 2003). Recently, *H. pylori* was also shown to induce production of macrophage migration inhibitory factor (MIF) from gastric epithelial cells, T cells, and macrophages (He et al., 2005; Xia et al., 2004). MIF is a versatile cytokine that mediates both innate and adaptive immunity and plays a role in chronic inflammation. It has been shown to upregulate NF-κB, Erk1/2, activator protein-1 (AP-1), and protein kinase C pathways leading to increased expression of IL-1β and IL-8 mRNA (Onodera et al., 2004; Ren et al., 2004). MIF may be an important early response to infection that upregulates proinflammatory pathways. Macrophages respond to *H. pylori* bacterial factors with the production of proinflammatory cytokines such as IL-1β, IL-6, and TNF-α, and nitric oxide, which are important in epithelial cell injury (Gobert et al., 2001). IL-1β is important in signaling leading to the production of other cytokines. It has also been implicated in inhibiting gastric acid production, which may be an important factor in the development of gastric carcinoma (El Omar, 2001). IL-6 has also been correlated with gastric cancer and severity of disease because of its antiapoptotic effect (Lin et al., 2001). It also induces T cells to produce IFN-γ that contributes to the overall response by upregulating expression of class II MHC on various cells and reducing proliferative rates of cells.

Ulcers

The ulcer phenotype is usually the result of upregulation of the inflammatory response by adhesion to the gastric epithelium. The inflammatory cytokines induced by the bacteria from the host cell lead to the recruitment of T cells and neutrophils to the site of infection. Upon activation, these cells produce proinflammatory cytokines that recruit B cells, mast cells, and macrophages, which damage gastric structure and function. Since *H. pylori* is persistent in infection and not easily cleared by antibiotics, chronic infection is common. Persistent infection leading to chronic inflammation causes tissue damage and ulceration (Fig. 50.6).

Carcinogenesis

The induction of carcinogenesis associated with *H. pylori* is multifaceted. During this process, the cell cycle must be modified so that cell proliferation rates overtake cell death rates. In addition, genetic mutation must occur and be maintained, leading to uncontrolled cell proliferation. The inflammatory response upregulated during infection also plays a role in carcinogenesis. IL-1β and TNF-α are both known to decrease gastric acid production, which may decrease tissue damage seen during ulceration and increase gastric atrophy. MIF, produced in response to *H. pylori*, may lead to

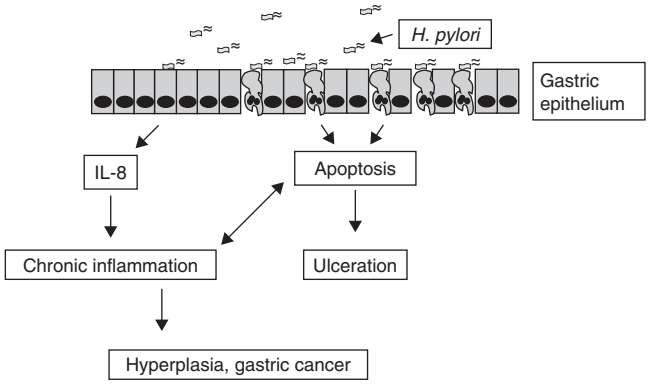

FIGURE 50.6 Inflammatory responses and altered cell turnover by the gastric epithelium are initial events leading to clinically significant diseases associated with *H. pylori* infection.

an increase in gastric epithelial cell proliferation (Xia et al., 2004). Inflammatory cytokines are also known to induce Cox-2 expression, which is upregulated during *H. pylori* infection (Romano et al., 1998; Zarrilli et al., 1999). Cox-2 catalyzes the conversion of arachidonic acid to prostagladins that play a role in inflammation and inhibit apoptosis. Cox-2 is found at elevated levels in many cancer types, and may be important in gastric cancer as well (Fig. 50.6).

During *H. pylori* infection, ROS are produced by the gastric mucosa (Jung et al., 2001). Neutrophils are one of the major sources of ROS, but gastric epithelial cells are also thought to produce it (Bagchi et al., 1996; Shimoyama et al., 2003). Epidemiologic studies have suggested that ROS may play a crucial role in the development of gastric cancer. Gastric epithelial cells may undergo DNA damage in the presence of high amounts of ROS, which could contribute to carcinogenesis.

Various studies have focused on the gastric epithelial cells affected by *H. pylori* and that become transformed. A study took advantage of laser microdissection to isolate the three main epithelial cell lineages from stomach tissue of mice infected with the *H. pylori* strain SS1 to show by gene expression profiling that the mucus-producing cell was the only epithelial cell type displaying a profound transcriptional response to the infection (Mueller et al., 2004). Neither parietal cells nor chief cells showed differential regulation of genes. In a model of gastric cancer, chronic inflammation was shown to result in the recruitment of bone marrow-derived epithelial cells (Houghton et al., 2004). In these studies on C57BL/6 mice transplanted with labeled bone marrow cells and infected with *H. felis*, most metaplasia, dysplasia, and cancer were found to be of donor origin. The group that made these observations suggested that persistent inflammation leads to tissue injury and eventual failure of stem cells in the tissue. The inflammatory process then leads to the recruitment and engraftment of bone marrow-derived circulating cells into the tissue stem cell niche where they replace the tissue stem cells (Houghton and Wang, 2005).

An interesting occurrence to note about the *H. pylori* disease process is that while expression of CagPAI and VacA virulence factors, along with the inflammatory responses induced during infection, is associated with both ulcerogenesis and carcinogenesis, these two outcomes are mutually exclusive of one another. This observation supports the notion that host factors or genetic susceptibility may play a role in disease outcome associated with *H. pylori* infections.

THE USE OF PROTEOMICS TO UNDERSTAND THE *H. PYLORI*-ASSOCIATED PATHOGENESIS

Proteomic analysis is a powerful technology that permits comprehensive inspection of protein expression in cells, tissues, and bodily fluids. Comparison of protein expression between control tissue and disease tissue, or tissue exposed to an insult, permits the detection of proteins altered in their expression. Thus, proteins whose expression is altered during disease could potentially be used as biomarkers for diagnosis and monitoring of infection and disease outcome. This technology has also been applied to analyze the full complement of proteins expressed by pathogens and *H. pylori* is one pathogen whose proteome has been extensively analyzed using two-dimensional electrophoresis (2-DE) and LC-MS (Govorun et al., 2003; Jungblut et al., 2000). However, this technology has not been exploited to understand how *H. pylori* induces disease. Three relevant recent studies have examined resected or biopsy tissue from gastric cancer patients by a similar approach that included 2-DE analysis followed by MALDI-TOF-MS (Baek et al., 2004; Ebert et al., 2005; Ryu et al., 2003). As controls, they used nonaffected tissue from the same patients. There was little congruence in the array of proteins whose expression was altered in the three studies, and there was no confirmation by an independent method such as Western blotting, with the exception of one protein in one of the studies (Ebert et al., 2005). The differences observed may be due to the study of different populations, differences in infecting strains, or both. A limitation of the studies to date is that they examined tissue that has been

infected for decades or is already transformed, and the samples contained multiple cell phenotypes, many of which are normal. Das et al. (2005) examined gastric epithelial cells that are the target of infection, and also cells that become transformed to give rise to gastric carcinoma. Using SELDI-TOF-MS combined with retentate chromatography, where proteins were selectively retained based on their chemical properties, they detected a panel of proteins whose expression differed ($p \leqslant 0.05$) in cells exposed to an inflammatory cytokine (IFN-γ), *H. pylori*, or both (Das et al., 2005). A total of 15 biomarkers in the N87 total cell lysate with a statistically significant $p \leqslant 0.05$ with at least twofold changes in their level of expression were discovered. We ensured that each of the peaks at the specified condition where it is induced had a signal to noise ratio $\geqslant 5.0$. Untreated gastric epithelial cells were used as a control to get the ratio from the epithelial cells treated with *H. pylori*, IFN-γ, and IFN-γ plus *H. pylori*. It was observed in these studies that the more differentially expressed biomarkers were obtained from IFN-pretreated cells exposed to *H. pylori* samples compared to cells treated only with *H. pylori*. Peaks were selected as induced if the ratio was $\geqslant$ 2.0, and repressed if the ratio was $\leqslant 0.5$. This might reflect the effect of IFN-γ on the expression of receptors used by *H. pylori*, which in turn helps the interaction of *H. pylori* with GEC (Fan et al., 1998). Annexin II was one biomarker identified in *H. pylori* infected GEC. Annexin II is a multifunctional protein that has been suggested to be involved in the pathogenesis of carcinoma.

VACCINES

The failures associated with the therapy include poor compliance, emergence of antibiotic resistant strains, and the potential for reinfection. These problems could be overcome with the use of an efficacious vaccine. Substantial interest has been shown in developing both therapeutic and prophylactic vaccines. The development of a prophylactic vaccine may not be cost-effective in the United States and Japan. However, regions with high infection rates and prevalent cancerous outcomes may benefit from such a vaccine.

Initial studies in the development of a vaccine require animal models to examine initial preparations. Since *H. pylori* is a strictly human pathogen, an animal model was one of the initial barriers in vaccine development efforts. After an animal model of *Helicobacter* infection was finally presented, Chen et al. (1992) were able to demonstrate that prophylactic immunization could protect against the challenge with *Helicobacter* species. A couple of years after this study was reported, mice infected with *H. felis* were used to show that therapeutic immunization could be effective (Doidge et al., 1994). Another important advance in vaccine development was the discovery of strains (e.g., Sidney strain) isolated from human gastric biopsies that would colonize mice. These adapted strains were crucial in the establishment of a mouse model of *H. pylori* infection. The guidelines for this model require that this strain of *H. pylori* consistently colonize multiple strains of mice to a high level, and establishes infection that may persist for many months (Lee and Chen, 1994) Both prophylactic and therapeutic immunizations have been found to be effective in the control of *H. pylori* colonization in mice (Ghiara et al., 1997; Kleanthous et al., 1998; Sanchez et al., 2001). However, these results in mice have yet to be reproduced in humans. There are several considerations that must be kept in mind in trying to extrapolate the results from studies in mice to humans. The mouse model of *Hp* infection using the Sydney strain (SS1) has a number of limitations, such as the lack of pathologic gastritis seen in humans. The SS1 strain lacks a functional cag pathogenicity island, and does not induce vacuole formation in HeLa cells or IL-8 production in human gastric epithelial cells. Another mouse model of infection uses the *H. felis* strain. However, the virulence mechanisms of this model may be radically different from those of *H. pylori* (no cytotoxin, no cag pathogenicity island, no adherence of the organism to epithelial cells). In the mouse model of *Hp* infection, TNF-α does not seem to play a role in the development of the inflammatory response, in contrast to humans where TNF-α is consistently found to be increased in the infected gastric mucosa of *H. pylori* infected individuals (Yamamoto et al., 2004). Furthermore, studies of *H. pylori* infection in outbred mice, which more closely resemble the outbred human population, showed that these mice mounted a Th2 response, while infections of humans with *H. pylori* induce a Th1 cell dominated response (Robinson et al., 2005). Differences in the immune response between humans and mice may reflect differences in the regulation of the gastric immune response that in mice do not lead to neutrophil recruitment, while in humans this is a hallmark of *H. pylori* infection.

Over the last few years, different groups have been working on developing vaccines against *H. pylori*, following a variety of vaccination strategies in humans and in animal models. The methods that have been attempted to develop a vaccine include whole-cell, single-antigen, and multicomponent preparations. Others have also incorporated the use of different vectors, such as those from *Salmonella* species.

Whole-Cell Vaccines

The fist attempt at vaccination using a whole-cell lysate employed oral immunization in mice and ferrets. This study resulted in the induction of IgG and IgA in gastrointestinal secretions and sera of these animals. Then, in studies where antigen preparation was supplemented with cholera toxin (CT), the IgG and IgA response was significantly increased (Czinn and Nedrud, 1991). However, at that time there was no acceptable animal model for *H. pylori* infection; hence, it was not possible to assess the protective effect of that vaccine preparation. The first animal model of the infection was based on *H. felis*, a gastric pathogen present in cats and dogs. In order to prove the protective effect of this vaccine candidate, mice were immunized with *H. felis* sonicates and CT, and subsequently challenged with *H. felis*. This study resulted in protection that reached a level of 96% against the acute infection (Lee and Chen, 1994). Later, various groups tested these vaccination schemes in a wide range of animals, including ferrets, gnotobiotic piglets, and monkeys, and also achieved high success rates (Eaton et al., 1998).

Other studies using *H. pylori* lysates also met some success in animal models. Using both oral and intramuscular immunization in mice, one group demonstrated the importance of LPS in the development of a vaccine. In a mouse model, *H. pylori* lysates containing LPS induced strong innate and antigen-specific Th1 responses, while mice receiving vaccine devoid of LPS induced a Th2 response (Taylor et al., 2006).

Although the protection achieved by vaccination with whole-cell extracts was very high, such an approach could encounter quality control and safety problems due to the variability of lot preparations and the presence of antigens potentially dangerous for humans. In addition to these problems, the use of CT as an adjuvant in humans is not acceptable. Nevertheless, the safety and immunogenicity of a formalin-inactivated, oral *H. pylori* whole-cell vaccine was tested in healthy and infected volunteers (Kotloff et al., 2001). In this study, the whole-cell vaccine was administered with or without a modified form of *Escherichia coli* heat-labile toxin (LT) as a mucosal adjuvant. After the first immunization, diarrhea, nausea and vomiting were observed. Also, a significant increase in fecal and salivary anti-*H. pylori* whole-cell IgA was observed in infected and uninfected subjects. This vaccination approach elicited significant increases in lymphocyte proliferation and production of IFN-γ in noninfected volunteers. However, the effectiveness of the vaccine in the reduction of the bacterial load was not reported.

Outer Membrane Vesicles

Like other Gram-negative bacteria, *H. pylori* sheds part of its outer membrane as vesicles. These outer membrane vesicles (OMV) contain porins, LPS, VacA, and the Lpp20 lipoprotein among other protein components. Thus, these components were incorporated into vaccine studies. In one study, mice immunized with OMV are protected from the challenge with *H. pylori*. The protection measured correlated with an IgG antibody response to an OMV component of 18 kDa, which is commonly expressed by *H. pylori* strains (Keenan et al., 1998). This OMV component was identified as lipoprotein 20 (Lpp20) using a monoclonal antibody. Further examination indicated that hybridoma backpacks secreting IgG antibodies against Lpp20 considerably reduced the bacterial load in infected mice (Keenan et al., 1998). Additionally, previous evidence indicates that this kind of antigen is a good vaccine candidate. Lpp20 was identified as a protective antigen in a mouse model, since administration of Lpp20 before the challenge resulted in significantly reduced bacterial numbers (Keenan et al., 2000). In order to further investigate this vaccine candidate, the efficacy of the immunization with OMV was compared between mouse and guinea pig models. These animals received intranasal immunization of recombinant Lpp20 (rLpp20) or OMV preparations from *H. pylori*, using CT as a mucosal adjuvant (Keenan et al., 2000). After immunization with rLpp20, the animals that were challenged with *H. pylori* SS1 strain induced a specific antibody response and a reduced level of *H. pylori* colonization in mice, but not in guinea pigs. On the other hand, immunization with OMV in both models elicited systemic and intestinal local immune response, characterized by specific IgG in serum and gastric samples in addition to IgA in bile and the gastric mucosa.

Recombinant Antigen-Based Vaccines

Studies by various groups showed that protection can be achieved by immunization with single antigens such as urease, VacA, catalase, NapA, heat-shock protein Hsp60, and the outer MP HpA. Most of those antigens were selected as potential vaccine candidates because they are abundant, surface exposed, well-conserved *H. pylori* proteins, and/or because they are major virulence factors.

Urease

The urease antigen is one of the most studied of the *H. pylori* major virulence factors, and thus has

received the attention of researchers for vaccine studies. Immunization with urease has had much success in mice (Ermak et al., 1998; Kleanthous et al., 1998; Sanchez et al., 2001). Studies suggested that protection of mice against *H. pylori* infection after immunization is dependent on MHC class II antigen presentation; hence, antiurease antibodies may not be necessary for protection (Ermak et al., 1998). Although it is a good vaccine candidate, the experience of *H. pylori* vaccine studies using recombinant urease in humans has been limited. A study conducted to evaluate the safety and immunogenicity of recombinant urease administered with *E. coli* heat-labile enterotoxin (LT) in healthy *H. pylori*-infected volunteers resulted in an increase in the titers of antiurease serum IgA and also in circulating antiurease IgA producing cells (Michetti et al., 1999). Although this effect did not result in complete removal of the bacteria, there was a significant reduction in gastric *H. pylori* density. Despite these promising results, side effects due to the administration of *E. coli* LT were evident in 66% of the volunteers. In order to try to circumvent the side effects due to the oral administration of LT, a subsequent study used a different route of administration. Based on experiments in mice showing that rectal and nasal immunization routes are as effective as the oral route, the subsequent study tested the safety and immunogenicity of *H. pylori* urease vaccine administered rectally using LT as adjuvant in infected and uninfected volunteers (Sougioultzis et al., 2002). Although LT and urease delivered rectally were well tolerated, the immune response to LT was more vigorous compared with the response to urease, since just 16.7% of the subjects had antiurease IgG antibodies and 8.3% developed antiurease IgA antibodies. In another study to determine the adjuvant properties of low doses of LT, a range of doses were evaluated in human volunteers against *H. pylori* using recombinant urease (Banerjee et al., 2002). The urease was administered enterically using acid-resistant capsules, and was also administered orally using soluble urease. Both methods were determined to be safe, without significant adverse effects. After the immunization, 50% of the volunteers who received the higher doses developed mild diarrhea. The proportion of volunteers developing mild diarrhea with the lower doses of LT did not differ from the baseline or from those receiving no LT. Seroconversion (defined as fourfold increase in titers of IgA and IgG or as more than 15 urease-specific IgG antibody secreting cells) was observed in 67%, 17%, 33%, and 25% of the subjects who received 2.5μg, 0.5μg, 0.1μg, and no LT, respectively. Significant cellular immune responses were observed only in the subjects receiving the highest dose of LT. These studies also concluded that the percentage of $\alpha2\beta7$ $CD69^+$ circulating lymphocytes, and $\alpha2\beta7$ $CD4^+$ and $\alpha2\beta7$ $CD45RO^+$ lymphocytes was significantly increased. This study showed that a dose of 2.5μg LT is required, but this dose also induced mild side effects in half of the volunteers.

VacA, NAP, and CagA

The rationale for using virulence factors vaccines is that the immunity induced against them confers protection. Among the other representative virulence factors of *H. pylori* are the CagA, the VacA, and the NAP.

One of the first attempts to use purified VacA as a prospective vaccine candidate showed that immunization with this antigen protected mice from the infection with an *H. pylori* strain expressing both CagA and VacA (Marchetti et al., 1995). A posterior study using recombinant VacA in a mouse model of infection showed that a chronic infection by *H. pylori* Type I strain ($CagA^+$ and $VacA^+$) can be successfully eradicated by intragastric immunization with VacA in combination with a nontoxic mucosal adjuvant in the form of a detoxified mutant of *E. coli* LT. Additionally, these investigators demonstrated that these protected mice were resistant to reinfection (Ghiara et al., 1997). Recently, the Beagle dog model was used to evaluate the safety, immunogenicity, and efficacy of therapeutic vaccine preparations (Rossi et al., 2004). The dogs were immunized with recombinant VacA, CagA, and NAP with alum intramuscularly. A good dose-dependent IgG response was generated without obvious adverse effects. The bacterial colonization and gastritis diminished after the immunization. This successful study suggests that antigen vaccines are a feasible approach to developing an *H. pylori* vaccine.

An important parameter usually considered in immunization protocols is the route of administration. Different administration routes have been combined to determine whether there are differences between them as well as to establish which combination is better. Using CagA and NAP to immunize BALB/c mice Vajdi and colleagues compared the mucosal route with parental routes of immunization. At the same time they wanted to establish whether the combination of mucosal or systemic priming followed by systemic or mucosal boosting would enhance humoral immunity (Vajdy et al., 2003). Their studies showed that mucosal and systemic antibody responses were enhanced with mucosal followed by parenteral immunization. Any single route or combination of immunization routes with CagA and NAP induced antigen-specific splenic IL-4 secreting cells. Interestingly, serum IgG1 was induced in response to

intranasal immunization alone or in combination with intramuscular immunization.

In order to further these studies, the safety and immunogenicity of a multicomponent vaccine administered with aluminum hydroxide as adjuvant was evaluated in human volunteers (Ruggiero et al., 2003). The vaccine consisted of CagA, VacA, and NAP plus aluminum hydroxide. This combination of antigens was administered intramuscularly to *H. pylori* uninfected individuals three times. The results of this study indicated that the vaccine was safe, with only some mild and temporary effects observed at the site of the injection. The results also showed that the vaccine was immunogenic and capable of inducing antibody responses to all three antigens.

A disadvantage of immunization with recombinant CagA and VacA is that not all strains express these proteins. Therefore, infection with such negative strains could not be prevented with these vaccines. However, these two virulence factors remain important targets since their presence is associated with the most virulent strains, as explained earlier in this chapter.

Salmonella-Vectored Vaccine

Attenuated *Salmonella* strains have been shown to be efficient live vaccine vectors, and able to induce mucosal, cellular, and humoral immune responses (Emoto et al., 1992; Tacket et al., 1997). For these vaccine studies, defined mutations have been incorporated into the *Salmonella* chromosome to obtain nonvirulent strains able to induce a strong immune response after oral administration. One of the first attempts made at this type of vaccine used plasmid-encoded urease A and B from *H. pylori* expressed in the attenuated *Salmonella typhimurium* strain SL3261 (Gomez-Duarte et al., 1998). Oral immunization of BALB/c mice with a ureA and ureB expressing *Salmonella* vaccine protected the mice from colonization with a mouse-adapted *H. pylori* strain and also induced serum and mucosal specific antiurease antibody responses (Gomez-Duarte et al., 1998). Similar results were reported by Corthesy-Theulaz et al. (1998) using live *S. typhimurium* phoPc expressing urease A and B from *H. pylori*. The combination of mucosal priming with *S. typhi* expressing *H. pylori* urease and parenteral boost with urease plus alum effectively enhanced the immune response and protected the mice against *H. pylori* infection (Londono-Arcila et al., 2002).

The first human immunization study of this type used a *S. typhi* strain where the *phoP/phoQ* virulence region was deleted. This strain was modified to express *H. pylori* urease subunits A and B, and was administered orally to volunteers (DiPetrillo et al., 1999). The immunized volunteers developed strong immune responses against *S. typhi* flagella and lipopolysaccharide antigens, but, intriguingly, there were no detectable mucosal or systemic antibody responses to urease. A later study, using *S. typhimurium* serovar expressing urease from *H. pylori* to immunize volunteers, resulted in a better response compared with the previous report (Angelakopoulos and Hohmann, 2000). Three of the six volunteers had urease-specific immunoglobulin production by blood mononuclear cells, indicating that attenuated *S. typhimurium* appears to be more effective than *S. typhi*. A summary of clinical trials to date is presented in Table 50.2.

Other Vectored Vaccines

Recently, a new potential *H. pylori* vaccine based on a poliovirus vector has been reported. In this vector, the poliovirus capsid genes were substituted with the

TABLE 50.2 Vaccine candidate trials in humans using different approaches

H. pylori status	Antigen	Route	Result	Reference
Uninfected	Urease and LT	Oral	Significant immune response (IgA and IgG)	Banerjee et al. (2002)
Infected	Urease and LT	Oral	No eradication of the infection, decrease in *H. pylori* density	Michetti et al. (1999)
Infected and Uninfected	Whole-cell (formalin-inactivated) and mutant LT (R192G)	Oral	Mucosal and systemic immune response, no eradication	Kotloff et al. (2001)
Uninfected	*Salmonella typhi* Δ*phoP/phoQ* expressing Urease A and B	Oral	No humoral or mucosal immune response	DiPetrillo et al. (1999)
Uninfected	*Salmonella typhimurium* Δ*phoP/phoQ* expressing Urease A and B	Oral	Antiurease specific antibodies	Angelakopoulos and Hohmann (2000)

gene for *H. pylori* urease B (UreB replicon) (Smythies et al., 2005). Immunization with UreB replicons induced humoral and cellular mediated immune responses in C57BL/6/DAB mice transgenic for the human poliovirus receptor (Novak et al., 1999). In testing the vaccine for the prophylactic and protective capacity, it was discovered that only 20% of the mice vaccinated before the challenge became infected compared with 80% percent of mice infected in the control group. Interestingly, 73% of the mice with previous *H. pylori* infection and then therapeutically vaccinated cleared the infection, indicating that therapeutic and prophylactic protection may be achieved through the use of this vaccine candidate (Smythies et al., 2005).

DNA-Based Vaccines

An alternative approach to the above-mentioned vaccines are the administration of DNA-based vaccines. Studies have shown that DNA vaccines are effective at eliciting humoral and cellular immune responses. Additionally, DNA vaccines are easy to produce and purify. One group of investigators showed that intracutaneous immunization of mice with DNA vaccines encoding *H. pylori* heat shock protein A and B induced specific antibodies against *H. pylori* and significantly suppressed bacterial colonization of the stomach as well as reduced the degree of gastritis in vaccinated mice (Todoroki et al., 2000). In a similar study, C57/BL6 mice were immunized intranasally or intracutaneously with a DNA vaccine encoding *H. pylori* catalase. This study showed that vaccinated mice were significantly protected from colonization, and had a lower degree of gastritis than controls (Miyashita et al., 2002). Furthermore, the innate and adaptative immune responses induced by an *H. pylori* ureB DNA construct administered intramuscularly and subcutaneously were analyzed in BALB/c mice (Hatzifoti et al., 2004). Immunized mice showed a sustained increase in the expression of IL-10 mRNA, as well as in the mRNA expression of b1-defensin. The antibody response against ureB was significantly increased after intramuscular immunization, whereas mice subcutaneously immunized did not increase the antibody response.

PROSPECTS FOR THE FUTURE

H. pylori is widely accepted as a very common human pathogen responsible for significant morbidity and mortality. This pathogen has developed unique features that have allowed it to chronically infect its host. Those properties were likely developed over the thousands of years that it has been in close association with humans. Work over that past decade has provided valuable insights to explain how it interacts with the host and causes disease. However, there are still many questions that need to be addressed to prevent infection and disease. Effective prophylactic and therapeutic vaccines are clearly needed. While trials have focused on key virulence factors of *H. pylori* as target antigens in immunization attempts, main targets that have been widely ignored are the adhesins responsible for initial binding to the host epithelium.

As stated earlier, several receptors have been described on the host cells, but those that are shown to deliver intracellular signals after *H. pylori* binds to them may be of major importance in novel therapeutic strategies. Likewise, the *H. pylori* adhesins that are shown to bind to these host cell receptors could become key targets of immunization.

With the advances that are being made in this field and the adaptation of novel technologies, such as proteomics, to characterize critical interactions between *H. pylori* and its host, the eradication of this human pathogen is probably not too distant.

KEY ISSUES

- Why only a fraction of infected individuals develops disease whereas most remain asymptomatic?
- Why are ulcerogenesis and carcinogenesis among infected individuals mutually exclusive processes?
- Critical in the development of vaccines is the understanding of how to elicit a protective immune response while avoiding responses that may become immunopathogenic.
- It will be critical to define what elements of the innate and/or adaptive immune response contribute to peptic and duodenal ulcer development as well as gastric carcinoma.
- It may be critical to examine whether the cytokines induced by the bacterium to promote inflammation and clearance could be central to gastric carcinoma development. It will be necessary to determine the most effective target antigens.
- In studies utilizing urease to immunize humans, observations made in mice have not been reproduced in humans.
- Urease is a logical target for immunization given its overall abundance, its location in the cell, and its functions.
- Human T cells, unlike mouse T cells, express class II MHC after they become activated and this

could be yet another mechanism whereby *H. pylori* circumvents the host response. It is not known at what stage *H. pylori* eradication may protect from cancer development. It is unclear whether individuals with advanced premalignant lesions can be helped by antibiotic clearance of *H. pylori*.

ACKNOWLEDGMENT

Intestinal Pathogenic *Escherichia coli*

Alfredo G. Torres
Departments of Pathology and Microbiology and Immunology, Sealy Center for Vaccine Development, University of Texas Medical Branch, Galveston, TX, USA

OUTLINE

ABSTRACT

Intestinal pathogenic *Escherichia coli* strains that cause diarrhea can be divided into at least six different categories, and each type is associated with a distinct pathogenic mechanism. Taken together, these organisms represent the most common causes of pediatric diarrhea worldwide. In recent years, a large amount of information has been generated regarding the virulence mechanisms used by the different categories of diarrheagenic *E. coli* to produce several distinct clinical syndromes. This review describes how their pathogenic schemes underlie the clinical manifestations, treatment approach, and epidemiologic investigation of these important pathogens and examines in detail the past and current progress in the development of vaccines against these categories of diarrheagenic *E. coli*.

INTRODUCTION

Diarrhea is a common problem that usually lasts a day or two and gradually disappears without any special treatment. However, prolonged diarrhea can be a sign of other problems. Diarrhea can cause dehydration, which is particularly dangerous in children and the elderly, and must be treated promptly to avoid serious health problems. Diarrhea caused by a variety of *E. coli* strains is a major problem in developing countries,

although traveler's diarrhea and hemorrhagic colitis are also a problem for industrialized countries. It has been estimated that *E. coli* is responsible for an estimated 780–900 million cases of diarrhea worldwide and at least 300,000–500,000 deaths annually. Taken together, these organisms represent the most common cause of pediatric diarrhea worldwide (Bern et al., 1992). There are numerous categories of diarrheagenic *E. coli* (Kaper et al., 2004), but only a few serotype combinations are associated with diarrheal disease (Nataro and Kaper, 1998). This chapter provides a brief description of the different categories of *E. coli*, as well as their pathogenic mechanisms, clinical relevance, and treatment. Further, this chapter also presents past and present progress made in the area of vaccinology against diarrheagenic *E. coli* and discusses future lines of research being pursued to improve current vaccines.

ETIOLOGIC AGENT(S)

E. coli can cause diarrhea by at least six different mechanisms, and each type is associated with a different pathotype and different virulence determinants (Table 51.1; Kaper et al., 2004; Torres et al., 2005). Enterotoxigenic *E. coli* (ETEC) is the major cause of traveler's diarrhea. Enteropathogenic *E. coli* (EPEC) causes watery diarrhea in infants and children. Enterohemorrhagic *E. coli* (EHEC) and enteroinvasive *E. coli* (EIEC) strains both produce bloody diarrhea, but while EIEC causes a more *Shigella*-like dysentery, EHEC infections more frequently cause kidney failure (hemolytic uremic syndrome [HUS]). Of these first four categories, ETEC, EPEC, and EIEC are responsible for the vast majority of cases in the developing world. Enteroaggregative *E. coli* (EAEC) is primarily associated with persistent diarrhea in children in developing countries and in AIDS-associated diarrhea, while diffusely adhering *E. coli* (DAEC) is a cause of childhood diarrhea and also traveler's diarrhea in Mexico and North Africa. ETEC, EPEC, EAEC, and DAEC preferentially colonize the small bowel, and EIEC and EHEC colonize the large bowel prior to causing disease. In general, the pathogenic process of diarrheagenic *E. coli* strains include: (i) ingestion of the organism; (ii) bacterial attachment via pili (fimbriae), fibrils, or outer membrane proteins; (iii) colonization of the intestinal mucosa; (iv) expression of bacterial mechanisms to manipulate the host cell cytoskeleton or to evade host defenses; (v) multiplication of the bacteria, and (vi) host damage and production of disease. The description of the mechanisms associated with disease, epidemiology, clinical manifestations, and treatment of the individual categories of diarrheagenic *E. coli* are discussed below.

TABLE 51.1 Summary of clinical syndromes and pathogenic mechanisms of diarrheagenic *Escherichia coli*

Classification (category)	Site affected	Clinical syndrome	Proposed pathogenic mechanism
Enterotoxigenic *E. coli* (ETEC)	Small intestine	Traveler's diarrhea. Watery stool, low fever, cramps, nausea	Hypersecretion of fluids and electrolytes stimulated by plasmid-mediated enterotoxins
Enteropathogenic *E. coli* (EPEC)	Small intestine	Infantile diarrhea with fever, nausea, vomiting	A/E[a] lesion formation and BFP-mediated microcolony stabilization
Enterohemorrhagic *E. coli* (EHEC)	Large intestine	Hemorrhagic colitis. Severe abdominal pain, watery diarrhea, possible leading to hemolytic uremic syndrome	Inhibition of protein synthesis by cytotoxins and A/E[a] lesion formation
Enteroinvasive *E. coli* (EIEC)	Large intestine	*Shigella*-like diarrhea. Fever, cramps, watery diarrhea followed by bloody stool	Tissue invasion and destruction of epithelial cells (plasmid-mediated)
Enteroaggregative *E. coli* (EAEC)	Small intestine	Infant diarrhea in developing countries and diarrhea in AIDS patients	Inhibition of fluid absorption by plasmid-mediated aggregative adherence (biofilm formation)
Diffusely adhering *E. coli* (DAEC)	Various sites	Diarrhea	Little is known about mechanisms causing diarrhea

[a]A/E, Attaching and effacing lesion formation causes destruction of enterocytes; BFP, bundle-forming pilus.

Enterotoxigenic *E. coli*

ETEC causes a self-limited illness, usually lasting fewer than 5 days, and is considered a major cause of childhood diarrheal disease in developing countries as well as a frequent cause of enteric illness among travelers and in soldiers deployed to those countries (Nataro and Kaper, 1998; Qadri et al., 2005). ETEC are acquired by ingestion of contaminated food and water and

produce a range of symptoms, usually of moderate severity, including nonbloody, watery diarrhea (cholera-like symptoms), and abdominal cramps.

Pathogenesis

ETEC colonize the proximal small intestine and adhere to enterocytes by means of the plasmid-encoded fimbrial factors (Fig. 51.1). Colonization is mediated by one or more proteinaceous fimbrial or fibrillar colonization factors (CFs) that are designated as colonization factor antigens (CFAs, e.g. CFA I and CFA II), coli surface antigen (CS), or putative colonization factors (PCFs) in ETEC infections of humans, or K-88 and K-99 in the case of animals (Gaastra and Svennerholm, 1996; Torres et al., 2005). After colonization, ETEC strains produce two classes of plasmid-encoded enterotoxins. The first class comprises the high-molecular-weight, heat-labile enterotoxins (LTI and LTII), which are structurally and functionally related to cholera toxin, and a second class, the low-molecular-weight, heat-stable enterotoxins (ST_A and ST_B) (Nataro and Kaper, 1998; Sears and Kaper, 1996). ETEC strains may express either one or both enterotoxins, and both classes are responsible for net secretion of fluid into the intestine and diarrhea. LTs produce diarrhea by activating the main chloride channel, and by stimulating prostaglandin synthesis and the enteric nervous system, both of which can stimulate secretion and inhibit absorption. STs are small peptides that resemble a mammalian peptide hormone (guanylin) and bind to the guanylin receptor. This binding results in elevation of cyclic AMP, which, through a series of steps, leads to secretion of chloride (Nataro and Kaper, 1998). In addition, ETEC strains have been reported to invade cultured human epithelial cells, although there are no clinical data to suggest that ETEC invades cells in vivo (Elsinghorst and Kopecko, 1992; Elsinghorst and Weitz, 1994). The ETEC factors associated with this invasion phenotype have been identified with the characterization of the Tia pathogenicity island (Tia-PAI) in some clinical ETEC isolates (Elsinghorst and Kopecko, 1992; Elsinghorst and Weitz, 1994).

Epidemiology

ETEC is usually a frequent cause of diarrhea in infants younger than 2 years of age, with the incidence of ETEC infections in developing countries decreasing between the ages of 5 and 15 years (Girard et al., 2006; Qadri et al., 2005). ETEC also is a major cause of traveler's diarrhea and accounts for approximately 280 million diarrhea episodes and more than 400,000 deaths annually (Steffen et al., 2005). ETEC is responsible for about 25% of persistent diarrheas and 26%

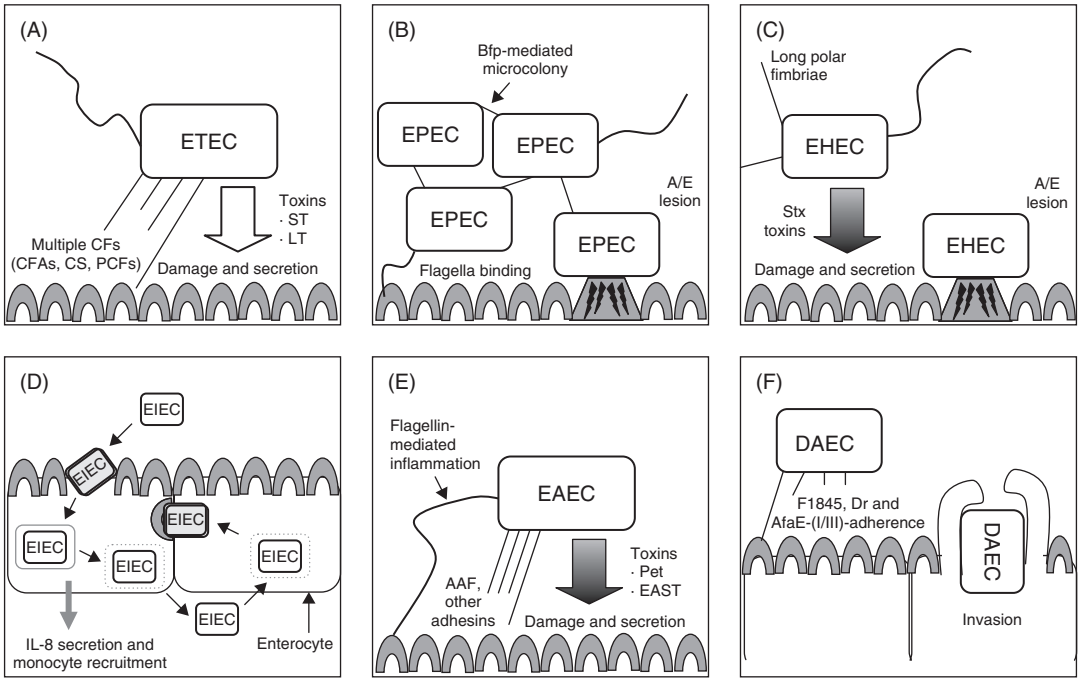

FIGURE 51.1 Diarrheagenic *E. coli* interactions with epithelial cells. The six categories of diarrheagenic *E. coli* each have unique features in their interaction with intestinal epithelial cells. Here, the interactions (e.g. mediated by fimbriae or other adhesins) of each category with a target cell, followed by damage (e.g. toxin-mediated) and the subsequent fluid secretion, are schematically represented. See text for further details.

of severe diarrheas requiring hospitalization and perfusions worldwide (Fig. 51.2; Qadri et al., 2005). Despite the overall low incidence, outbreaks of ETEC are being increasingly recognized in the United States, and just between 1996 and 2003, 16 ETEC outbreaks were identified; three occurred on cruise ships and the rest within US territory (Beatty et al., 2004).

Clinical Disease

Infection with ETEC can cause profuse watery diarrhea and abdominal cramping. Fever, nausea (with or without vomiting), chills, appetite loss, headache, muscle aches, and bloating can also occur, but are less common. Illness develops 1–3 days after exposure and usually lasts 3–4 days. Some infections may take a week or longer to resolve. Symptoms rarely last more than 3 weeks. Most patients recover with supportive measures alone and do not require hospitalization or antibiotics (Qadri et al., 2005).

Treatment

Most infected persons will recover within a few days without requiring any specific treatment. In the case of infants and children with diarrhea, clear liquids or premixed oral rehydration solutions are recommended to prevent dehydration and loss of electrolytes (CDC, 2005). Bismuth subsalicylate also may be used as treatment (one fluid ounce or two 262-mg tablets every 30 min for up to eight doses in a 24-h period). ETEC is frequently resistant to common antibiotics, including trimethoprim-sulfamethoxazole and ampicillin. Because resistance to antibiotics is increasing worldwide, the decision to use an antibiotic should be carefully weighed against the severity of illness and the risk of adverse reactions. Currently, fluoroquinolones are the drugs of choice. Commonly prescribed regimens are 500 mg of ciprofloxacin twice a day or 400 mg of norfloxacin twice a day for 3–5 days (CDC, 2005).

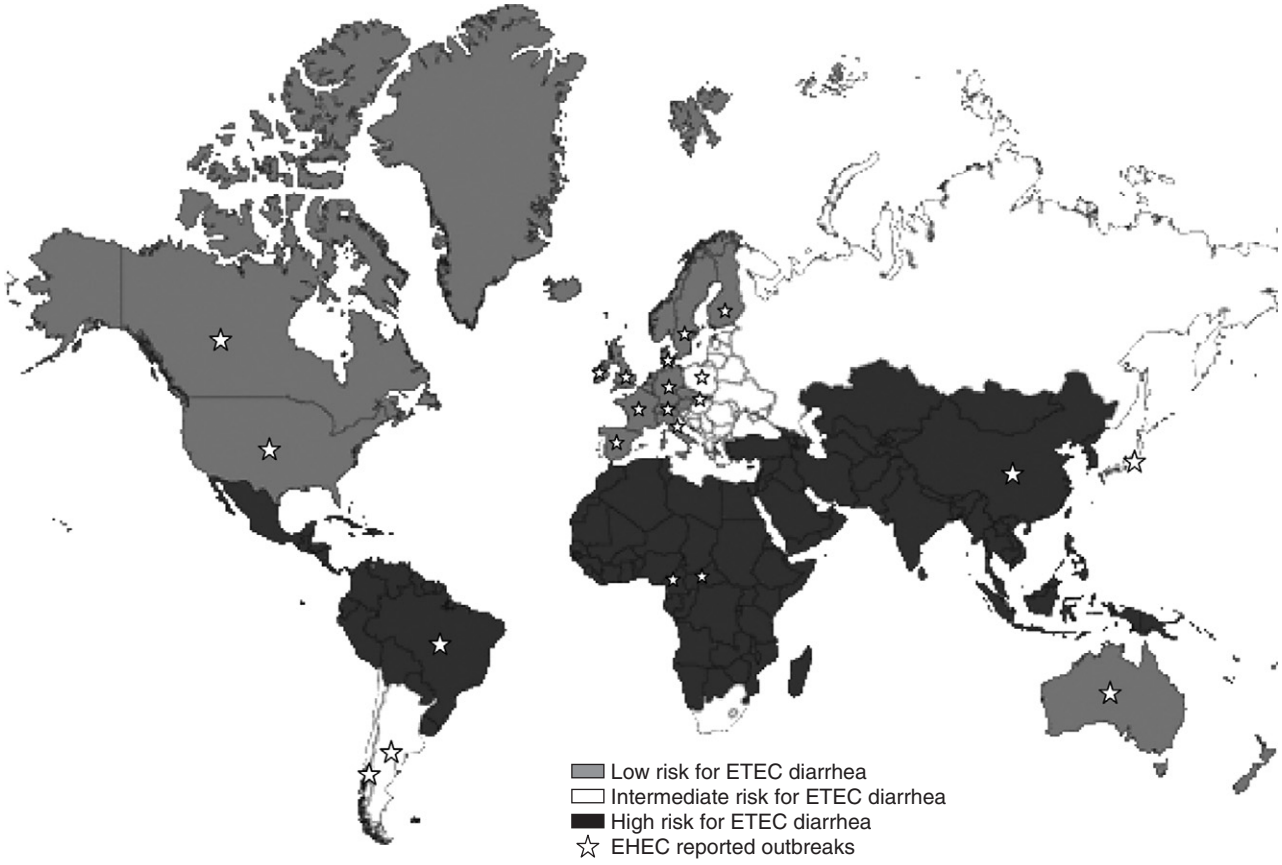

FIGURE 51.2 Areas of risk for traveler's diarrhea caused by enterotoxigenic *E. coli* and distribution of reported outbreaks due to enterohemorrhagic *E. coli* (EHEC) worldwide. The world is divided into three risk levels (low, intermediate, and high) of traveler's diarrhea for travelers from industrialized countries. The star symbols represent countries reporting outbreaks of enterohemorrhagic *E. coli*, O157:H7 being one of the predominant serotypes.

Enteropathogenic *E. coli*

EPEC is an important category of diarrheagenic *E. coli* that has been linked to infant diarrhea in the developing world. However, in industrialized countries, the frequency of these organisms has decreased, but they continue to be an important cause of diarrhea (Nataro and Kaper, 1998). EPEC strains can be classified as typical and atypical isolates. In general terms, EPEC produces a characteristic histopathological lesion known as attaching and effacing (A/E) on intestinal cells and do not produce Shiga toxins (Stx). Typical EPEC of human origin possesses a virulence plasmid known as the EAF (EPEC adherence factor) plasmid, while an atypical EPEC does not posses this plasmid; this is the basic difference between the two groups of organisms.

Pathogenesis

The central mechanism of EPEC pathogenesis is the adhesion to small bowel enterocytes and destruction of the normal microvillar architecture, initiating the formation of A/E lesions, which are characterized by microvilli destruction, intimate adherence of bacteria to the intestinal epithelium, pedestal formation, and aggregation of polarized actin and other elements of the cytoskeleton at sites of bacterial attachment. Cytoskeleton derangements are accompanied by an inflammatory response and diarrhea. The majority of genetic determinants for the production of A/E lesions are located on the pathogenicity island known as locus of enterocyte effacement (LEE) (Fig. 51.1) (Kaper et al., 2004; Torres et al., 2005). The LEE is present in all EPEC strains as well as in other A/E positive strains, including strains of EHEC and other enteric pathogens (Torres and Kaper, 2001). Many EPEC strains produce a characteristic adherence pattern, called localized adherence, in tissue-cultured cells (Scaletsky et al., 1984). This phenomenon is associated with the presence of the large EAF plasmid, which carries the so-called EAF sequence and also encodes type IV fimbriae, known as bundle-forming pili (BFP), which interconnect bacteria within microcolonies and thus promote their stabilization (Nataro and Kaper, 1998). The EAF plasmid is not essential for the formation of A/E lesions, although its presence enhances the efficiency of lesion formation due to the presence of the regulatory region known as Per (Mellies et al., 1999), as well as BFP, whose role in cell adhesion would similarly increase the efficiency of A/E lesion formation (Torres et al., 2005).

Epidemiology

EPEC serotypes are strongly associated with diarrhea in children <1 year of age. In this age group, these serotypes have been found to be the main cause of endemic diarrhea in several, well-controlled studies carried out in Brazil (Gomes et al., 1991; Toledo et al., 1983). The frequency of typical EPEC serotypes in children >1 year of age is lower and similar to the frequency in controls (2–4%). Adult infections are rare and usually associated with other conditions (Nataro and Kaper, 1998). A remarkable epidemiologic difference between typical and atypical EPEC serotypes is their geographic distribution. Typical EPEC serotypes have traditionally been associated with outbreaks of infantile diarrhea, and, in fact, the first EPEC strains isolated in different countries were of serotypes O55:H6 and O111:H2 (Trabulsi et al., 2002). In the past, these epidemic serotypes were frequently identified in industrialized countries as a cause of outbreaks and sporadic cases of diarrhea, but at present they are very rare (Nataro and Kaper, 1998). In these countries today, serotypes without the EAF plasmid predominate (Bokete et al., 1997; Scotland et al., 1996). The situation in developing countries is not well defined, but several studies in Brazil in the 1980s and early 1990s showed a high frequency of typical serotypes (Trabulsi et al., 2002). In the case of atypical strains, these isolates have been associated with prolonged diarrhea in children (Nguyen et al., 2006).

Clinical Disease

EPEC primarily causes acute diarrhea, although many cases of protracted EPEC diarrhea have also been reported (Donnenberg, 1995; Levine and Edelman, 1984). The infection can often be quite severe, and many clinical reports emphasize the severity of the disease (Rothbaum et al., 1982). In outbreaks from developing countries, a mortality rate of up to 30% has been reported (Senerwa et al., 1989), and in developed countries with the full range of modern treatment available, mortality is much lower, although deaths can still result (Rothbaum et al., 1982). In addition to profuse watery diarrhea, vomiting and low-grade fever are common symptoms of EPEC infection. The presence of the A/E lesion is associated with disarrangement of the digestive–absorptive enzyme system, leading to malabsorption of nutrients (Nataro and Kaper, 1998).

Treatment

As with other diarrheal pathogens, the primary goal of treatment of EPEC diarrhea is to prevent dehydration by correcting fluid and electrolyte imbalances. Oral rehydration may be sufficient for milder cases, but more severe cases require parenteral rehydration. A variety of antibiotics have been used to treat EPEC and have proved useful in many cases (Donnenberg, 1995), but multiple antibiotic resistance is common for EPEC (Donnenberg, 1995).

Enterohemorrhagic *E. coli*

EHEC were first recognized as a cause of human disease in 1982 (Riley et al., 1983) and are associated with diarrhea and hemorrhagic colitis (Karmali, 1989). EHEC is the only pathotype commonly responsible for diarrhea in children in the United States (Frenzen et al., 2005) and *E. coli* O157:H7, in particular, has emerged as the most virulent member of this pathotype, responsible both for outbreaks and sporadic cases of diarrhea in North America (Kaper et al., 2004). EHEC are defined by their ability to produce one or more Shiga toxins (Stx) (Tesh and O'Brien, 1991), which mediate the systemic complications of EHEC infections, and the induction of the characteristic attaching and effacing lesions on intestinal epithelia (Fig. 51.1) (Kaper et al., 2004; Torres and Kaper, 2001). In some people, particularly children under 5 years of age and the elderly, the infection can also cause a complication called HUS. In the United States, HUS is the principal cause of acute kidney failure in children, and most cases of HUS are caused by *E. coli* O157:H7.

Pathogenesis

Pathogenesis involves establishment of the organism in the gut, where it adheres to colon epithelial cells, probably mediated by the long polar fimbriae, and induces the attaching and effacing lesions produced by LEE pathogenicity island-encoded proteins as well as other factors found in O157-specific islands elsewhere in the genome (Torres et al., 2005). EHEC produce one or more Shiga toxins (also known as verocytotoxins) whose systemic absorption leads to potentially life-threatening complications (Fig. 51.1; Robinson et al., 2006). Not all Stx-producing *E. coli* strains contain the LEE and the terms Shiga toxin-producing *E. coli* (STEC) or verotoxin-producing *E. coli* (VTEC) are used to describe any *E. coli* strain that produces Stx, whereas EHEC is used to denote only the subset of LEE-positive, Stx-producing *E. coli*. The ability to produce one or more phage-encoded Stxs is the most important virulence characteristic of EHEC strains (Robinson et al., 2006). Toxin production mediates both local and systemic disease. Local intestinal effects cause the development of bloody diarrhea as Stx is internalized by the cells of the gut where it blocks cellular protein synthesis and may lead to apoptosis. HUS results from microvascular disease when the toxins enter the blood stream and bind to receptors on endothelial cells abundant in kidneys and brain (Nataro and Kaper, 1998).

Epidemiology

EHEC/STEC strains are the most frequently identified diarrheagenic *E. coli* serotypes in North America and Europe, with *E. coli* O157:H7 as the most common STEC serotype isolated in these countries (Frenzen et al., 2005). The CDC estimates indicate that STEC O157 infections cause 73,000 illnesses annually, resulting in more than 2000 hospitalizations and 60 deaths (Fig. 51.2) (Frenzen et al., 2005). From 1998 to 2002, the U. S. officials in 49 states reported 350 outbreaks representing 8598 cases of *E. coli* O157:H7; 1493 hospitalizations (17%); 354 cases of HUS (4%); and 40 deaths (0.5%) (Rangel et al., 2005). Recent data collected by the CDC in 2006 revealed that from 17,252 laboratory-confirmed cases of foodborne infections, 590 cases were attributed to *E. coli* O157 infections and 209 to non-STEC O157 infections, which demonstrate that the incidence of infections caused by STEC O157 have not decreased significantly as compared with previous years, and suggesting that further measures are needed to prevent foodborne illness in the United States (CDC, 2007).

Clinical Disease

The clinical manifestations of EHEC, particularly *E. coli* O157:H7, typically include the sudden onset of abdominal cramps followed by watery diarrhea, which becomes bloody (Nataro and Kaper, 1998). People generally become ill by 2–8 days (average of 3–4) after being exposed to *E. coli* O157:H7. Diarrhea usually lasts 2–14 days and sometimes the infection leads to nonbloody diarrhea. Nausea, vomiting, and usually little or no fever are typical. Progression to HUS, characterized by microangiopathic hemolytic anemia, thrombocytopenia, and renal failure, complicates 2–7% of *E. coli* O157:H7 cases (Griffin and Tauxe, 1991).

Treatment

Treatment is usually supportive and antibiotics are not usually recommended in the case of EHEC/STEC infections (AMA et al., 2004). Some studies have suggested that children who suffered hemorrhagic colitis are at greater risk of HUS if they are treated with antibiotics (Wong et al., 2000). For this reason, most clinicians do not recommend antibiotics for treatment of EHEC/STEC infections. Further, children suffering from bloody diarrhea should not be given antimotility agents.

Enteroinvasive *E. coli*

EIEC may produce an illness known as bacillary dysentery. The EIEC strains responsible for this disease are closely related to *Shigella* spp., and therefore EIEC infections are often associated with fever. Following the ingestion of EIEC, the organisms invade the

epithelial cells of the intestine, where they induce a local inflammatory response. Diarrhea can be bloody, but is usually watery and without blood or mucus.

Pathogenesis

The characteristic virulence determinants of EIEC are indistinguishable from those of *Shigella* spp. and include the presence of a virulence plasmid of ~220 kbp and the pathogens' ability to induce their entry into epithelial cells and disseminate from cell to cell (Fig. 51.1; Parsot, 2005). The pathogenicity factors found in the virulence plasmid include a type three secretion apparatus (TTSA) that spans the bacterial envelope, translocators that travel through the TTSA and insert into the host cell membrane to form a pore (translocon), and effectors that travel through the TTSA and the translocon and are injected within the eukaryotic cell. Once in the colonic mucosa, EIEC (similar to *Shigella* spp.) are proposed to cross the epithelial layer by invading M cells to be delivered to resident macrophages. Subsequently, they induce apoptosis and reach the basolateral pole of epithelial cells, in which they induce their entry. Movement of intracellular EIEC leads to the formation of protrusions and dissemination of bacteria within the epithelium. Release of cytokines and chemokines, including IL-1 by apoptotic macrophages and IL-8 by infected enterocytes, promotes recruitment of monocytes that migrate through the epithelial barrier, facilitating the entry of luminal bacteria into epithelial cells and increasing invasion of the epithelium (Prats and Llovet, 1995).

Epidemiology

EIEC is less common than ETEC or EPEC in the developing world and is associated with only a few characteristic serotypes (Nataro and Kaper, 1998). Though it has been responsible for outbreaks in both adults and children, it is much less common than ETEC, EPEC or EHEC. The incidence of EIEC in developed countries is believed to be low, but occasional foodborne outbreaks have been identified.

Clinical Disease

The clinical presentation closely resembles that of shigellosis with fever, abdominal cramps, rectal urgency, tenesmus, and watery or bloody diarrhea, lasting 5–7 days. The disease can appear within 24 h of infection with EIEC. In some persons, especially young children and the elderly, the diarrhea can be so severe that the patient needs to be hospitalized.

Treatment

Treatment recommendations are identical to that proposed for shigellosis. The greatest concern in treating EIEC disease is to replace the fluids and electrolytes (sodium, potassium, etc.) lost in the diarrhea. No controlled trials have examined the role of antimicrobial therapy though use of trimethoprim and sulfamethoxazole helps to eradicate susceptible strains of EIEC (DuPont, 1997). Further, ampicillin, nalidixic acid, or ciprofloxacin are also recommended; however, persons with mild infections will usually recover quickly without antibiotic treatment.

Enteroaggregative *E. coli*

EAEC is a diarrheal enteropathogen defined by aggregative adherence (AA) to cultured epithelial cells. EAEC has been implicated as an emerging cause of acute and chronic diarrhea in both developing and developed countries (Kahali et al., 2004; Nataro et al., 1998). Several epidemiological investigations of diarrhea suggest that EAEC is an important etiologic agent (Nataro et al., 1995; Nataro and Kaper, 1998) and, recently, it been shown that EAEC is an unrecognized cause of community-acquired diarrhea in infants in the United States (DuPont, 2005).

Pathogenesis

EAEC is defined by its ability to adhere to cultured cells in a "stacked brick" appearance (Okeke and Nataro, 2001). This phenotype, termed AA, is associated with specific fimbriae (AAFs) encoded by plasmids (pAAs) (Fig. 51.1; Harrington et al., 2006; Nataro et al., 1998). Other factors are associated with this adherence pattern, indicating its multifactorial nature (Torres et al., 2005). Several toxins expressed by EAEC strains have already been identified. Among the well-known toxins are EAEC heat-stable toxin (EAST1) and plasmid-encoded toxin (Pet), both of which are encoded by pAAs (Nataro et al., 1998). Furthermore, a serine protease involved in the colonization process (Pic) is encoded by the chromosome from prototype strain 042 (Henderson et al., 1999). Inflammation is a hallmark in EAEC-infected patients, and recent data indicated that the flagellin of EAEC strains induced the release of IL-8 from Caco-2 cells in culture (Steiner et al., 2000).

Epidemiology

EAEC strains were first recognized in 1987 and are most often associated with illnesses in different settings, including endemic diarrhea of infants in both

industrialized and developing countries (Harrington et al., 2006; Okeke and Nataro, 2001), chronic diarrhea among human immunodeficiency virus/acquired immunodeficiency syndrome patients, and traveler's diarrhea. Asymptomatic infection can cause subclinical inflammatory enteritis and growth disturbances. Several outbreaks of EAEC diarrhea have also been described. Prospective studies suggest that in well-nourished populations in industrialized countries, EAEC may be a cause of endemic sporadic diarrhea. For example, a large prospective surveillance study in the UK implicated EAEC among the major pathogens at all ages (Wilson et al., 2001).

Clinical Disease

EAEC infection comprises watery diarrhea, occasionally with blood and mucus. Several studies have suggested that patients infected with EAEC manifest intestinal inflammation, marked by the presence of fecal lactoferrin and proinflammatory cytokines, notably interleukin (IL)-8 (Greenberg et al., 2002; Steiner et al., 2000). Further data have suggested that even asymptomatic carriage of EAEC strains can result in evidence of low-level enteritis (Steiner et al., 1998).

Treatment

Patients who are dehydrated should receive oral administration of solutions with electrolytes, and antibiotics are not usually recommended because EAEC can be resistant to treatment with antibiotics. However, a clinical trial of ciprofloxacin showed that diarrhea improved in AIDS patients infected with EAEC (Wanke et al., 1998).

Diffusely Adhering *E. coli*

DAEC strains are a heterogeneous group of isolates, all of which exhibit diffuse adherence (DA) to epithelial cells in the classical laboratory assay of adherence to HEp-2 or HeLa cells (Cravioto et al., 1991). The association of DAEC with diarrheal disease is not as strong as the other *E. coli* categories (Jallat et al., 1993, 1994), and little is known about the mechanism of pathogenesis. However, it is clear that DAEC isolates are associated with watery diarrhea that can become persistent in young children (Kaper et al., 2004; Le Bouguenec, 1999).

Pathogenesis

The DA pattern of DAEC isolates is due to the production of adhesins. About 75% of DAEC strains produce a fimbrial adhesin (designated F1845) encoded by the *daa* operon or express adhesins encoded by a family of *afa/dra/daa*-related operons (Fig. 51.1; Le Bouguenec and Servin, 2006; Torres et al., 2005). Unlike the virulence factors from pathovars associated with severe acute diarrhea (EHEC, ETEC, and EIEC), and the virulence factors only found in extraintestinal *E. coli*, the *afa/dra/daa* operons are genes that are expressed in a variety of genetic backgrounds (Escobar-Paramo et al., 2004). The *afa/dra/daa* operons are also interesting because they reportedly code for both afimbrial (such as AfaE-I and AfaE-III) and fimbrial (such as F1845 and Dr) adhesive structures on the bacterial surface and constitute the first known example of a single operon promoting both adhesion to epithelial cells and invasion into these cells (Le Bouguenec and Servin, 2006).

Epidemiology

DAEC infections are not well studied but have been recognized as a cause of diarrhea in the developing world, particularly among children. DAEC are infrequently identified in the United States. In a number of epidemiological studies, DAEC strains have been associated with diarrheal disease in different geographic areas (Lopes et al., 2005). However, DAEC virulence markers associated with diarrhea are yet to be clarified.

Clinical Disease

The clinical features of DAEC isolates are poorly described, and the diagnosis available is based on tissue culture assays looking for DA. However, a retrospective case-control study performed with a small group of children revealed that, among clinical signs, vomiting, but not diarrhea, was significantly associated with the presence of DAEC in children suffering from gastroenteritis (Poitrineau et al., 1995). Further prospective studies of children in France and Brazil showed a significant correlation between DAEC infection and diarrhea (Forestier et al., 1996; Scaletsky et al., 2002).

Treatment

As with many other diarrheagenic *E. coli* pathovars, oral rehydration therapy can help replace fluids and salts lost due to *E. coli*-induced illness. No information is currently available about antibiotic-resistant DAEC clinical isolates.

VACCINES

The development of vaccines against diarrheagenic *E. coli* strains, like any other enteric pathogen, represents

a serious challenge because of the large number of serotypes involved and the requirement to induce immunity that is effective in the gut (Nataro and Kaper, 1998). Ideally, a vaccine against diarrheagenic *E. coli* should be administered by the mucosal route in order to elicit mucosal protection. Vaccines using live, attenuated bacteria have been developed to determine whether or not they can protect via the mucosal route against heterologous diarrheagenic *E. coli* infections (Girard et al., 2006). New, efficient mucosal adjuvants for human use have been designed based on, among others, *E. coli* toxins, with the aim of improving the induction of mucosal Thl and Th2 responses (Eriksson and Holmgren, 2002). Further, transgenic plants offer a new strategy for the development of safe, oral subunit vaccines against diarrheal diseases such as ETEC infection (Tacket, 2004). Even with all the recent progress, there are no vaccines currently approved to prevent diarrhea caused by diarrheagenic *E. coli* (with the possible exception of ETEC infection). The following section summarizes the state of the art in vaccine research and development to combat diarrheagenic *E. coli* infections, with a special emphasis on three pathotypes of *E. coli* (ETEC, EHEC, and EPEC), where most of the progress in vaccine development has accumulated in recent years.

Vaccines against ETEC

Several attempts have been made to develop a vaccine that will be effective against pathogenic *E. coli*, specifically ETEC (Svennerholm and Steele, 2004). ETEC comprises many different O:H serotypes, multiple antigenically distinct CFs types, and three different toxin phenotypes (LT only, ST only, or LT/ST). To confer broad-spectrum protection, vaccines must immunize against this heterogeneous array of ETEC pathogens (Nataro and Kaper, 1998; Steffen et al., 2005). Natural history studies of ETEC infections in children in developing countries, epidemiological evidence in children and adults, and results from experimental challenge studies in volunteers, suggest that ETEC infections are immunizing, as reflected by declining rates of ETEC diarrhea and lower ratios of symptomatic-to-asymptomatic ETEC infections with increasing age, and that multiple infections with antigenically diverse ETEC strains lead to broad-spectrum protection against ETEC diarrhea (Levine and Svennerholm, 2001). It has been suggested that protective immunity appears to be mediated by secretory IgA (SIgA) antibodies directed against fimbriae, other surface antigens, and LT. Interestingly, the ST toxin does not elicit neutralizing antibodies following natural infection (Svennerholm and Savarino, 2004). Overall, cumulative evidence suggests that immunization against ETEC early in life may be an effective preventive strategy. Further, travelers going from industrialized to developing countries constitute another important potential target population for vaccination against ETEC. Therefore, different strategies have been used to deliver ETEC fimbriae and toxin antigens in the form of inactivated or live candidate vaccines to elicit protective human immune responses (Levine and Svennerholm, 2001).

Inactivated and Subunit Vaccines

One of the best-studied ETEC vaccines has been developed by investigators at the University of Goteborg (Sweden), and is an oral, whole-cell vaccine consisting of five strains expressing the CFs: CFA/I, CFA/IV (CS4 and CS6), CFA/IV (CS5 and CS6), CFA/II (CS2 and CS3), and recombinant cholera toxin B subunit (CTB). This composition is designed to induce protection against the most common CFs expressed by ETEC strains. Phase II studies of a two-dose regimen of this vaccine have been conducted in Israel, Nicaragua, the United States, and in immunologically naive populations of Sweden (Jertborn et al., 1998; Svennerholm and Steele, 2004). In these studies, the vaccine was found to be safe and immunogenic, as manifested by induction of mucosal antibody responses to CTB and to the CFA components of the vaccine. These results have been supported by further studies in Egyptian adults and children (Hall et al., 2001) and in Bangladeshi children (Qadri et al., 2003). A pilot efficacy trial of this vaccine in Austrian tourists traveling to developing country destinations found the vaccine to confer about 80% protection against ST–ETEC diarrhea (the only toxin phenotype detected in this study) (Wiedermann et al., 2000). The vaccine was well tolerated in all studies with only mild side effects. However, a preliminary report on the efficacy of this vaccine in Egyptian infants and children indicates that the vaccine was relatively inefficient (conferring less than 20% protection) against ETEC infections in the very young (Boedeker, 2005; Savarino et al., 2002).

One vaccine for which protective efficacy against ETEC has been demonstrated in phase III studies is a whole-cell/recombinant B subunit (WC/rBS) oral cholera vaccine (Dukoral™), which also provides cross protection against ETEC (Girard et al., 2006). The WC/rBS vaccine was designed to stimulate antitoxic as well as antibacterial immunity against cholera and consists of two main vaccine components. The first is the nontoxic CTB, which is known to induce protective antitoxic IgA immunity. The second is heat- and formalin-killed, whole bacterial cells of *Vibrio cholerae*. The WC/rBS vaccine has also been shown to have up

to 60% protective efficacy against LT–ETEC-mediated traveler's diarrhea (Clemens et al., 1988; Haberberger et al., 1991; Scerpella et al., 1995). Thus, the protection against ETEC diarrhea after vaccination with the WC/rBS vaccine is mediated specifically through antitoxic immunity rather than by antibodies against the bacterial cells. The phase III efficacy field trial with this vaccine was initiated in 1985 in rural Bangladesh to study the protection afforded by the WC/rBS vaccine against LT–ETEC (Clemens et al., 1988). The protective efficacy against LT-producing ETEC observed in this trial was 67%. However, it was not possible to demonstrate protection for more than 3 months after vaccination, but since the study was done in an ETEC-endemic population, the data were sufficient to prove efficacy against traveler's diarrhea. The efficacy of the WC/rBS vaccine has also been investigated in a study involving tourists who traveled to Morocco from Finland (Peltola et al., 1991). The oral WC/rBS vaccine was found to prevent 23% of all diarrhea episodes and 52% of episodes due to ETEC, particularly LT-producing ETEC, but this protection reportedly did not last longer than a few months. A third efficacy study was conducted in 1992 among US students going to Mexico (Scerpella et al., 1995). In this study, the WC/rBS vaccine was given after arrival in Mexico, with protection expected to be conferred within 7 days of administration of the second dose. This study confirmed the findings of the Finnish study, with a 50% protective efficacy conferred.

Other vaccines currently in development include one using transcutaneous immunization (TCI) with a mixture of fimbrial antigen CS6 and LT administered on a 0-, 1-, and 3-month schedule via skin patches. This trial regimen was found to induce serum antibodies and antibody-secreting cells in a majority of adult volunteers. Delayed-type hypersensitivity, suggesting T-cell responses, was seen in 14 of the 19 volunteers receiving LT and CS6. This study has demonstrated that protein antigens delivered by a simple patch could induce systemic immune responses but only in the presence of an adjuvant such as LT (Guerena-Burgueno et al., 2002). Whether TCI also elicits protective mucosal immunity at the intestinal level still remains to be demonstrated. Lastly, feeding volunteers with transgenic corn or potatoes expressing the LTB resulted in significant serum and gut antibody responses (Tacket, 2004).

Live Vaccines

Evidence indicates that anti-CFA and anti-LT immune responses play important roles in mediating protection against ETEC disease (Svennerholm et al., 1997; Tacket and Levine, 1997). The idea of using live, toxin-free mutants as effective oral vaccines came from previous findings, indicating that a spontaneous mutant, which had lost its ST and LT toxins but continued to express CFs (e.g. CFA/II), provided 75% protection against challenge with an LT^+, ST^+, CFA/II^+ strain (Levine, 1986). Therefore, further attenuation was needed to produce a prototype vaccine for ETEC and different strategies have been attempted thereafter.

Considerable success has been achieved utilizing attenuated ETEC strains as vectors of key protective antigens. Two nontoxigenic ETEC strains (variant of a CFs [CS1 plus CS3]-positive ETEC) were attenuated by mutagenesis of the *aroC* and *ompR* genes or the *aroC*, *ompC*, and *ompF* genes, respectively, to be used as candidate live, oral attenuated vaccines. The mutagenized strains were found to be well tolerated and immunogenic when fed to human volunteers (Turner et al., 2001). Based on these results, the development of a vaccine that protects against a diverse range of ETEC strains was the next step. Therefore, an attenuated CFA/I-expressing ETEC vaccine candidate was constructed by deleting the ST and EAST1 (enteroaggregative *E. coli* heat-stable toxin) genes and introducing defined deletion mutations into the *aroC*, *ompC*, and *ompF* chromosomal genes. The vaccine candidate, administered in two formulations, fresh culture and frozen suspension, was tested in a phase I clinical evaluation of the safety and immunogenicity, and results showed no evidence of significant adverse events related to vaccination (Turner et al., 2006). The vaccine was well tolerated and immunogenic in healthy adult volunteers, and this finding represents a significant milestone in the development of a live attenuated ETEC vaccine.

The live ETEC vaccine approach is also being pursued by investigators at the Center for Vaccine Development at the University of Maryland. Their strategy utilizes live, attenuated, *Shigella*-based multivalent *Shigella*/ETEC hybrid vaccines for expression of ETEC fimbrial and LT antigens (Altboum et al., 2001). In their studies, the genes encoding the production of CFs (CS2 and CS3 fimbriae) were isolated and expressed in an attenuated *Shigella flexneri* 2a strain CVD 1204, which carried a mutation in the *guaBA* genes. Animals immunized with *Shigella* expressing CS2 and/or CS3 developed serum antibodies that agglutinated *Shigella*, as well as ETEC strains bearing the homologous fimbriae, findings that supported the feasibility of a multivalent vaccine against shigellosis and ETEC diarrhea. CVD 1204 has also been used to express individually CFA/I, CS2, CS3, and CS4, as well as a detoxified version of the human ETEC variant of a heat-labile toxin (LThK63) (Barry et al., 2003). Following mucosal immunization of guinea pigs with a mixed formulation of two or more *Shigella* strains expressing the different CS antigens and modified LT,

immune responses were observed against each ETEC antigen plus the *Shigella* vector. When each strain expresses multiple ETEC antigens, combinations of attenuated *Shigella* strains allow development of a mixed formulation containing relevant immunogens from both pathogens. Accordingly, new prototype attenuated strains have been constructed, and each contains expression plasmids encoding one or two ETEC antigens (Barry et al., 2006). Therefore, live attenuated strains of *S. flexneri* 2a, *S. sonnei*, and *S. dysenteriae* 1 containing deletions in *guaBA* genes as well as in genes encoding enterotoxins have been constructed and subsequently used as a live vector for the expression of one or two critical ETEC antigens. The resulting *Shigella* derivative strains were able to elicit serum and mucosal antibody responses against the live vector as well as the ETEC antigens, further supporting the use of mixtures of live *Shigella* derivatives expressing ETEC antigens as immunogenic multivalent vaccines.

Current and Future Status of ETEC Vaccine Development

As described above, several attempts have been made to develop a vaccine that will be effective against ETEC infections. To date, only the WC/rBS ETEC vaccine has been evaluated for protective efficacy in a field trial in children in endemic areas. Unfortunately, this vaccine did not induce significant protection in this important target group (Svennerholm and Savarino, 2004). Further studies may potentially provide information that will contribute to the development of a more effective vaccine because to date, no prospective alternative ETEC vaccine is available for licensing within the next 3–5 years.

Vaccines against EHEC

Enterohemorrhagic *Escherichia coli* O157:H7, for which cattle are an important reservoir, is an important pathogen of humans and the main source of illness, either through direct contact (petting zoos) or by consumption of contaminated meat products, or indirectly, through consumption of fruits and vegetables that have been watered with contaminated water. Therefore, scientific efforts have focused on the development of vaccines for people and cattle to prevent or treat food contaminated by this particular *E. coli* serotype. So far, no vaccines have been approved, but some vaccine candidates, which are discussed below, have advanced to clinical trials.

Subunit Vaccines

It has been documented that high serum titers of antibodies to the lipopolysaccharide (LPS) of *E. coli* O157:H7 are detectable after asymptomatic infection (Bell et al., 1997; Chart et al., 1991). The protective role that these antibodies play is suggested in populations having frequent contact with cattle, such as dairy farm workers, who have higher serum titers of antibodies to *E. coli* O157:H7 and a lower risk of symptomatic infection than does the general population (Haack et al., 2003; Reymond et al., 1996). Based on these premises, a research group at the U.S. National Institutes of Health produced a polysaccharide conjugate vaccine. This vaccine consisted of an *E. coli* O157:H7 O-specific polysaccharide covalently linked to recombinant exoprotein A of *Pseudomonas aeruginosa* (O157-rEPA). In a phase I trial, the investigators showed that the conjugate vaccine administered to healthy adults was safe and elicited high serum IgG LPS antibody titers with bactericidal activity (Konadu et al., 1998). The same vaccine has been tested in a phase II clinical trial in 2- to 5-year-old children and the results demonstrated that children who received one or two doses had increased titers of serum IgG LPS antibodies (Ahmed et al., 2006). Further, 1 week after the first dose was administered, most patients (81%) responded with a >fourfold increase in serum IgG LPS antibodies, and, at 6 weeks, all children responded with an >eightfold increase; a second dose did not elicit a booster response. Serum samples of patients at 26 weeks after the first dose was administered had high titers of bactericidal activity that correlated roughly with serum IgG LPS antibody titers (Ahmed et al., 2006). Because the O157-rEPA vaccine was shown to be safe and immunogenic in young children, a phase III trial concurrent with routine infant immunization is planned.

Other compelling targets for vaccine development are the cytotoxins (Stx1 and Stx2), because expression of these Shiga toxins is universal in antigenically diverse EHEC strains and serotypes. In addition, it has been shown that they play a central role in severe pathogenesis and there is a good correlation between EHEC isolates expressing prototypic Stx2 and a more severe course of illness (Marcato et al., 2005). Following this rationale, an acellular vaccine consisting of the nontoxic B subunit from prototypic Stx2 was constructed and tested in animals. Data indicated that rabbits immunized with a recombinant preparation of the prototypic Stx2 B subunit were protected from a subsequent challenge with a lethal dose of Stx2 holotoxin (Marcato et al., 2001). However, effective vaccination in this study was found to be unpredictable unless LPS was included with the antigen. Since the presence of endotoxin would be unacceptable in a human vaccine, a second study was designed to investigate ways to safely augment the immunogenicity of the recombinant Stx2 B subunit containing <1 endotoxin unit

per ml. The study revealed that sera from mice immunized with such a preparation, conjugated to keyhole limpet hemocyanin and administered with the Ribi adjuvant system, displayed the highest Stx2 B-subunit-specific IgG titers, and, when animals were challenged with a lethal dose of Stx2 holotoxin, 100% of the vaccinated mice were protected, supporting further evaluation of a Stx2 B-subunit-based human EHEC vaccine (Marcato et al., 2005).

Another promising approach being pursued in the development of EHEC candidate vaccines is a plant-based oral vaccine to either reduce colonization of *E. coli* O157:H7 or protect against systemic intoxication by Stx2. Transgenic plants offer the flexibility to function as low-cost, efficient, and practical oral delivery systems for vaccine antigens to stimulate mucosal immunity or to boost and shift initial immunity to a mucosal antibody response (Lauterslager et al., 2001; Tacket, 2004). The first EHEC antigen to be tested was the LEE-encoded adhesin intimin. The selection of this adhesin as a candidate vaccine was based on previous studies showing that antibodies against the carboxy-terminal third of intimin blocked adherence of wild-type *E. coli* O157:H7 to HEp-2 cells (Gansheroff et al., 1999), and that colostrum from pigs immunized with *E. coli* O157:H7 intimin contains anti-intimin antibodies that can protect suckling piglets from colonization with *E. coli* O157:H7 (Gansheroff et al., 1999). Since the data suggest that antibodies specific to intimin play an important role in blocking adherence of the bacterium to host cells and can protect the host from *E. coli* O157:H7-mediated disease, the *Nicotiana tabacum* cell line NT-1 was modified by means of *Agrobacterium*-mediated transformation to express the C-terminal binding domain of intimin (Judge et al., 2004). Mice immunized intraperitoneally with intimin expressed from the plant cells, fed transgenic plant cells, or both, generated an intimin-specific mucosal immune response when primed parenterally and then boosted orally and also exhibited a reduced duration of *E. coli* O157:H7 fecal shedding after challenge (Judge et al., 2004). Because the results with the plant-based vaccine against intimin were so encouraging, this group used the same strategy to express a genetically inactivated Stx2 toxoid to stimulate an immune response in the gut against Stx2 and, more importantly, to protect against systemic Stx2 intoxication (Wen et al., 2006). In this study, the immunized mice produced Stx2-specific mucosal IgA and Stx2-neutralizing serum IgG. It was also shown that oral immunization fully protected mice from the challenge, demonstrating that a plant-based oral vaccine can confer protection against lethal systemic intoxication (Wen et al., 2006). The EHEC oral plant-based vaccine shows promise for protection against the severe, sometimes life-threatening, consequences of STEC infection, against which no other suitable treatments or therapies are currently available; however, further work is required to determine whether or not the use of this expression system is the best approach in developing an EHEC vaccine.

Current and Future Status of EHEC Vaccine Development

A number of early studies strongly suggested that decreased shedding of *E. coli* O157:H7, as well as a reduction in the number of cattle that excrete this serotype, could cause a significant reduction in the prevalence of the bacteria in cattle and the farm environment, which could potentially lead to a decline in the incidence of human *E. coli* O157:H7-related disease (Hancock et al., 1998; Jordan et al., 1999; Zhao et al., 1998). Based on these observations, investigators at the University of British Columbia have designed and initiated field studies of *E. coli* O157:H7 secreted products (effectors from the LEE-encoded type III secretion system) as a subcutaneously administered bovine vaccine (Potter et al., 2004). The *E. coli* O157:H7 vaccine was tested in cattle in an initial trial and showed reduction in the duration, frequency, and quantity of *E. coli* O157:H7 shed in cattle following experimental challenge. In addition, the experimental vaccine was shown to significantly reduce shedding of the organism under conditions of natural exposure (Potter et al., 2004). A subsequent field trial was designed to determine the effectiveness of an *E. coli* O157:H7 vaccine in reducing fecal shedding of *E. coli* O157:H7 in pens of feedlot cattle (Van Donkersgoed et al., 2005). This study demonstrated that the *E. coli* O157:H7 vaccine did not significantly reduce the proportion of cattle shedding *E. coli* O157:H7 in their feces. Failure to see any vaccine efficacy was attributed to a poor immunological response to the vaccine either because of alterations of protein conformation, and hence epitopic changes due to formalin fixation, or due to application of a vaccination strategy different from the one used in the previous study (Van Donkersgoed et al., 2005). Despite this drawback and some technical issues, which remain to be resolved, the use of vaccination to decrease foodborne pathogens in reservoir animals seems to hold significant theoretical promise, and has been demonstrated by the purchase of the rights to produce and commercialize the vaccine Bioniche Life Sciences Inc., a research-based, technology-driven Canadian biopharmaceutical company. Recent controlled challenge studies demonstrated that vaccination with Bioniche's *E. coli* O157:H7 Type III secreted protein vaccine (three doses, 3 weeks apart) resulted in a 36.5% reduction

in the number of days the bacterium was shed in the feces, and a 2.28 $\log_{10}$ reduction in the number of bacteria being shed in the feces; resulting in a vaccine efficacy of more than 99% (Rogan, 2007). Further, a large-scale feedlot study was also recently conducted in 2004 across 19 commercial feedlots to evaluate the efficacy of only two vaccinations, upon entry and again at reimplantation. This study demonstrated that, as compared to unvaccinated cattle on a pen basis, vaccinated cattle had a 75% lower probability of being colonized by *E. coli* O157:H7, indicating that the vaccine reduced environmental exposure of cattle to *E. coli* O157:H7 (Rogan, 2007). Based on these results, the company is scaling up production of the vaccine in anticipation of its commercial launch in Canada because Bioniche Life Sciences has received authorization from the Canadian Food Inspection Agency to make the vaccine available to veterinarians. However, the approval is conditional, and the company has to provide substantial evidence that the vaccine works.

Vaccines against EPEC

No vaccines against EPEC infections have been approved, but some vaccine candidates have been developed. Some of these candidate vaccines are derived from observations indicating that experimental infection of human volunteers with EPEC-produced IgG antibodies against the protein intimin (Levine et al., 1985). It was observed in another study that human volunteers rechallenged with homologous or heterologous EPEC strains developed an IgG response mainly against LPS O antigen and intimin, but not to bundle-forming pili major subunit (BfpA) (Donnenberg et al., 1998). Further, antibody responses against BfpA, intimin, and the type III secretion proteins EspA and EspB have been investigated in Brazilian children naturally infected with EPEC, and the results showed that IgG antibodies against BfpA and EspB were the most commonly found, followed by anti-EspA and intimin antibodies (Martinez et al., 1999). Overall, these data suggest that Bfp and LEE-encoded products are produced in vivo during natural EPEC infections and elicit an immune response against heterologous EPEC virulence determinants, which serve as the basis for the development of candidate vaccines. Therefore, an EPEC recombinant BfpA and EspB candidate vaccine has been generated. Next, the frequencies of naturally occurring IgA antibody activities to the EPEC recombinant vaccine were compared in feces of breast-fed and artificially fed Brazilian infants hospitalized for acute watery diarrhea (de Souza Campos Fernandes et al., 2003). The study found that the frequencies of anti-EPEC IgA copro-antibodies in either breast or artificially fed children <6 months of age were comparable, and would allow a correlation to be established between the presence of anti-EPEC copro-antibodies and protection to clinical infection during infancy (de Souza Campos Fernandes et al., 2003). The high prevalence of anti-BfpA fecal antibodies demonstrates that this virulence factor is highly immunogenic in vivo; however, further studies with human volunteers are required to determine whether the EPEC recombinant vaccine is protective against natural EPEC infections.

Another approach being used in the development of a candidate vaccine is the construction of an attenuated EPEC strain. The *ler* (LEE-encoded regulator) gene product is a central regulator for the genes encoded on the LEE-pathogenicity island of A/E pathogens, including human EPEC and EHEC as well as animal isolates (Torres and Kaper, 2001). Although an in vivo role for Ler in bacterial virulence has not been documented, it has been hypothesized that a *ler* deletion mutant should be attenuated for virulence, and may retain immunogenicity (Zhu et al., 2006). To test this hypothesis, investigators at the University of Maryland constructed a *ler* mutant of a rabbit EPEC (rEPEC) strain (rEPEC constitutes a member of A/E-producing *E. coli* family and isolates of different serotypes have been shown to be causative agents of rabbit enteritis) to examine the effect of *ler* on in vivo virulence, and to determine if intragastric inoculation of an attenuated rEPEC *ler* mutant was immunogenic and could protect rabbits against subsequent challenge with the wild-type strain. The preliminary results demonstrated that the Ler protein of rEPEC is critical for both in vitro pathogenic effects and in vivo virulence, and that immunization with this isogeneic *ler* mutant protected rabbits from fatal challenge with the virulent parent strain (Zhu et al., 2006). The same investigators have now assessed the degree of homologous (serotype-specific) and heterologous (cross-serotype) protection induced by immunization with either rEPEC *ler* mutant strains of different serotypes, or with a prototype strain which expresses a full array of *ler* upregulated proteins (Zhu et al., 2007). The data demonstrated serotype-specific protection induced by the isogenic *ler* mutants. However, cross-serotype protection was not induced by the *ler* mutant, but only by the prototypical rEPEC strain expressing a full set of LEE-encoded proteins. These results are consistent with the hypothesis that cross-serotype protection requires the expression and induction of antibodies to LEE-encoded virulence factors, including intimin and secreted proteins, whereas serotype-specific protection can be induced even when the expression of these

virulence factors is markedly downregulated (Zhu et al., 2007). This serotype-specific protection is a drawback in the development of an effective EPEC (and potentially an EHEC) vaccine because although serotype-specific vaccines may be useful for some serotypes (e.g. EHEC O157:H7) that are highly prevalent in certain areas, ideal vaccines should cross protect against all of the major serotypes likely to be encountered.

PROSPECTS FOR THE FUTURE

The genomic plasticity observed in intestinal pathogenic *E. coli* strains resulted in a highly versatile species that is capable of colonizing, and multiplying in and damaging diverse environments. The increased understanding of the mechanisms by which pathogenic *E. coli* can cause diarrhea has dramatically changed the current perspective of this species. However, the ability of various *E. coli* virulence factors to affect such a wide range of cellular functions has produced an unexpected high level of complexity in order to develop an effective vaccine.

KEY ISSUES

- Although significant advances have been made in the field of intestinal pathogenic *E. coli* vaccine research and development, there still remain several outstanding issues and challenges, which need to be addressed.
- The immunogenicity and efficacy of licensed vaccines, such as WC/rBS oral cholera/ETEC vaccine, remain to be elucidated in infants, and they have yet to be fully implemented in areas where the disease is endemic.
- Vaccine candidates against ETEC and other diarrheagenic *E. coli* strains also face serious challenges.
- For those candidate vaccines already in clinical trials, there are initial indications that the immunogenicity might be lower in infants in less-developed countries than in those from industrialized countries, and, therefore, the clinical efficacy of these vaccines needs to be evaluated in infant populations in developing countries.
- The diarrheagenic *E. coli* candidate vaccines also have to cope with the multiplicity of protective antigens that need to be included in the vaccine and with the geographical diversity of circulating serotypes of the bacteria.
- The immune correlates of protection are not clearly understood for any of these intestinal pathogenic *E. coli* vaccines.
- Although many of these challenges remain to be overcome, the involvement of the public health sector and the high priority given to vaccine research and development in this field bode well for the future.
- A combined public health effort coupled with the extensive and active investigations being conducted by the academic and research community should finally bring hope for the control of diarrheal diseases in infants and young children around the globe.

OUTLINE

ABSTRACT

Lyme disease is the most prevalent vector-borne disease in North America and Europe. It is an important emerging disease, with increasing incidence and expanding endemic regions. Lyme disease was first described as a clinical entity in North America in the late 1970s and its spirochetal etiology identified in 1982. Clinical manifestations consistent with Lyme disease were described in Europe in the early 1900's. The infection is caused by a subset of species of the *Borrelia burgdorferi* sensu lato complex. In nature, the *Borrelia* are obligate host-associated spirochetes that are maintained in an enzootic cycle involving *Ixodes* ticks, and small mammals, birds, and lizards. Humans are incidental hosts, and are of no significance in the enzootic cycle. Clinical manifestations of early-stage disease

in humans, with the exception of the pathognomonic erythema migrans rash, are generally nondescript. However, long-term infection can lead to serious dermatological, arthritic, cardiac, and neurological sequelae that can be debilitating. The potentially serious and costly nature of Lyme disease dictates the need for improved preventive strategies. There is currently no vaccine that is commercially available for use in humans. This chapter reviews the history, current status, and future directions of Lyme disease vaccine development.

INTRODUCTION

Lyme disease is an emerging zoonotic infection caused by spirochete species of the *Borrelia burgdorferi* sensu lato complex (Burgdorfer et al., 1982; Benach et al., 1983). This complex consists of 10 species, with *B. garinii*, *B. afzelii*, and *B. burgdorferi* being most frequently associated with disease in humans (Barbour and Hayes, 1986; Baranton et al., 1992; Marconi and Garon, 1992b; Welsh et al., 1992; Fukunaga et al., 1993, 1996; Kawabata et al., 1993; Marconi et al., 1995; Postic et al., 1998). While all three species occur in Europe and Asia, only *B. burgdorferi* has been demonstrated in North America. Additional species that may be associated to a lesser extent with human disease include *B. valaisiana* (Rijpkema et al., 1997; Diza et al., 2004) and *B. lusitaniae* (Collares-Pereira et al., 2004) which have been identified in Europe, and *B. lonestari* in the southern United States. *B. lonestari* is thought to be the causative agent of a Lyme-like disease referred to as southern tick-associated rash illness (STARI) or Masters disease (Masters et al., 1998; Varela et al., 2004). The true incidence of STARI remains to be determined and has been the subject of considerable debate.

The Lyme disease spirochetes are maintained in an enzootic cycle involving *Ixodes* ticks and a wide variety of animals and reptiles (Brown and Lane, 1992; Keirans et al., 1996; Gern et al., 1998). *Ixodes scapularis* (formerly *I. dammini* (Oliver et al., 1993)) is the primary arthropod vector in the eastern and midwestern regions of North America, and *I. pacificus* in the western United States (Lane et al., 1991). In Europe, *I. ricinus* is the dominant vector, while *I. persulcatus* and *I. nipponensis* are important in Asia (Hengge et al., 2003). *Borrelia lonestari* is vectored by the lone star tick, *Amblyomma americanum*, and is the only putative Lyme disease spirochete that is carried by a tick species that is not part of the *Ixodes* complex.

The Lyme disease spirochetes are strictly dependent on animal reservoirs for population maintenance, as transovarial transmission of the spirochetes in ticks does not occur at a biologically significant level (Barbour and Hayes, 1986). Lyme spirochetes are maintained in a 2-year enzootic cycle (Fig. 52.1). In spring, uninfected larvae hatch from eggs and take a blood meal from a small mammal or bird in late summer. If the larvae feed to repletion on an infected mammal they have the potential to become infected. After completion of the blood meal, the larvae molt to the nymph stage and become dormant as they overwinter. When the infected nymphs emerge during the late spring/early summer of the following year they feed on, and potentially infect, a wide range of small animals that are competent to serve as reservoirs for the Lyme disease spirochetes (Keirans et al., 1996; Gern et al., 1998; Steere et al., 2004). In North America, the white-footed mouse, *Peromyscus leucopus*, is a major, though not the only, mammalian reservoir. After nymphs complete the blood meal, they molt to become sexually differentiated adults, and feed on larger mammals. Deer and other large mammals are important in the enzootic cycle primarily due to the

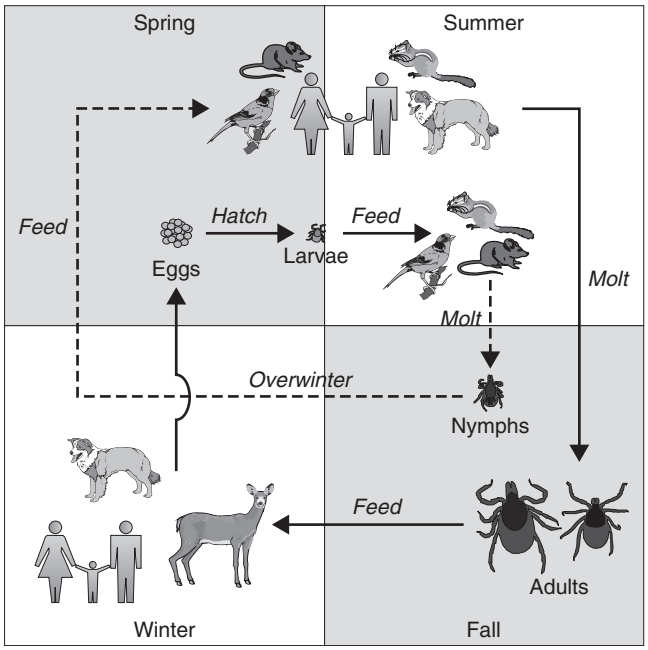

FIGURE 52.1 Life cycle of the *Ixodes* vector ticks and enzootic transmission of the Lyme disease spirochetes. The schematic depicts the general life cycle of *Ixodes* ticks and the enzootic cycle of the Lyme disease spirochetes. The dashed arrows demonstrate the portion of the life cycle during which transmission from infected to uninfected mammals may occur.

fact that they can support large numbers of adult ticks and can serve to distribute ticks over a wider geographic area. Humans are incidental hosts and are not significant in the enzootic cycle.

HISTORY OF LYME DISEASE

Lyme disease, originally termed Lyme arthritis, was first recognized as a clinical entity in North America in 1977 (Steere et al., 1977a, 1977b, 1978). The occurrence of an unusually large number of cases of arthritis in children in the three contiguous communities of Lyme, Old Lyme, and East Haddam, Connecticut prompted epidemiological studies that culminated in 1982 with the identification of a previously unrecognized tick-borne spirochete as the causative agent (Burgdorfer et al., 1982; Benach et al., 1983; Steere et al., 1983). This agent was determined to belong to the genus *Borrelia* and was subsequently designated *B. burgdorferi* (Johnson et al., 1984). Retrospective PCR analyses of preserved ticks and tissue samples collected from *Peromyscus* mice demonstrated the presence of *B. burgdorferi* in North America well before it was recognized as a distinct clinical entity. *B. burgdorferi* was demonstrated in some samples dating back to 1894 (Persing et al., 1990; Marshall et al., 1994). Early 20th century reports of an arthritic condition common on Long Island, New York, and locally referred to as "Montauk knee," appear to represent the first clinical descriptions of Lyme disease in North America. In Europe, clinical manifestations consistent with Lyme disease had been separately described in the early 20th century, though the individual symptoms were not recognized under the umbrella of a single clinical entity (Herxheimer and Hartmann, 1902; Afzelius, 1921; Bannwarth, 1944; Hellerstrom, 1951; Hollstrom, 1951). The description of Lyme disease and its spirochetal etiology in America was followed by its recognition as a cause of disease in Europe (Ackermann, 1983; Ackermann et al., 1984).

ETIOLOGIC AGENT

The spirochetes share a common morphology and ultrastructure; however, at the genetic level they comprise a highly diverse monophyletic phylum, the *Spirochaetes* (Paster et al., 1991). The order *Spirochaetales* is divided into three families, the *Leptospiraceae*, *Brachyspiraceae* (alternatively *Serpulinaceae*), and *Spirochaetaceae*. The family *Spirochetaceae* contains six major genera: *Treponema*, *Brevinema*, *Spirochaeta*, *Cristispira*, *Spironema*, and *Borrelia* (Paster et al., 1991; Paster and Dewhirst, 2001). *B. burgdorferi* was the first *Borrelia* species to be demonstrated as a causative agent of Lyme disease. Subsequent molecular phylogenetic analyses have demonstrated the existence of 10 closely related species that form the *B. burgdorferi* sensu lato complex (Schmid et al., 1984; Marconi and Garon, 1992a, 1992b; Marconi et al., 1992; Wang et al., 1999b). These species include *B. burgdorferi*, *B. garinii* (Baranton et al., 1992), *B. afzelii* (Busch et al., 1996), *B. valaisiana* (Wang et al., 1999b), *B. lusitaniae* (Le Fleche et al., 1997), *B. andersonii* (Marconi et al., 1995), *B. bissettii* (Postic et al., 1998), *B. lonestari* (Barbour et al., 1996b), *B. japonica* (Kawabata et al., 1993; Marconi et al., 1995), *B. tanukii* (Fukunaga et al., 1996), *B. turdae* (Fukunaga et al., 1996), and *B. sinica* (Masuzawa et al., 2001). As described above, only a subset of these species has been definitively demonstrated as causative agents of disease in humans.

The *Borrelia* are microaerophilic, Gram-negative bacteria that have a helical or flat-wave morphology that can be readily visualized using dark-field microscopy (Fig. 52.2). They range from 0.18 to 0.25 μm in diameter and from 4 to 30 μm in length. Cultivation can be achieved in a complex culture medium (e.g., BSK-H, BSK II) supplemented with rabbit serum (6%) (Barbour, 1984; Ruzic-Sabljic et al., 2006). The optimal temperature range for growth is from 33 to 37°C (Barbour, 1984; Ruzic-Sabljic et al., 2006). The *Borrelia* have a two membrane system similar to that of Gram-negative bacteria, but lack lipopolysaccharide

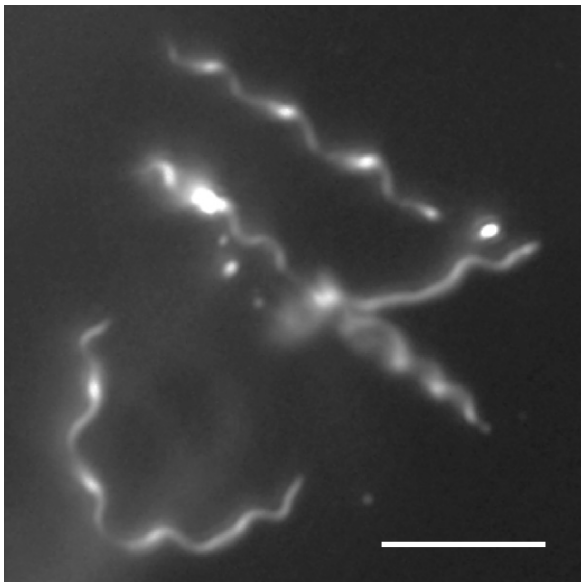

FIGURE 52.2 Darkfield photomicrograph of *Borrelia burgdorferi*. B31MI strain grown at 33°C in BSK-H medium, 100× original magnification, scale bar is 10 μm. Note the characteristic spiral morphology.

(Takayama et al., 1987). The spirochetes are unique among bacteria in that they possess two sets of internal flagella that anchor within the inner membrane but reside primarily within the periplasmic space. The individual sets of flagella anchor at opposite ends of the cell and extend approximately three-fourths of the length of the cell, overlapping at the center. Mutants lacking flagella are nonmotile and lack the characteristic spiral morphology (Sadziene et al., 1991). The "corkscrew like" motility of the spirochetes is a critical feature that allows for their efficient movement through viscous media such as the dermal extracellular matrix (Charon et al., 1992; Goldstein et al., 1994, 1996; Li et al., 2000; Wolgemuth et al., 2006).

At the genetic level, the *Borrelia* possess a unique segmented genome that consists of linear and circular DNA (Barbour and Garon, 1987, 1988). Complete or partial genome sequences have been determined for several Lyme disease spirochete strains and for the related relapsing fever spirochetes, *Borrelia turicatae* and *B. hermsii* (Dunn et al., 1994; Barbour et al., 1996a; Fraser et al., 1997; Caimano et al., 2000; Glockner et al., 2004, 2006). The genome of the Lyme disease spirochete, *B. burgdorferi* strain B31MI, was among the first bacterial genomes to be completely determined (Fraser et al., 1997). The B31MI genome has 1516 open reading frames encoded on a linear chromosome (910 kbp), 12 linear plasmids (lp; 5–54 kbp), and 9 circular plasmids (cp; 9–32 kbp), some of which appear to be prophage (Fraser et al., 1997; Eggers and Samuels, 1999; Casjens et al., 2000; Eggers et al., 2000; Zhang and Marconi, 2005). The telomeric structure of the chromosome and linear plasmids are similar to that of the poxviruses, with covalently closed terminal hairpins (Barbour and Garon, 1987; Hinnebusch et al., 1990; Casjens et al., 1997). Plasmid composition varies considerably among isolates (Iyer et al., 2003; Terekhova et al., 2006), and can change during in vitro culture or in vivo passage (Barbour, 1988; Schwan et al., 1988; Persing et al., 1994; McDowell et al., 2001a). Some plasmids are universal among isolates and appear to be critical (e.g., cp26), while others are not required for survival but correlate with a high-infectivity phenotype (e.g., lp28-1, lp25) (Marconi et al., 1993; Tilly et al., 1997; Purser and Norris, 2000; Labandeira-Rey and Skare, 2001; Labandeira-Rey et al., 2003; Byram et al., 2004; Grimm et al., 2004). It is likely that infectivity and virulence are mediated by combined individual or synergistic effects of genes on multiple plasmids (McDowell et al., 2001a). Recent studies suggest that specific "ribosomal spacer types" may be an indicator of the invasiveness and dissemination properties of a strain (Iyer et al., 2001; Ojaimi et al., 2005). Consistent with the fastidious growth requirements of the *Borrelia* and their host dependence in vivo, the genome contains only a limited number of genes that encode proteins involved in biosynthetic pathways. The *Borrelia* are largely incapable of de novo amino acid, lipid, nucleotide, or enzyme cofactor synthesis (Fraser et al., 1997).

EPIDEMIOLOGY

Lyme disease is the most prevalent vector-borne disease in Europe and North America. A standardized case definition was developed in 1991 and revised in 1996 (Wharton et al., 1990; Anonymous, 1997). Lyme disease is a reportable disease in the United States, with an average of 21,600 cases reported per year (2002–2006) (Fig. 52.3). However, the actual number is certainly much greater, as physician compliance with reporting ranges from 7 to 36% (Matteson et al., 1992; Coyle et al., 1996; Meek et al., 1996; Campbell et al., 1998; Young, 1998; Orloski et al., 2000; Naleway et al., 2002). In the United States, Lyme disease is concentrated in the northeast, with the highest per capita incidences occurring in Delaware, Connecticut, New Jersey, Massachusetts, Pennsylvania, and New York (McNabb et al., 2007) (Fig. 52.4). In Europe, a standard case definition is not in place and there is limited data regarding the incidence of Lyme disease (Anonymous, 1995). At least 85,000 cases are documented each year; however, as in the United States this is thought to be a significant underestimate of the actual incidence (Lindgren and Jaenson, 2006). Recent studies estimate that the incidence in Europe may be approximately 200 cases per 100,000 persons per year (Derdakova and Lencakova, 2005; Smith and Takkinen, 2006) and steadily rising (Smith and Takkinen, 2006). The highest reported incidences occur in Slovenia, Austria, the Netherlands, Germany, and Sweden. Lyme disease incidence correlates with the population dynamics of its mammalian reservoirs and tick vectors. Changes in these variables are due at least in part to climatic and environmental changes that alter the natural vegetation and other ecological factors. The historical trend involving the transformation of farmland into suburban woodlots, an environmental transition that is favorable for deer and *Ixodes* ticks, appears to have been a significant contributor to the emergence of Lyme disease. It has been suggested that recent climate changes have altered the distribution of vector ticks in Europe (reviewed in Lindgren and Jaenson, 2006). Ongoing climatic changes in North America are predicted to result in the continuing expansion of the northern range of *I. scapularis* (Brownstein et al., 2003; Ogden et al., 2006a, 2006b).

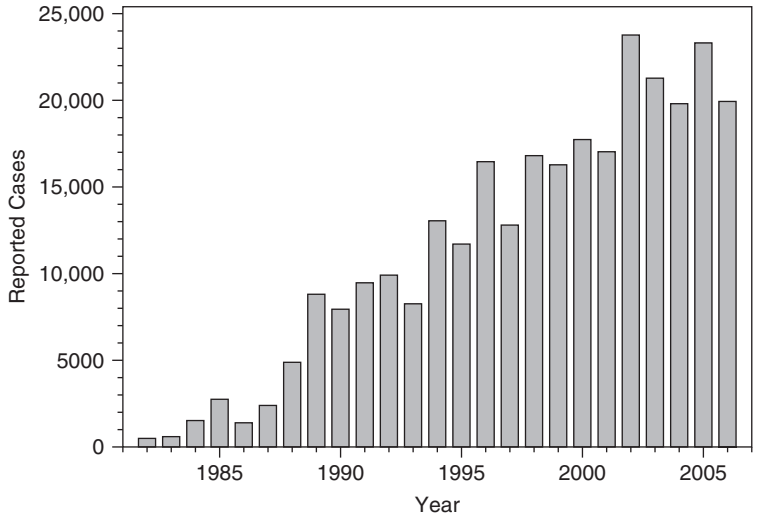

FIGURE 52.3 Reported cases of Lyme disease per year, 1982–2006. The data represent the total cases per year for the United States, as reported to the U.S. Centers for Disease Control and Prevention. A standard case definition was introduced in 1991, and revised in 1996. Lyme disease remains a reportable disease, though there is evidence that a significant proportion of cases go unreported.

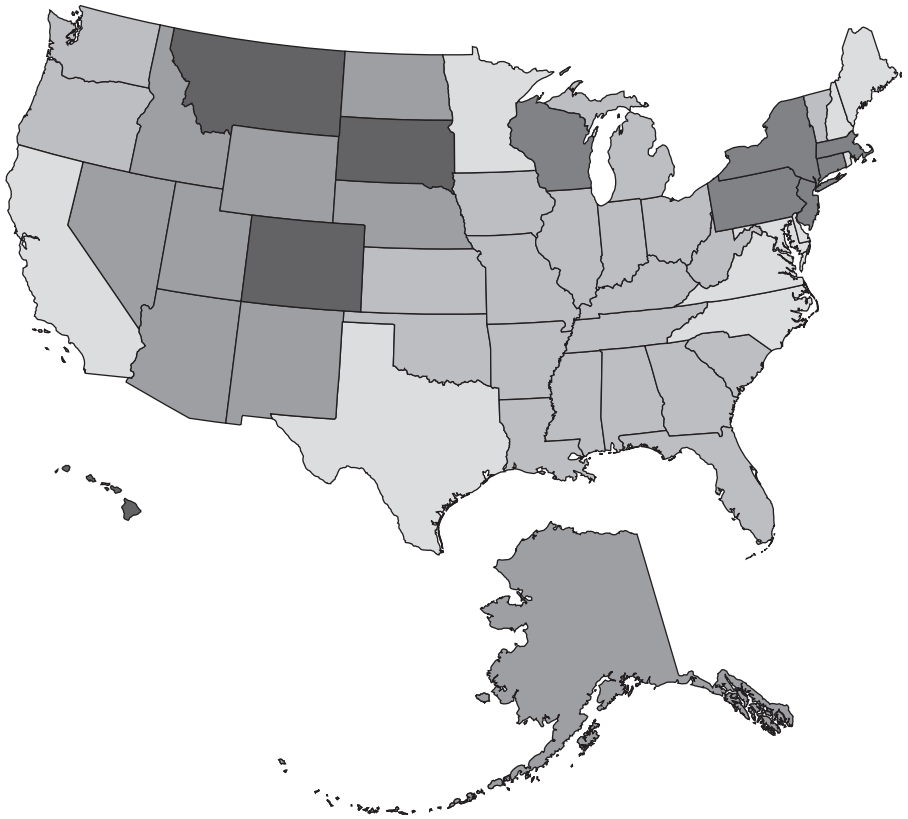

FIGURE 52.4 Reported cases of Lyme disease by state. The data represent the aggregate number of cases reported to the U.S. Centers for Disease Control and Prevention between 1992 and 2006. Each change in color represents a logarithmic increase in the total number of cases, shown as purple (0–10 cases), blue (10–99), green (100–999), yellow (1000–9999), and orange (>10,000). The greatest majority of Lyme disease cases occur in the northeast states and in Wisconsin, likely due to environmental conditions suitable for the tick vector (see color plate section).

Public Health Significance

With the increasing incidence of Lyme disease, expansion of its endemic areas, and its recognition in areas previously thought to be free of this disease, it is clear that this tick-transmitted infection remains a significant public health threat. At the present time, preventive strategies focus primarily on tick avoidance and promotion of public awareness of the signs and symptoms of disease. Demographic profiles of persons with Lyme disease indicate primarily a suburban and rural risk. The disease has a significant socioeconomic impact and has altered recreational and behavioral patterns out of concern over tick exposure. Fortunately, treatment for early Lyme disease is generally successful. If, however, the infection is not diagnosed early or remains untreated, it can become a debilitating disorder with significant physical, emotional, and economic impacts on infected individuals. Numerous studies have been undertaken to assess the cost of Lyme disease treatment, and the point at which vaccination becomes cost-effective. A recent study assessing the economic impacts of Lyme disease found that the direct medical cost of early Lyme disease treatment was $464, and late disease was $1380 (Zhang et al., 2006). When direct medical costs, indirect costs, nonmedical costs, and productivity losses were included, the average Lyme disease case costs approximately $8200 (Zhang et al., 2006). Calculations based on the number of cases reported indicate that over $200 million is spent nationwide. Another study estimated the costs for Lyme disease treatment in the United States at approximately $500 million per year (based on an estimated national incidence of 4.73 per 100,000 persons and 1996 dollars) (Maes et al., 1998). Both of these figures are likely significant underestimates, since the large majority of cases are not reported (Matteson et al., 1992; Coyle et al., 1996; Meek et al., 1996; Campbell et al., 1998; Young, 1998; Orloski et al., 2000; Naleway et al., 2002). Although more difficult to quantify, as discussed above concerns over contracting Lyme disease have also led to behavioral modifications, such as decreased outdoor activity that have hidden socioeconomic costs. Because of its significant health and economic impacts, reducing the number of annual Lyme disease cases has been made a national priority by the Healthy People 2010 program of the United States Department of Health and Human Services (Anonymous, 2000; Poland, 2001).

CLINICAL DISEASE

Lyme disease is transmitted to humans primarily by infected nymphal stage ticks. Successful transmission requires a feeding period of approximately 48 hours (Piesman et al., 1991; Piesman, 1993). Prompt and careful removal of ticks can dramatically decrease the potential for spirochete transmission and resulting disease. With initiation of a blood meal, the spirochetes transit from the tick midgut into the salivary glands and then into the skin of the mammal. The presence and amplification of the spirochete population in the skin, along with their lateral dissemination through the dermis results in the pathognomonic, expanding, annular or macular skin rash, erythema migrans (EM) (Afzelius, 1921). In recognition of the central clearing that may occur with the expansion of the EM, the rash is commonly described as having a "bull's eye" appearance. EM develops in only 60–85% of infected individuals and can be highly variable in appearance with no central clearing. In the absence of central clearing, EM can often mimic rashes or local reactions induced by other arthropods. In some cases secondary EM lesions occur at sites distant from the tick bite. Secondary EM lesions are caused by spirochetes that disseminate from the initial site of infection and establish new foci of infection. This phenomenon tends to occur at a higher frequency with *B. burgdorferi* infections. The EM rash may be accompanied by local mild itching, paresthesia, or in rare cases, pain (Nadelman and Wormser, 1995; Steere, 2001; Hengge et al., 2003; Stanek and Strle, 2003). Constitutional symptoms of early infection include headache, fever, arthralgia, regional lymphadenopathy, and myalgia (Steere et al., 1977a; Nadelman and Wormser, 1995). If not diagnosed early and treated promptly, the spirochetes can colonize distal tissues and persist. Late-stage clinical manifestations may include serious cardiac, dermatological, arthritic, and/or neurological sequelae (Nadelman et al., 1990; Goodman et al., 1995; Wormser et al., 2005). Some late-stage clinical manifestations appear to be species-specific. Severe dermatological manifestations (acrodermatitis chronica atrophicans, ACA), arthritis, or neurological complications correlate with infection by *B. afzelii*, *B. burgdorferi*, and *B. garinii*, respectively (van Dam et al., 1993; Lebech et al., 1994; Balmelli and Piffaretti, 1995; Busch et al., 1996; Rijpkema et al., 1997; Lunemann et al., 2001).

The development of arthritis is a significant concern in patients with late-stage disease, particularly in United States where *B. burgdorferi* is the dominant etiologic agent of Lyme disease. Nearly 60% of patients will experience intermittent arthritic attacks that are typically unilateral and commonly affect large joints (Steere et al., 1977b, 1987; Eiffert et al., 1998; Steere and Glickstein, 2004; Drouin et al., 2008). Though viable spirochetes are difficult to demonstrate in synovial fluid, the presence of *Borrelia* DNA has been demonstrated

by PCR (Karch and Huppertz, 1993; Nocton et al., 1994; Jaulhac et al., 1996). Lyme arthritis appears to result from strong innate and adaptive immune responses to the spirochetes (Hardin et al., 1979; Steere et al., 1979; Yssel et al., 1991; Yin et al., 1997; Gross et al., 1998b; Glatzel et al., 2002; Brown et al., 2003; Steere and Glickstein, 2004; Guerau-de-Arellano et al., 2005). In some cases, the arthritis may progress to a chronic and highly debilitating joint inflammation that does not resolve with antibiotic treatment. A large proportion of patients with chronic Lyme arthritis harbor HLA-DR4 alleles of MHC II, particularly DRB1*0401. It has been proposed that the basis for the development of Lyme arthritis is autoimmunity induced by one or more cross-reactive T-cell epitopes of *Borrelia* outer surface protein A (OspA) (Kalish et al., 1993; Kamradt et al., 1996; Gross et al., 1998a; Chen et al., 1999; Gross and Huber, 2000; Meyer et al., 2000; Steere et al., 2001; Trollmo et al., 2001; Steere and Glickstein, 2004; Drouin et al., 2007). In a hamster model of Lyme arthritis, vaccination with r-OspA has been demonstrated to exacerbate Lyme arthritis (Croke et al., 2000).

Cardiac involvement in Lyme disease patients in both Europe and the United States has been well documented. Carditis, marked by macrophage and $CD4^+$ lymphocyte infiltration, may develop in up to 10% of Lyme disease patients during early infection (Barthold et al., 1991; Asch et al., 1994; Ruderman et al., 1995; Nagi et al., 1996; Guerau-de-Arellano et al., 2005). Cardiac manifestations may include conduction disorders (Steere et al., 1980; van der Linde et al., 1990, 1991; Sigal, 1995; Nagi et al., 1996), ventricular arrhythmias (Cox and Krajden, 1991; Bartunek et al., 2001), and ventricular dysfunction (Steere et al., 1980; Karadag et al., 2004). Several studies have documented an association of cardiomyopathy with the presence of Lyme spirochetes in the myocardium (de Koning et al., 1989; Stanek et al., 1990; van der Linde et al., 1990; Lardieri et al., 1993), and with Lyme disease seropositivity (Klein et al., 1991; Stanek et al., 1991; Seinost et al., 1998; Bartunek et al., 2001).

In addition to EM, other dermatological manifestations of Lyme disease include ACA and lymphocytoma. These manifestations are common during late-stage disease, particularly in European patients. ACA is a chronic and progressive atrophic skin disorder that occurs primarily on extensor surfaces of the hands and feet (Asbrink et al., 1984; Asbrink and Hovmark, 1990; Asbrink, 1991; Hengge et al., 2003). It begins with skin edema and discoloration progressing very slowly to atrophy, with thin, wrinkled, discolored, sometimes sclerotic skin (Asbrink, 1991; Stanek and Strle, 2003). In approximately 60% of patients with ACA, peripheral neuropathy, muscle weakness, cramping, and pain occur (Kindstrand et al., 1997, 2000, 2002; Mullegger, 2004). Less frequently, lesions of the bones and joints may be found in the general area of the involved skin (Mullegger, 2004). Borrelial lymphocytoma is a less severe manifestation characterized by local infiltration of B-lymphocytes at a defined site, typically in the earlobe, areola, or scrotum (Hovmark et al., 1986; Asbrink and Hovmark, 1990; Strle et al., 1992, 1996; Berger, 1997; Maraspin et al., 2002; Hengge et al., 2003; Mullegger, 2004). Lyme lymphocytoma presents as a sharply demarcated bluish red nodule or plaque that is not typically associated with other constitutional symptoms. Lymphocytomas generally resolves within 1–12 weeks following antibiotic treatment (Asbrink, 1991; Strle et al., 1992, 1996; Wormser et al., 2006).

Neurological complications of Lyme disease (neuroborreliosis) may develop within weeks of infection in approximately 10% of untreated patients (Ackermann et al., 1988; Logigian et al., 1990; Gerber et al., 1996; Oschmann et al., 1998). Neuroborreliosis most commonly manifests itself as radiculoneuritis involving the abdomen and chest, or by cranial neuritis, often affecting the facial nerve and resulting in palsy (i.e., Bell's palsy) (Halperin et al., 1988, 1989, 1990a; Oschmann et al., 1998). Other neurological complications include peripheral neuropathy with paresthesia (Logigian et al., 1990), and aseptic meningitis with intermittent mild-to-severe headaches (Oschmann et al., 1998; Coyle and Schutzer, 2002; Nachman and Pontrelli, 2003). Mild encephalopathies have also been reported, especially in association with *B. burgdorferi* infection (Halperin et al., 1990b, 1991; Logigian et al., 1990).

Treatment

Approaches to the treatment of Lyme disease have been the subject of some controversy. Specifically, there are divergent opinions on the duration of antibiotic treatment and the route of administration (Reid et al., 1998; Auwaerter, 2007; Feder et al., 2007; Stricker, 2007). The origins and arguments for and against differing treatment approaches are beyond the scope of this chapter; however, the data clearly indicate that when Lyme disease is diagnosed early, most cases are responsive to antibiotic therapy. A 2–4 week course of doxycycline has proven effective (Wormser et al., 2006). Amoxicillin is an alternative in those patient groups where doxycycline is contraindicated. Intravenous ceftriaxone (2–4 week course) is generally reserved for patients with neuroborreliosis, cardiac involvement, or late Lyme disease. All of the

above treatment regimes are appropriate for individuals with Lyme arthritis. The possibly autoimmune-mediated antibiotic-refractory form of Lyme arthritis is treated with NSAIDs or synovectomy (Schoen et al., 1991; Steere and Angelis, 2006; Wormser et al., 2006).

Immune Response to Infection

Infection with the Lyme disease spirochetes typically evokes a slowly developing but strong humoral immune response. Several immunodominant antigens have been identified, characterized, and exploited in diagnostics or explored for their potential as vaccine candidates. Recently, the utility of a peptide in the C-terminal domain of the VlsE antigenic variation protein (Zhang and Norris, 1998b) as a diagnostic antigen for Lyme disease has been demonstrated (Liang and Philipp, 1999). The C6 peptide ELISA is now considered to be a key tool in Lyme disease diagnostics. While several antigens have been demonstrated to elicit bactericidal antibody, natural infection does not culminate in immune clearance or lead to the development of protective immunity. In untreated naturally or experimentally infected mammals, the Lyme spirochetes can persist long-term, and perhaps indefinitely.

The ability to persist despite a strong humoral response is essential for completion of the enzootic cycle and for population maintenance in nature. The spirochetes must survive long enough within their mammalian hosts to allow transmission into feeding, uninfected ticks which can then pass the infection to naïve animals. Several divergent and potentially synergistic mechanisms that contribute to immune evasion and persistence have been described. Differential expression of the expansive repertoire of surface protein encoding genes over the course of infection may allow the spirochetes to alter their antigenic profile (Revel et al., 2002; Ojaimi et al., 2005; Caimano et al., 2007). This process may also aid in the establishment of infection in immunologically primed hosts.

Antigenic variation may also be important in evasion of antibody responses and persistence (Zhang and Norris, 1998a; Liang and Philipp, 1999; McDowell et al., 2002; Norris, 2006). In the Lyme disease spirochetes, the underlying mechanism for antigenic variation is unidirectional segmental gene conversion (Zhang and Norris, 1998a). Partial *vlsE* gene cassettes undergo recombination with the single *vlsE* expression site in the *Borrelia* genome resulting in the generation of new antigenic variants of this dominant surface antigen. Successful immune evasion and long-term colonization of mammals also requires mechanisms that allow for complement evasion. Serum-resistant strains of *Borrelia* have been demonstrated to evade complement through the binding of negative regulators of the complement cascade such as factor H, and factor H–like protein 1 (Hellwage et al., 2001; Kraiczy et al., 2001, 2004a, 2004b; Alitalo et al., 2002; McDowell et al., 2003; Brooks et al., 2005; Rogers and Marconi, 2007). The binding of these regulatory proteins increases serum resistance.

VACCINES

First-Generation OspA Subunit Vaccines

Following the discovery of the etiologic agent of Lyme disease, significant research effort was expended on vaccine development. OspA, a protein that is highly expressed by the Lyme disease spirochetes during in vitro cultivation was the focus of most of the early vaccine development strategies. Preclinical trials of OspA vaccination demonstrated protection in animal models of Lyme disease, either as a recombinant protein or lipoprotein, or expressed on the surface of *E. coli*, *Salmonella typhimurium*, or *Mycobacterium bovis* (BCG) (Fikrig et al., 1990, 1991; Schaible et al., 1990; Simon et al., 1991; Stover et al., 1993; Aydintug et al., 1994; Langermann et al., 1994; Probert and LeFebvre, 1994; Chang et al., 1995; Dunne et al., 1995; Lovrich et al., 1995; Luke et al., 1997b; Philipp et al., 1997; Gomes-Solecki et al., 2006). Two OspA-based vaccine candidates, ImuLyme (Pasteur Merieux-Connaught) and LYMErix (SmithKlineBeecham), were subsequently developed and tested. The ImuLyme vaccine consists of a recombinant OspA lipoprotein purified following expression in *E. coli* (Sigal et al., 1998). In the LYMErix formulation, a lipid moiety was added to recombinant OspA after protein purification, and the vaccine was adsorbed to alum adjuvant (Erdile et al., 1993; Steere et al., 1998). The presence of the lipid motif enhances vaccine immunogenicity by interaction with TLR2 (Yoder et al., 2003). Since there is significant sequence diversity in *ospA*, the sequence chosen for vaccine development was one that represented the most prevalent OspA phyletic type in North American Lyme disease spirochete isolates (Wilske et al., 1996). Initial clinical testing demonstrated safety and efficacy in human subjects (Keller et al., 1994; Wallich et al., 1994; Schoen et al., 1995; Van Hoecke et al., 1996; Sigal et al., 1998; Steere et al., 1998). In phase III studies, an enrollment of 11,000 was achieved for each of the trials. The vaccines were administered as two 30μg doses, administered 1 month apart, with a booster vaccination at 12 months. The vaccine efficacy following

the first two doses was 68% and 49% for ImuLyme and LYMErix, respectively. In the second year, following the 12 month booster vaccination, efficacy rose to 92% for ImuLyme and 76% for LYMErix. Overall, OspA-based vaccines appeared to be safe and well tolerated during phase III studies. Side effects were not remarkable and consisted of those typically associated with vaccination (e.g., minor soreness, redness, swelling at the injection site, low grade fever, chills). FDA approval was given for the LYMErix vaccine at the end of 1998; no application for ImuLyme approval was submitted (Nigrovic and Thompson, 2007). The LYMErix vaccine was subsequently recommended by the CDC Advisory Committee on Immunization Practices for use in populations at high risk for contracting Lyme disease (Anonymous, 1999).

OspA is a linear-plasmid-encoded 28 kDa lipoprotein (Howe et al., 1986; Barbour and Garon, 1988) that structurally consists of two globular domains composed almost entirely of beta-sheets that are connected by a unique single-layer beta-sheet (Fig. 52.5) (Li et al., 1997; Makabe et al., 2006). Crystallographic structures have indicated that there is a possible ligand-binding site formed in the C-terminal globular domain (Li et al., 1997; Makabe et al., 2006). OspA is expressed in the tick vector (Fingerle et al., 1995; Leuba-Garcia et al., 1998), and may be responsible for adhesion of spirochetes to the wall of the tick midgut (Pal et al., 2004a). During transit from the midgut to the tick salivary glands, OspA expression is downregulated; thus, spirochetes entering the mammalian host do not express the OspA protein (Schwan et al., 1995). Vaccination with OspA induces an anti-OspA antibody response that blocks transmission of spirochetes from the tick to the mammalian host by killing or immobilizing the spirochetes within the tick midgut (de Silva et al., 1996, 1999). Since the spirochetes are, in large part, killed prior to entry into the mammalian host, this mechanism of action largely precludes the elicitation of anamnestic responses. The effectiveness of the vaccine is thus dependent on the presence of sufficient levels of circulating anti-OspA antibody. The requirement for high circulating antibody titer likely explains the need for yearly booster immunizations to maintain efficacy. During the second year of the ImuLyme trial, for example, there was no difference in protection between unvaccinated patients and vaccinated patients that had received the two initial vaccinations, but not the 12 month booster (Sigal et al., 1998). The incomplete (49% in year one; 76% in year two) protection provided by the LYMErix vaccine, the lack of safety and efficacy data for children, and apparent requirement for frequent booster immunizations to maintain protection are all factors that suggest that the development of new and improved Lyme disease vaccines are needed.

Within a year of its introduction, LYMErix was being anecdotally associated with development of arthritis. The possible association between the vaccine and these adverse events was well publicized, particularly by Lyme disease advocacy groups. Lawsuits, including a class-action, alleging vaccine-related harm

FIGURE 52.5 Crystal structure of OspA. The ribbon diagram is derived from the OspA crystal structure 2G8C (Makabe et al., 2006). The conformationally determined epitope recognized by a protective mAb (LA-2) is noted in blue (Golde et al., 1997; Ding et al., 2000). The peptide that may be associated with autoimmune-inducing cross-reactivity with the LFA-1 protein is highlighted in red (see text). The N-terminus is at the upper right of the figure (see color plate section).

began to be filed in 1999. OspA is expressed to some degree during natural mammalian infection (Coyle et al., 1995; Schutzer et al., 1997; Akin et al., 1999), and it was recognized early in vaccine development and confirmed in later studies that the immune response to OspA may be associated with development of antibiotic-refractory arthritis. In particular, there was reported to be an association between arthritis development and particular MHC II alleles (HLA-DR4) (Kalish et al., 1993; Kamradt et al., 1996; Gross et al., 1998a; Chen et al., 1999; Gross and Huber, 2000; Meyer et al., 2000; Steere et al., 2001; Trollmo et al., 2001; Steere and Glickstein, 2004; Drouin et al., 2008). During investigations into possible mechanisms, a predicted OspA T-cell epitope was found to be similar to one predicted for lymphocyte function antigen 1 (LFA-1), prompting speculation that this epitope could be the basis of an autoimmune arthritis (Gross et al., 1998a; Trollmo et al., 2001). It is still not clear, however, that OspA-induced LFA-1 cross-reactivity is, in fact, the cause of autoimmune arthritis (Steere et al., 1990, 2001; Nocton et al., 1994; Gross et al., 1998a; Chen et al., 1999; Hemmer et al., 1999; Meyer et al., 2000; Rose et al., 2001; Trollmo et al., 2001; Drouin et al., 2008).

While concerns, real or perceived, continued to mount, post-approval phase IV studies of LYMErix safety were undertaken by the manufacturer. These studies were originally designed to monitor 25,000 vaccine recipients, and 75,000 age- and sex-matched unvaccinated controls; however, by November of 2000, only 10% of the planned enrollment had been met. The results of the phase IV study to date were presented to an FDA advisory panel in January, 2001. The data did not demonstrate an association between vaccination and development of autoimmunity (Anonymous, 2001a, 2001b). Also presented were data from the Vaccine Adverse Event Reporting System (VAERS), in which the CDC and FDA analyzed adverse events reported between approval in December, 1998, and July, 2000. With 1.4 million distributed doses, there were 905 reported adverse events, of which 102 were coded as arthritis, arthrosis, or rheumatoid arthritis and 12 as facial paralysis, both of which had been postulated to be autoimmune sequelae of Lyme disease (Lathrop et al., 2002). There was no apparent temporal association between the development of arthritic problems and vaccine administration, though reports of arthritis were more often reported after the second and third immunizations. The reported rate of both arthritis and facial paralysis was below what was expected as background (Lathrop et al., 2002). The conclusion of the VAERS study was that there were no unexpected or unusual patterns of adverse events associated with LYMErix vaccination. The 2001 FDA panel found no reason to remove the vaccine from the market or modify its labeling. Continued media coverage of the potential vaccine-associated adverse events in combination with the above described limitations of the vaccine led to decreased acceptance of LYMErix, and sales continued to decline. Citing poor sales performance, GSK removed the LYMErix vaccine from the market in 2002.

Licensed Veterinary Vaccines

In endemic areas of North America and Europe, a large proportion of companion pets are exposed to *Ixodes* ticks and the Lyme disease spirochetes, a subset of which develop arthritic disease (reviewed in (Skotarczak, 2002). Several veterinary Lyme disease vaccines are currently available. Three are formulations of *B. burgdorferi* bacterin (e.g., Merilym, Merial, Germany; LymeVax, Fort Dodge, USA; Galaxy Lyme, Schering Plough, USA) (Chu et al., 1992; Wiedemann and Milward, 1999; Levy, 2002). A European bacterin vaccine uses a combination of *B. garinii* and *B. afzelii* cells (Biocan B, Bioveta, Czech Republic) (Rapuntean et al., 2003; Nepereny et al., 2007). Recombinant OspA-based vaccines, administered either with (ProLyme, Intervet, USA) or without (Recombitek Lyme, Merial, USA) adjuvant (Levy et al., 1993; Conlon et al., 2000; Wikle et al., 2006) are also available. All of the veterinary vaccines employ a two-dose immunization protocol with boosters recommended yearly. Very limited data are available regarding adverse events or efficacy. A comparison of the humoral immune response to veterinary vaccine preparations demonstrated that while all elicit an antibody response that is reactive with the vaccine strain from which the bacterin or OspA was derived, there was only minor reactivity with heterologous *Borrelia* species (Topfer and Straubinger, 2007), a point that has also been demonstrated in several other studies (Johnson et al., 1988; Ma et al., 1995; Gern et al., 1997; Shang et al., 2001). This suggests that the currently available vaccines will not convey broad protective coverage.

VACCINES IN DEVELOPMENT

Rationale for Second-Generation Vaccines

Pharmacoeconomic studies indicate that the benefit of vaccination against Lyme disease will be greatest when based on individual risk assessments, with cost effectiveness occurring when used for persons with an annual risk of contracting Lyme disease that

exceeds 1% (Meltzer et al., 1999; Shadick et al., 2001). Rates of infection between 1% and 3% occur in certain focal areas of the United States and Europe (Hanrahan et al., 1984; Fahrer et al., 1991; Orloski et al., 2000). In the U.S., the reported incidence in 2005 ranged from 0.019% to 0.077% in the 10 states with the highest reported levels of Lyme disease (McNabb et al., 2007). As discussed above, the number of reported cases underestimates the actual incidence, which in these states may exceed 1% (Matteson et al., 1992; Coyle et al., 1996; Meek et al., 1996; Campbell et al., 1998; Young, 1998; Orloski et al., 2000; Naleway et al., 2002). The calculations of the disease incidence at which vaccination becomes cost-effective have been based on assumptions that may be invalid for a second-generation vaccine. Specifically, models have assumed a requirement for three successive vaccinations, with yearly boosters, or projected a cost for vaccination repeated on a yearly basis. While these assumptions were reasonable for the first-generation vaccines (discussed above), future vaccines may not have the same requirements. Lyme vaccination could also have other, less tangible, benefits that are not included in typical cost/benefit analyses, including increased outdoor recreation and reduced use of prophylactic antibiotic treatment secondary to uncomplicated tick bite.

Discovery and Basic Science

Of critical importance in Lyme disease vaccine development is an understanding of the subset of proteins or antigens that are expressed during each phase of the enzootic cycle and specifically during mammalian infection. Several studies have documented environmentally mediated changes in global gene expression profiles (Liang et al., 2002a; Revel et al., 2002; Narasimhan et al., 2003; Ojaimi et al., 2005; Caimano et al., 2007). *Borrelia* gene regulation is not completely understood and the mechanisms that alter gene expression during the infectious cycle are complex and multifactorial. In an effort to develop growth conditions that more closely mimic those encountered by spirochetes in the mammalian environment, Akins et al. (1998) developed a rat dialysis membrane chamber implant model. In this model, cultures of *Borrelia* are placed in dialysis membranes and implanted into the peritoneal cavity of host mammals (Akins et al., 1998). After explanting the chambers several days later, the spirochetes can be harvested and the transcriptome and proteome assessed. Bacteria cultivated under these conditions are referred to as "host-adapted." While this model has its limitations, it appears that the expression patterns in host-adapted bacteria are similar to that seen in infected mice. For example, OspA production, which has been demonstrated to be downregulated with the onset of tick feeding, is also downregulated in the host-adapted spirochete model. As mentioned above, OspA is expressed by spirochetes residing in the tick midgut, but it is rapidly downregulated when the spirochetes enter the mammalian host (Schwan et al., 1995). The production patterns of outer surface protein C (OspC) in host-adapted bacteria, a potential vaccine candidate discussed in detail below, also mimics that seen in infected mammals. Spirochetes in unfed ticks do not produce OspC. With the initiation of the blood meal, OspC expression is upregulated and maintained through the early stages of mammalian infection. OspC is a dominant surface antigen and its expression is critical for the establishment of mammalian infection (Tilly et al., 1997, 2006, 2007; Grimm et al., 2004; Pal et al., 2004b; Stewart et al., 2006; Fingerle et al., 2007; Gilbert et al., 2007). Transcriptional control of both OspA and OspC is dependent, at least in part, on a complex regulatory network involving RpoS (Hubner et al., 2001; Alverson et al., 2003; Caimano et al., 2004, 2005; Yang et al., 2005; Lybecker and Samuels, 2007). The ideal Lyme disease vaccine candidate(s) will be either constitutively expressed, or upregulated by tick feeding and expressed during infection in mammals. Antibody to vaccine candidates with these properties have the potential to block transmission of spirochetes from the tick vector and/or kill spirochetes that have been transmitted into vaccinated mammals. In addition, the vaccine candidate should display sufficient conservation, or at least manageable diversity, within naturally exposed epitopes that are presented by intact spirochetes. It should be genetically stable and be encoded by an essential plasmid or be chromosomally encoded. Of those genes upregulated in the mammal, only a small subset will exhibit these properties and thus be of utility in vaccine development. Some of the proteins that have been assessed as potential vaccine candidates include OspC, DbpA, OspE (p21), Elp (paralogous gene family 163), OspF (bbk2.10, pG), Mlp proteins, p35 (BbK32), and p37 (BbK50) (Akins et al., 1995, 1998, 1999; Schwan et al., 1995; Stevenson et al., 1995; Marconi et al., 1996; Fikrig et al., 1997; Yang et al., 2000, 2003a, 2003b; Hefty et al., 2001, 2002; McDowell et al., 2001b; Liang et al., 2002a, 2002b; Brooks et al., 2003; Ojaimi et al., 2003). OspA, OspB, OspC, OspF, DbpA, BBK32, and VraA have been shown to provide some protection against challenge in mice (Telford et al., 1993; Nguyen et al., 1994; Probert and LeFebvre, 1994; Wallich et al., 1994; de Silva et al., 1996; Fikrig et al., 1997; Feng et al., 1998; Hanson et al., 1998; Liang et al., 2001; Labandeira-Rey et al., 2001). Immunogenic, upregulated proteins that

have not been shown to be protective include OspD, OspE, BmpA, and VlsE (Nguyen et al., 1994; Probert and LeFebvre, 1994; Gilmore et al., 1996; Liang et al., 2001). In spite of the large number of potential vaccine candidates that have been investigated, OspA and OspC remain the primary foci of subunit vaccine development.

Nonprotein targets are also being assessed for potential utility in Lyme disease vaccine development. The *Borrelia* do not produce lipopolysaccharide, but do produce glycolipids on their outer surface that may be unique to the *Borrelia*. During infection, a strong immune response is mounted against some of these nonprotein antigens (Wheeler et al., 1993; Hossain et al., 2001). One glycolipid in particular, acylated cholesteryl galactoside (ACG), has been the focus of investigation as a vaccinogen because of its immunogenicity during infection (Ben-Menachem et al., 2003; Schroder et al., 2003). ACG induces an IgM antibody response when administered to mice or rabbits in micellar form in PBS, or in DMSO, squalene, or Freund's adjuvants (Ben-Menachem et al., 2003). A protein conjugate of ACG has been synthesized, and is currently being tested for use as a Lyme disease vaccine (Pozsgay and Kubler-Kielb, 2007).

Critical to the testing of Lyme disease vaccine candidates is the recognition that the protein production profiles of the spirochetes can be significantly altered by cultivation and differ from that of spirochetes present in fed ticks. Hence, the route of infection can influence the outcome of challenge experiments. The majority of challenge experiments have been carried out using cultivated spirochetes that are needle inoculated either subcutaneously or intradermally. Decorin-binding protein A (DbpA), a candidate vaccinogen that is expressed in the mammalian host, has been shown to be protective against infection by needle inoculation, but not against infection by tick bite (Cassatt et al., 1998; Feng et al., 1998; Hagman et al., 1998, 2000; Hanson et al., 2000). In contrast, mice immunized with OspA are protected when challenge is administered by either the tick or needle inoculation route (Fikrig et al., 1992; Telford et al., 1993). The OspC protein has also been shown to be protective against infection by either route (Gilmore et al., 1996; Probert et al., 1997). In challenge experiments, consideration must also be given to potential immunological changes at the site of infection that are mediated by biologically active components of tick saliva (Anguita et al., 2002; Brossard and Wikel, 2004; Ramamoorthi et al., 2005; Titus et al., 2006). These findings highlight the complexity of both bacterial protein regulation and the environment surrounding the bacterium during transit from the tick and early infection, and the need to consider this complexity in designing and interpreting vaccine challenge experiments.

Second-Generation OspA Subunit Vaccines

Efforts are now underway to alter the composition of the original OspA-based vaccines to improve theoretical coverage and reduce the potential for adverse events. As described above, there was concern that the LYMErix vaccine formulation may induce autoimmune responses in patients having an HLA-DR4 MHC II allele. Within the OspA protein, there is a predicted T-cell epitope that displays some homology to a sequence in the human LFA-1 protein (Fig. 52.5). It has been speculated that this specific domain may be the basis of putative autoimmune reactions (Gross et al., 1998a; Trollmo et al., 2001). A modified recombinant *B. burgdorferi* OspA in which this potentially cross-reactive epitope was altered has been generated and tested in mice. This modified OspA protein elicited protective antibodies in mice at a level similar to that of the wild-type OspA protein, but did not stimulate HLA-DR4-positive T-cells specific for the wild-type OspA molecule (Willett et al., 2004). The elimination of reactivity with the potentially autoimmune-inducing peptide may alleviate some concern about the safety of OspA-based Lyme disease vaccines; however, there remains significant doubt about the mechanism of OspA-induced autoimmune arthritis and the identity of potential autoreactive proteins (Drouin et al., 2008).

Studies with monoclonal antibodies suggest that the protective epitopes of OspA reside in the C-terminal domain of the protein and are conformationally determined (e.g., the LA-2 epitope) (Fig. 52.5) (Sears et al., 1991; Huang et al., 1998; Ding et al., 2000). Several studies have attempted to use OspA truncations lacking the N-terminal domain of the protein to both reduce vaccine size and eliminate peptides potentially associated with autoimmune reactions. Recombinant OspA truncations expressed with N-terminal polyhistidine fusions (but not with glutathione S-transferase N-terminal tags) elicited protective antibody responses (Bockenstedt et al., 1996). Immune responses to OspA fragments could also be enhanced by targeted replacement of charged amino acids in a C-terminal domain cavity with hydrophobic amino acids. The replacements increased the domain stability, and the resultant protein had antigenic properties similar to wild-type OspA (Koide et al., 2005).

Future efforts to exploit OspA in the development of a more broadly protective vaccine must address issues pertaining to OspA sequence variation.

There are at least seven serotypes of OspA. Serotype 1 is produced by *B. burgdorferi*, serotype 2 by *B. afzelii*, and serotypes 3–7 by *B. garinii* (Wilske et al., 1993). Multivalent-chimeric OspA proteins have been developed that incorporate the protective epitopes from three or more OspA serotypes (Gern et al., 1997). A trivalent vaccine that included OspA from each Lyme disease genospecies provided broad protection for mice challenged by tick infection (Gern et al., 1997). Baxter Vaccines is currently planning clinical trials of an OspA-based chimeric vaccine that incorporates the protective regions of six predominant OspA serotypes on three recombinant proteins (Anonymous, 2007).

OspC Subunit Vaccines

OspC Structure, Regulation, and Function

OspC has received considerable attention in the effort to develop a broadly protective Lyme disease vaccine. OspC possesses several features that render it a desirable vaccine candidate. It is a 22 kDa immunodominant lipoprotein that is tethered to the spirochete outer membrane by an N-terminal tripalmitoyl-S-glyceryl-cysteine (Brooks et al., 2006). It is encoded on a ubiquitous and highly stable 26 kbp circular plasmid (cp26) (Marconi et al., 1993) and the sequence of OspC does not undergo mutation during infection (Stevenson and Barthold, 1994; Hodzic et al., 2000). Crystal structures have been obtained for several OspC variants. These analyses demonstrated OspC to be largely helical in structure, with five alpha helices connected by loops (Eicken et al., 2001; Kumaran et al., 2001). Based on size exclusion, cross-linking, immunological, and structural analyses, OspC appears to form homodimers, and based on the extensive buried interface of the dimer, it has been postulated that it is the dimeric form of the protein that is biologically active (Bunikis and Barbour, 1999; Huang et al., 1999; Eicken et al., 2001; Kumaran et al., 2001; Zuckert et al., 2001; Earnhart et al., 2005).

OspC is an essential virulence factor that is critical for the establishment of early infection in mammals (Margolis and Rosa, 1993; Tilly et al., 1997, 2006, 2007; Byram et al., 2004; Grimm et al., 2004; Pal et al., 2004b; Rosa, 2005; Stewart et al., 2006). *ospC* deletion mutants in several *Borrelia* strains are not infectious in mammals, either by subcutaneous injection or tick transmission (Grimm et al., 2004; Pal et al., 2004b). Although its precise role in the transmission process has not yet been definitively demonstrated it has also been postulated to be required for the passage of spirochetes from the midgut to the salivary glands in the tick (Probert and LeFebvre, 1994; Gilmore et al., 1996; Pal et al., 2004b; Fingerle et al., 2007). Additionally, OspC may bind and transport an immunomodulatory tick salivary gland protein (Salp15) that interferes with CD4+ T-lymphocyte function (Anguita et al., 2002; Ramamoorthi et al., 2005). These analyses collectively suggest that anti-OspC antibodies have the potential to interfere with some of the critical early events in transmission and in the establishment of infection in mammals.

OspC Phylogenetics

A complicating factor in the exploitation of OspC as a vaccine candidate is that it is highly variable in sequence. However, recent analyses have shed important light on the nature of OspC variation. Molecular phylogenetic analyses have revealed that OspC sequences form at least 38 distinct OspC phyletic clusters or OspC types (Seinost et al., 1999a; Wang et al., 1999c; Earnhart and Marconi, 2007c). Within OspC phyletic clusters, amino acid sequences are >95% identical, whereas between types, identity ranges from approximately 55–80% (Wang et al., 1999c; Attie et al., 2007; Earnhart and Marconi, 2007c). Sequence variation within OspC occurs in distinct domains that are surface-exposed and antigenic (Earnhart et al., 2005, 2007). While an individual strain expresses only a single OspC type, multiple OspC types have been demonstrated in spirochetes recovered form ticks, mammals, or Lyme disease patients from small geographic areas (Wang et al., 1999c; Lin et al., 2002; Alghaferi et al., 2005; Earnhart et al., 2005; Anderson and Norris, 2006). The maintenance in nature of different OspC types has been postulated to be driven by balancing selection, where the maintenance of multiple relatively stable alleles in a population is more advantageous than the directional selection of a single, most fit allele (Wang et al., 1999c; Rannala et al., 2000; Kreitman and Di Rienzo, 2004). The maintenance of multiple alleles in the population may aid in circumventing the immune response in naturally immunologically primed reservoir animals. Early studies hypothesized strains producing OspC types A, B, I, and K were primarily associated with invasive infections in humans (Seinost et al., 1999a; Lagal et al., 2003); however, based on more recent studies it is now apparent that strains producing several additional OspC types can also cause invasive infection (Alghaferi et al., 2005; Earnhart et al., 2005). OspC variation arises primarily through genetic exchange and recombination and not by hypermutation with concomitant immune selection (Livey et al., 1995; Marti Ras et al., 1997; Wang et al., 1999a; Dykhuizen and Baranton, 2001; Bunikis et al., 2004; Attie et al., 2007; Earnhart and Marconi, 2007c).

This is of importance in vaccine design, as it implies potential natural restrictions on the extent to which the OspC sequence can change. With the recent significant advances in our understanding of the sequence diversity of OspC, it is now possible to devise strategies to exploit the variation within OspC in vaccine development.

Immune Response to OspC

While OspC is highly antigenic and can elicit protective antibody responses, the protective range is narrow (Probert and LeFebvre, 1994; Gilmore et al., 1996; Bockenstedt et al., 1997; Probert et al., 1997; Mathiesen et al., 1998; Rousselle et al., 1998; Gilmore and Mbow, 1999; Mbow et al., 1999; Seinost et al., 1999b; Wallich et al., 2001; Jobe et al., 2003; Scheiblhofer et al., 2003; Brown et al., 2005). The basis for the limited protective range of OspC has been determined to be due to the above described sequence variation. In a recent study, clonal populations of *B. burgdorferi* producing different OspC types were used to infect mice, serum was harvested and then used to screen an immunoblot consisting of a panel of OspC proteins of different phyletic types (Earnhart et al., 2005). These analyses demonstrated that the antibody response elicited during early infection is OspC type-specific suggesting that it is the type-specific domains of the protein that are presented at the bacterial cell surface. As infection progresses, a broader array of OspC epitopes in widely separated domains of the protein become recognized by the antibody response (Earnhart et al., 2005, 2007). This is most likely due to the antibody-mediated lysis of cells, release of OspC, and the recognition of epitopes that are normally shielded in viable intact spirochetes. Further analyses have demonstrated that antibody elicited to the variable domains displays OspC type-specific bactericidal activity (Buckles et al., 2006; Earnhart et al., 2007; Earnhart and Marconi, 2007b). The identification of epitopes that are presented by native OspC during the early stages of infection and that elicit bactericidal antibody is an important step towards the design of an effective and broadly protective OspC-based vaccine.

In an effort to develop a polyvalent OspC vaccine, Baxter Vaccines tested an OspC recombinant protein cocktail consisting of up to 14 full-length OspC proteins of different types. However, these formulations did not elicit sufficient antibody titers against the essential type-specific epitopes of each OspC variant included in the vaccine. In addition, unacceptable reactigenicity was reported (Hanson and Edelman, 2004). The inclusion of numerous full-length proteins in the vaccine formulation may have resulted in the misdirection of the immune response by presenting immunodominant but nonprotective epitopes. A potential approach to solving this problem is to generate a recombinant chimeric protein that consists entirely of protective epitopes from those OspC types associated with disease in humans.

OspC Epitope Mapping

The successful development of a polyvalent chimeric vaccine requires the systematic identification of protective epitopes from diverse OspC sequences. Surprisingly few studies have sought to identify the naturally presented epitopes in different OspC type proteins. Initial studies of type A OspC suggested at least one protective epitope may be conformationally defined (Gilmore et al., 1996; Gilmore and Mbow, 1999; Mbow et al., 1999). While conformationally defined epitopes can be important in eliciting protective immunity, linear epitopes are more easily incorporated into chimeric constructs. The C-terminus of OspC harbors a linear epitope that is highly conserved among OspC types and which has been shown to induce antibodies in infected mammals and in humans (Lovrich et al., 1991, 2005, 2007; Mathiesen et al., 1998; Jobe et al., 2003). This highly conserved C-terminal sequence has not, however, been demonstrated to elicit a broadly protective response and hence it is not in and of itself sufficient to elicit broad protection against strains expressing different OspC types. OspC type-specific linear epitopes that may be of utility in the construction of a chimeric, polyvalent vaccine have been identified by screening series of OspC truncations and subfragments derived from multiple OspC types with sera derived from mice experimentally infected with clonal *B. burgdorferi* isolates (Earnhart et al., 2005, 2007). Two linear epitopes have been identified: the "loop 5" and the "helix 5" epitopes. The loop 5 epitope is comprised of the C-terminal portion of alpha helix 3 and loop 5 (Eicken et al., 2001; Kumaran et al., 2001), while the helix 5 epitope encompasses the fifth alpha helix and a small region C-terminal to this helix (Fig. 52.6) (Earnhart et al., 2005, 2007; Yang et al., 2006). These epitopes are recognized by antibody that develops during experimental infection in mice and natural infection in humans (Earnhart et al., 2005, 2007; Buckles et al., 2006). Both epitopes map to surface-exposed domains of OspC that are highly variable between OspC types but conserved within each type. A recombinant protein containing the type A OspC loop 5 epitope elicited antibodies in mice that demonstrate type-specific, complement-dependent antibody-mediated killing in vitro (Buckles et al., 2006). The ability to generate

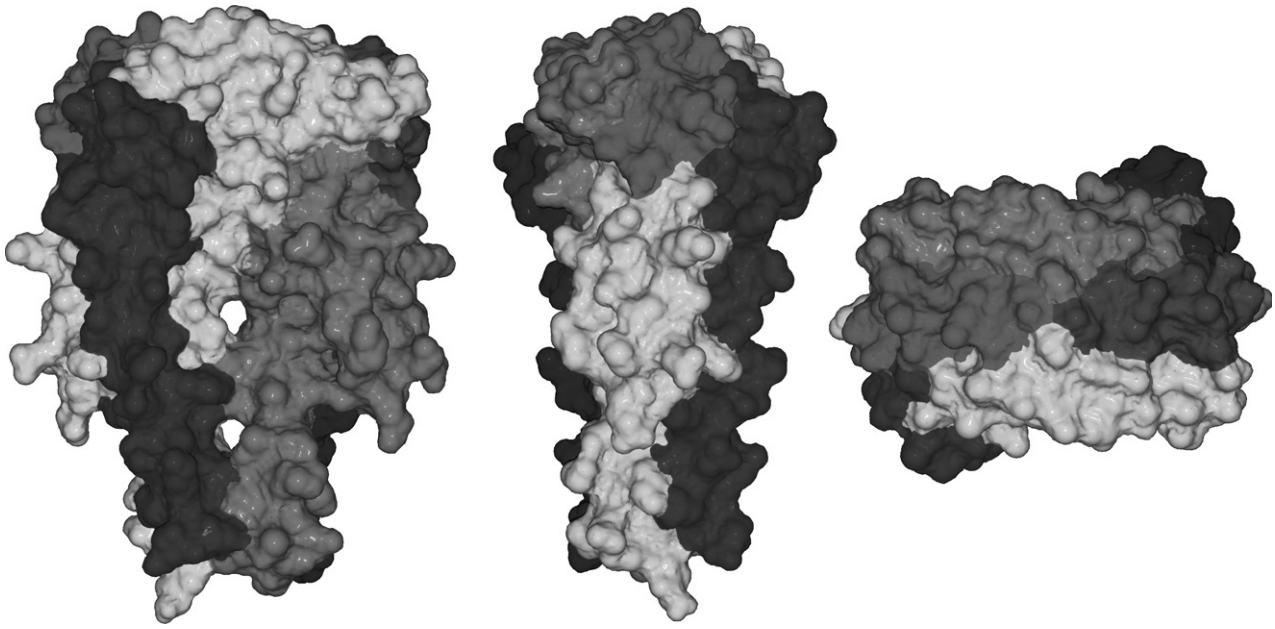

FIGURE 52.6 Crystal structure of outer surface protein C. The diagram is derived from the type A OspC crystal structure 1GGQ (Kumaran et al., 2001). A surface representation of the OspC molecule is shown in three rotations. The locations of the two regions in which epitopes have been mapped in multiple OspC types are denoted in red (loop 5 region) and blue (helix 5 region). The molecule is a homodimer; the component monomers are differentiated using darker and lighter color shades. A portion of both the N- and C-termini is omitted from the structure (see color plate section).

a protective response using isolated linear epitope-containing sequences further indicates the potential of a polyvalent, epitope-based chimeric OspC vaccine.

Development of a Polyvalent OspC Vaccine Based on Mapped Epitopes

Chimeric vaccines consisting of a series of immunodominant epitopes have been explored in the development of vaccines against malaria (Hanson and Edelman, 2004; Caro-Aguilar et al., 2005), group A streptococci (Dale, 1999; Hu et al., 2002; Kotloff et al., 2004; Kotloff and Dale, 2004; Dale et al., 2005; McNeil et al., 2005), and several viruses (Wang et al., 1999d; Bouche et al., 2005; Fan et al., 2005; Apt et al., 2006). Data suggest that a broadly protective OspC vaccine will require the inclusion of epitopes from approximately 28 OspC types (Earnhart and Marconi, 2007c). Such a construct is predicted to provide protection against all major Lyme disease spirochete species associated with human disease, and to be effective in both Europe and North America. Possible cross-protection elicited by some epitopes may reduce the total number of epitopes required to achieve this goal.

A prototype tetravalent chimeric recombinant OspC-based vaccine has been produced that incorporates epitope-containing regions from types A, B, K, and D. This "ABKD" vaccine elicited antibodies in mice that bind OspC as presented on the surface of intact and viable spirochetes and mediate bactericidal activity by a complement-dependent mechanism (Buckles et al., 2006; Earnhart et al., 2007). It is noteworthy that a decrease in epitope-specific titer was observed for epitopes progressing from the N- to the C-terminus of the chimeric protein. The antibody titer to the type D epitope was 1.7 logs lower than that observed for the N-terminally located type A epitope (Earnhart et al., 2007). This effect did not appear to be due to C-terminal degradation of the construct since the addition of C-terminal tags that have been reported to stabilize recombinant proteins did not improve antibody titer (Earnhart and Marconi, 2007a). This observation suggests that the tertiary structure of the chimeric protein influences antibody titer to specific epitopes. The antibody titer to C-terminal epitopes of the ABKD construct was improved by epitope reiteration and by increasing the solubility of the construct (Earnhart and Marconi, 2007a). A similar observation of decreasing antibody titer to C-terminal epitopes had been reported for the streptococcal M protein vaccine (Dale et al., 1993, 1996).

The ABKD OspC construct has recently been expanded to include four additional OspC types (E, N, I, and C) that were predicted, based on phylogenetic analysis, to provide broad protection (Earnhart and Marconi, 2007c). This octavalent vaccine (OspC-A8.1)

induced type-specific antibodies against all incorporated epitope-containing regions, though there was decreased titer to the C-terminal epitope similar to the tetravalent vaccine (Earnhart and Marconi, 2007b). The OspC-A8.1 vaccine induced IgG2b and IgG2a antibody isotypes, which have the ability to fix complement (Earnhart and Marconi, 2007b). In addition, the OspC-A8.1 hyperimmune serum efficiently labeled intact *B. burgdorferi* strains bearing each of the component OspC types (Earnhart and Marconi, 2007b). These initial studies with OspC-based chimeric proteins represent the first attempts in the Lyme disease field to construct a vaccine consisting exclusively of epitopes that are recognized during early infection, and that may protect against diverse strains from both Europe and North America. Vaccines that provide global coverage are essential in this era of frequent and rapid world travel.

A theoretical concern with vaccination against a subset of epitopes is the potential to drive selection in nature toward OspC types not included in the vaccine. This would tend to increase the proportion of the population bearing formerly rare OspC types. However, as humans are incidental hosts, it is unlikely that vaccination of specific high-risk human populations would significantly alter the population distribution of strains expressing specific OspC types in nature. Studies are currently underway to extend the breadth of potential protection using additional constructs that incorporate OspC types from the three Lyme disease *Borrelia* species.

Combination Subunit Vaccines

The combination of two or more different recombinant immunogens in a Lyme disease vaccine formulation has been investigated in a limited number of studies. Studies that assessed the efficacy of a cocktail of recombinant OspC proteins derived from different Lyme disease spirochete isolates are described above. Attempts have also been made to enhance protective efficacy using combinations of unrelated proteins. In one study, possible synergy in immune responses were assessed using a combination of OspA and DbpA (Hanson et al., 2000). Like OspA, DbpA is an established surface-exposed lipoprotein (Hagman et al., 1998) that elicits some degree of protection as assessed using the mouse infection model (Feng et al., 1998; Hanson et al., 1998). When compared with the protection elicited by each individual protein, the OspA/DbpA combination protected against a 100-fold greater challenge dose and also conveyed a higher degree of protection against challenge with heterologous strains. Tick challenge was not assessed in this study and subsequent analyses suggest that immunization with DbpA does not protect against tick challenge (Hagman et al., 2000). In a different analysis, a combination of three different antigens were tested: OspC, DbpA, and fibronectin-binding protein (BBK32) (Brown et al., 2005) were generated as recombinant proteins and administered as a cocktail. BBK32 is a surface-exposed lipoprotein (Guo et al., 1995; Probert and Johnson, 1998) that is thought to contribute to adherence by the Lyme disease spirochetes (Seshu et al., 2006). The triple combination vaccine was shown to be more effective than single or paired vaccination. In these analyses, only the needle challenge model was assessed.

DNA-Based Vaccines

The use of DNA vaccines encoding *Borrelia* outer surface proteins has also been explored. Mice immunized with plasmid or vaccinia virus expressing *Borrelia* OspA or OspC exhibited varying degrees of protection against different *B. burgdorferi* strains (Simon et al., 1996; Zhong et al., 1996; Luke et al., 1997a; Scheiblhofer et al., 2003; Scheckelhoff et al., 2006). A DNA vaccine encoding an OspA–OspC fusion that was administered by intramuscular injection also elicited a protective immune response (Wallich et al., 2001). However, in the case of the OspA–OspC fusion it was determined that protection was due solely to the antibody response to OspA. In contrast, in a separate study, *ospC* fused to the human tissue plasminogen activator leader sequence in a pCMV vector elicited protective responses. This construct was introduced into mice by two routes: intradermal needle inoculation (Th1 response) and gene gun (Th2 response). Both approaches were equally effective in eliciting protective responses, suggesting that a successful Lyme disease vaccine is not restricted to induction of a certain Th type of immune response (Scheiblhofer et al., 2003). It is important to note however that no studies employing DNA-based vaccines that have been published to date have demonstrated broad protective capability.

Wildlife Vaccine Strategies

Additional approaches being considered in Lyme disease prevention and control include reducing the carriage rate of the Lyme disease spirochetes in ticks through the vaccination of mammalian reservoirs or the development of anti-tick vaccines that can be used to control tick populations. Focusing first on pathogen-specific control approaches, in one study approximately 1000 wild *Peromyscus* mice in southern Connecticut were immunized intraperitoneally with

up to three doses of OspA or with a control protein in Freund's adjuvants. The reduction in Lyme disease transmission efficiency was reported to be 48%, 92%, and 99% for 1, 2, or 3 doses of OspA, compared with control mice (Tsao et al., 2004). The mean decrease in *B. burgdorferi* infection prevalence in the test area was determined to be 16%. While the outcome was significant, the data also served to highlight the importance of other mammalian species in the Lyme disease enzootic cycle. The ability to effectively reduce the carriage rate of the Lyme disease spirochetes in endemic areas will require the development of vaccine delivery strategies that can be applied to a diverse range of mammals (Tsao et al., 2004).

Parenteral vaccination wildlife strategies are, for numerous reasons, not a practical approach for Lyme disease control. Oral delivery is clearly the most viable approach to wildlife vaccination, and could theoretically be designed to reach a broad range of reservoir hosts. OspA has been the focus of most efforts to develop an oral bait vaccine (Gomes-Solecki et al., 2006; Scheckelhoff et al., 2006). Gomes-Solecki et al. (2006) demonstrated that mice immunized by oral gavage with *E. coli* expressing OspA developed a IgG2a/2b systemic antibody response that led to 89% protection against challenge by the tick route. In addition, an eightfold reduction in spirochetal numbers in ticks fed on vaccinated mice was observed. Protective responses have also been demonstrated using other bacterial delivery platforms (Fikrig et al., 1990, 1991; Dunne et al., 1995). Oral administration of purified lipidated OspA has been demonstrated to elicit a protective antibody response in mice (Luke et al., 1997b). An orally delivered recombinant vaccinia virus expressing *ospA* has also been demonstrated to evoke protective responses (Scheckelhoff et al., 2006). The overall feasibility of oral delivery strategies in wildlife remains unclear, and is complicated by the diversity of animals that can serve as reservoirs and the variations in their diets and feeding patterns. It remains to be determined if a baiting strategy can be developed that will prove all-encompassing. It is possible that species-specific baiting strategies will allow for the maintenance of Lyme disease spirochete populations in a subset of animal species and that once protective immunity wanes (or bait vaccine is no longer distributed) Lyme disease spirochete populations will become rapidly re-established. In addition, will it be economically feasible to distribute bait vaccines targeting multiple reservoir species over the large and expanding endemic regions for Lyme disease?

As discussed above, an alternative approach to prevent transmission of Lyme disease and other tick-borne disease in humans is to control tick populations. Several studies have sought to identify tick proteins that can be used to as vaccines. Two broad groups of vaccine candidates have been defined: the "concealed" and "exposed" antigens. Concealed antigens are those to which the mammalian immune cells are not typically exposed, such as proteins on the surface of the tick gut. Exposed antigens, such as tick salivary proteins, are those with the potential to elicit responses within mammals during the feeding process (Nuttall et al., 2006). The *Boophilus microplus* Bm86 gut epithelium glycoprotein serves as one example of a concealed tick antigen. *B. microplus* is a tick species associated with debilitating infestations of cattle (Rand et al., 1989; Willadsen, 2004, 2006). Vaccination with Bm86 elicits antibody that can enter the tick and inhibit feeding, reduce tick burden and lower tick reproductive efficiency (Jonsson et al., 2000; Trimnell et al., 2005). Two examples of concealed antigens that may be of utility in ultimately reducing *Ixodes* tick populations (and possibly other ticks as well) are subolesin (4D8) and 5′ nucleotidase (4F8). Vaccination with these proteins has been demonstrated to significantly reduce tick infestation on sheep (Almazan et al., 2003, 2005a, 2005b). Exposed tick antigens that are being investigated for reducing tick populations include a series of *Ixodes* salivary proteins. Ten potential candidate proteins of *Ixodes scapularis* have been described (Xu et al., 2005). Some of these, such as the tick-produced serine protease inhibitors, have known functional roles (Mulenga et al., 2001, 2003; Sugino et al., 2003; Imamura et al., 2005, 2006). Immunization with the recombinant salivary serine protease inhibitor, Iris, partially protects against adult female and nymphal ticks (Prevot et al., 2007). Other exposed antigens of interest in vaccine development include Salp14, Salp15, TROSPA, and 64P (Anguita et al., 2002; Pal et al., 2004a; Ramamoorthi et al., 2005; Soares et al., 2005; de la Fuente and Kocan, 2006; Pedra et al., 2006).

POSTEXPOSURE IMMUNOPROPHYLAXIS

Postexposure passive immunization as a treatment modality for Lyme disease has been assessed in animal models. Passive immunization with serum from mice that were experimentally infected with *B. burgdorferi* does provide some degree of protection but only when administered prior to challenge (Barthold and Bockenstedt, 1993). Once an active infection is established, passive immunization with "infection-derived serum" reduces disease manifestations and decreases spirochetal burden but does not eliminate infection

(Barthold and Bockenstedt, 1993; Shih et al., 1995; Barthold et al., 1996, 2006). Passive immunization with hyperimmune serum generated against several recombinant *Borrelia* proteins including arthritis-related protein and OspA has been reported to reduce specific clinical manifestations and overall disease severity but not to clear infection (Johnson et al., 1986; Schaible et al., 1990; Fikrig et al., 1993; Zhong et al., 1997; Feng et al., 2000; Barthold et al., 2006). Passive immunization with hyperimmune serum to DbpA has also been investigated (Barthold et al., 2006); however, while it is clear that there is some improvement in disease there are conflicting reports regarding infection resolution (Feng et al., 1998; Hanson et al., 1998; Barthold et al., 2006). In contrast to that observed with OspA, DbpA, and Arp, passive immunization with anti-OspC immunization is protective (Mbow et al., 1999) and can resolve established infection in mice (Zhong et al., 1997, 1999). The efficacy of passive immunization has not been assessed in humans as a means of immunoprophylaxis. The role of immunoprophylaxis in the treatment of Lyme disease is likely to be limited, particularly in light of the effectiveness of antibiotic therapy.

PROSPECTS FOR THE FUTURE

It has been nearly 30 years since the recognition of Lyme disease as a distinct clinical entity. This disease, caused by a unique and highly complex group of bacteria, remains a significant human health concern. As the incidence of Lyme disease continues to increase and its endemic regions spread, there is a pressing need for the development of new preventive strategies. After years of intense research effort in which there were major steps forward in our understanding of the pathogenesis of the Lyme disease spirochetes, it is somewhat ironic that some of the first proteins identified in these bacteria, OspA and OspC, remain at the forefront of subunit vaccine development. When the LYMErix vaccine was voluntarily pulled from the market in 2002, the general consensus appeared to be that the need for, and possibly the commercial viability of, a Lyme disease vaccine had passed. However, in the past few years it has been increasingly clear that the need remains. Efforts are underway to revive OspA-based vaccines or to develop new polyvalent OspC-based chimeric recombinant proteins. In addition, vaccination strategies that seek to interfere with the maintenance of the Lyme disease spirochetes in nature, either by decreasing their carriage by mammalian reservoirs or by reducing tick populations, are also being actively pursued. With the dramatic steps forward that have occurred in our understanding of the enzootic cycle of Lyme disease and the immunological responses to the pathogen, there is reason to be confident that new highly effective vaccines that are commercially viable in North America and Europe will be developed.

KEY ISSUES

- Lyme disease is the leading vector-borne disease in North America and Europe and, despite underreporting and incomplete data, it is clear that its incidence is increasing.
- In view of the serious sequelae of Lyme disease, and the possibility that early disease will go unrecognized, immunoprophylaxis is highly desirable, particularly in regions of high disease endemicity.
- Though the OspA-based LYMErix vaccine was never conclusively associated with adverse vaccine reactions, the negative publicity surrounding its voluntary removal from the market has created a potential barrier to the adoption of future Lyme disease vaccines.
- The use of OspA vaccines reformulated to eliminate potentially autoimmune-inducing T-cell epitopes may have poor acceptance because of the limited duration of protection and requirement for annual boosters.
- Lyme disease vaccines based on OspA or OspC must take into account protein sequence heterogeneity among and within *Borrelia* species.
- Using host-adaptation techniques and microarray and immunoproteome analyses, new potential vaccinogens have been identified that are expressed and immunogenic in the mammalian host.
- OspC is a leading second-generation vaccine candidate, but its development has been hampered by significant sequence heterogeneity in the population of Lyme disease *Borrelia*.
- Epitope mapping studies and phylogenetic analyses have enabled the creation of polyvalent, epitope-based OspC vaccines with the potential for broad protection, and the ability to rely on an anamnestic response during infection.
- Vaccination of wildlife involved in the enzootic cycle is an attractive means by which the incidence of Lyme disease could be reduced; however, due to the complex array of potential carriers, the results to date have not been encouraging.

- Vaccination against tick vector proteins may be an alternative approach to reduce the incidence of Lyme disease by targeting the vector, particularly if the anti-tick vaccine is efficacious at reducing or eliminating pathogen transmission.

Neisseria meningitidis

Nadine G. Rouphael[1], *Shanta M. Zimmer*[1] *and David S. Stephens*[1,2]
[1]Division of Infectious Diseases, Department of Medicine, Emory University School of Medicine, Atlanta, GA, USA
[2]Laboratories of Microbial Pathogenesis, Atlanta VA Medical Center, Decatur, GA, USA

OUTLINE

ABSTRACT

Neisseria meningitidis causes epidemic and sporadic meningitis, and/or septicemia, resulting in significant morbidity or death. Invasive meningococcal disease is the result of microbial factors influencing the virulence of the organism, environmental conditions facilitating exposure and acquisition, and host susceptibility factors favoring bacterial colonization, invasion, and survival. *N. meningitidis* colonizes 8–25% of human upper respiratory tracts with the highest rates in adolescents. Fulminant meningococcemia is a dramatic presentation. Within hours, otherwise healthy subjects may become severely ill, develop hypotension and organ failure, and despite effective antibiotics and aggressive supportive care, 10–15% of patients die and up to 20% of survivors have lifelong sequelae. Meningococci are classified according to their capsular polysaccharide into 13 serogroups of which A, B, C, Y, X, and W-135 are responsible for most endemic and epidemic disease. *N. meningitidis* causes an

estimated 1.2 million cases per year with an estimated death toll of 135,000. Disease rates, in particular meningitis rates, are highest in the African "meningitis belt," where serogroup A outbreaks are prevalent. Recently, serogroup W-135 has caused outbreaks associated with the Muslim hajj pilgrimage, and serogroup Y emerged as a cause of endemic disease in the United States, Israel, and South Africa. Chemoprophylaxis is effective in known contacts and limited outbreak settings. Rapid emergence of resistance (e.g., rifampin) and access and availability of drugs limit this approach in large epidemic outbreaks. Prevention of meningococcal disease by vaccination remains the best control strategy. Polysaccharide vaccines against serogroups A, C, Y, and W-135, in use since the 1970s, are safe and effective; however, they do not produce long-lasting immunity and are of limited effectiveness in children under 2 years of age, and repeated doses may result in hyporesponsiveness. New meningococcal polysaccharide–protein conjugate vaccines are now impacting incidence. In late 1999, the United Kingdom successfully introduced conjugate serogroup C meningococcal vaccines, later introduced by other European countries and Canada. In 2005, a quadrivalent (A, C, Y, and W-135) meningococcal conjugate vaccine was licensed in the United States. Even though the duration of protection is unknown, these conjugate vaccines induce herd immunity, memory responses, antibody affinity maturation, and better immunogenicity in infants, young children, and adults. However, certain infant strategies are associated with rapidly waning immunity, and memory responses alone do not appear to protect because of the short incubation of the disease. A major hurdle in achieving control of meningococcal disease is the development of an effective vaccine strategy for sub-Saharan Africa. Another challenge is the development of safe and immunogenic serogroup B meningococcal vaccines due to the poor immunogenicity of the serogroup B polysaccharide and the theoretical risk of inducing autoimmunity with serogroup B polysaccharide-containing vaccines. Vaccines against serogroup B meningococcal disease have been developed based on outer-membrane vesicles. These vaccines are effective against epidemic strains but usually do not confer cross-protection against heterologous strains. Through the recent availability of the meningococcal genome sequences, new protein-based vaccine candidates have been identified for serogroup B.

INTRODUCTION

Neisseria meningitidis is a leading worldwide cause of sepsis and meningitis, with the highest increase in infants, young children, and adolescents resulting in significant morbidity and mortality. The pathogen has a unique ability among the different etiologic agents of bacterial meningitis to cause major epidemics, case clusters, and hyperendemic as well as endemic disease. Meningococcal epidemics in sub-Saharan Africa have occurred for 100 years (Greenwood, 1999) as large outbreaks at a frequency of 5–10 years or smaller yearly outbreaks in a region of over 18 countries described as the meningitis belt (Lepeyssonnie, 1963). Other regions of Africa also have high rates of meningococcal disease. Thousands of cases occur in the United States, Canada, Europe, parts of South America, Australia, New Zealand, and China. Up to 70–85% of cases were fatal in the pre-serum therapy and pre-antibiotic eras; today, the overall mortality rate in meningococcemia remains high, between 10% and 15% (Sharip et al., 2006). Vaccination against meningococci is the most effective means of disease prevention. Significant advances have improved our understanding of meningococcal biology, pathogenesis, epidemiology, transmission and carriage, clinical presentation, diagnosis, and treatment and led to progress in the development of the next generation of meningococcal vaccines.

HISTORY

Weichselbaum (1887) was the first to identify the meningococcus from the cerebrospinal fluid (CSF) of a patient with meningitis. Epidemics of meningococcal meningitis were first described in 1805 in Geneva, Switzerland, by Vieusseux (1805), and in 1806 in Medfield, Massachusetts, by Danielson and Mann (1806). By the beginning of the 20th century, the recognition of meningococcal carriage in healthy individuals was made (Kiefer, 1896), especially in crowded situations such as those seen in military recruit camps (Glover, 1918). Treatment for meningococcal disease included serum therapy introduced in 1913 (Flexner, 1913) and sulfonamides first introduced in 1937 (Schwentker et al., 1937). Sulfonamides were used not only for treatment but also for chemoprophylaxis (Khuns et al., 1943). Emergence of resistance to sulfonamides (Schoenback and Phair, 1948) in the 1960s prompted the development of the first vaccines against meningococci (Artenstein et al., 1970).

ETIOLOGIC AGENT

N. meningitidis is a fastidious, encapsulated, aerobic gram-negative diplococcus and an exclusive pathogen

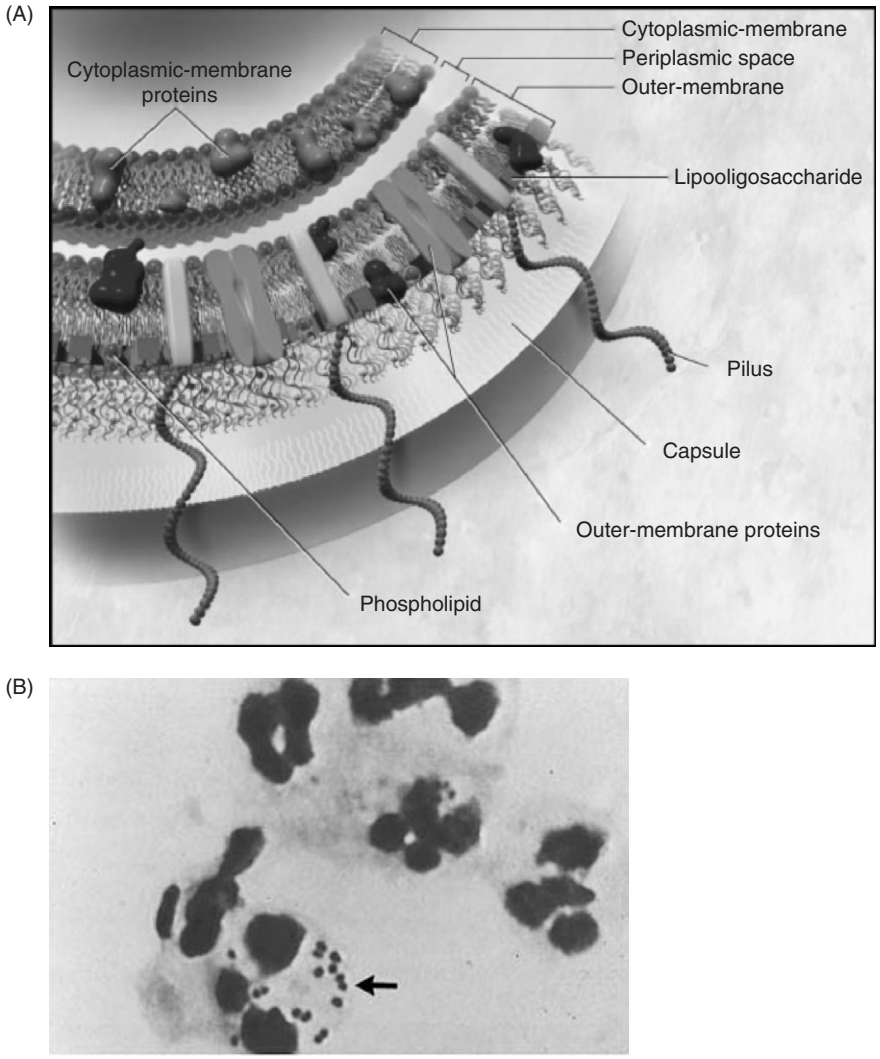

FIGURE 53.1 (A) Cross-sectional view of the meningococcal cell membrane showing the cytoplasmic membrane, outer membrane, and capsule. Phospholipid, lipooligosaccharide, outer-membrane proteins, and pili extending through the capsule are all part of the outer membrane. [Adapted from Rosenstein et al. (2001) with permission from Massachusetts Medical Society.] (B) *Neisseria meningitidis* are intracellular gram-negative diplococci as seen in the CSF of patient with meningitis. [Adapted from Rosenstein et al. (2001) with permission from Massachusetts Medical Society.]

of humans (Fig. 53.1). Meningococci are traditionally classified according to serologic typing (Frasch et al., 1985). This classification is based on structural differences in capsule (serogroup), major outer-membrane protein (OMP) porins (serotype), other OMPs (serosubtype), and lipooligosaccharides (LOS) (immunotype). At least 13 serologically distinct meningococcal groups have been defined on the basis of their capsule (Branham, 1953). Meningococci are highly transformable, and the transformation can lead to a genetic change in capsule structure and therefore in serogroup (Swartley et al., 1997; Vogel et al., 2000). Molecular and genetic techniques have been developed to identify related meningococcal strains. The molecular techniques used (Caugant et al., 1986) include pulsed-field gel electrophoresis (PFGE) (Bevanger et al., 1998), multilocus enzyme electrophoresis (MLEE) (Weis and Lind, 1998), multilocus sequence typing (MLST) (Maiden et al., 1998), and polymerase chain reaction (PCR) (Mothershed et al., 2004).

PROTECTIVE IMMUNE RESPONSE

Bactericidal antibodies and complement are considered major mechanisms in the protection against meningococcal disease. Opsonization and phagocyte killing also appear important.

The meningococcal carrier state is an immunizing process with appearance of antibodies in serum 2 weeks after nasopharyngeal colonization of pathogenic and nonpathogenic meningococci. Goldschneider et al. (1969a, 1969b) found that age-specific incidence of meningococcal disease is inversely proportional to the prevalence of serum bactericidal antibodies (SBA) to the meningococcus. Up to 60–80% of young adults will have detectable serum meningococcal bactericidal antibodies. Further, sera from susceptible hosts lack antibodies to the causative meningococcal strains during an epidemic. Finally, individuals with congenital or acquired deficiencies of immunoglobulins or complement are at increased risk for invasive meningococcal disease (Castagliuolo et al., 1986). Although specific immunity is generally protective, this immunity is not absolute; meningococcal disease can occur in a rare number of individuals with preexisting antibody titers that are considered protective (Greenwood et al., 1987; Kayhty et al., 1981).

Complement is required for both bactericidal activity and opsonophagocytosis (Nicholson and Lepow, 1979). Individuals deficient in both the early and late components of the complement system are at increased risk for the disease (Densen, 1991; Nielsen et al., 1989; Alper et al., 1970; Ellison et al., 1983). Compared to the general population, these patients usually experience less severe but more recurrent disease at an older age with uncommon serogroups (Fijen et al., 1989, 1999). Up to 10–20% of invasive meningococcal disease in adults is associated with a complement defect. The mannose-binding lectin (MBL) pathway of complement activation can be genetically variable and has been associated with differences in susceptibility to meningococcal disease in one-third of all cases (Hibberd et al., 1999; Bax et al., 1999). Other genetic polymorphisms affecting the risk of acquiring meningococcal disease have also been described (including polymorphisms in TNF, FcγRIIA, FcγRIII, PAI-1, ACE-1, IL-1Ra, IL-1β, and TLR4) (Emonts et al., 2003).

PATHOGENESIS

Humans are the only known host for the meningococcus. Nasopharyngeal colonization is present in 8–25% of adults (Greenfield et al., 1971; Stephens, 1999; Caugant et al., 1994), and the duration of carriage can vary from days to many months (Fig. 53.2). Transmission among humans occurs through respiratory secretions, but the inoculum size needed for transmission is unknown. Acquisition of *N. meningitidis* in the upper respiratory tract may be asymptomatic, result in colonization, infrequently cause local inflammation or disease (e.g., pneumonia), produce fulminant sepsis after access to the bloodstream, may produce fulminant sepsis or seed secondary sites such as CSF, joints or pericardium. Disease usually occurs 1–14 days after acquisition of the pathogen.

Invasive disease is dependent on environmental factors, meningococcal virulence, and host factors (refer to Protective Immune Response). Environmental factors that impair the integrity of the human nasopharyngeal mucosa such as tobacco (Fischer et al., 1997), exposure to low humidity, dust, and coinfections (Moore et al., 1990) increase the incidence of colonization, transmission, mucosal invasion, and invasive meningococcal disease.

Major contributors to the virulence of *N. meningitidis* include capsular polysaccharide, other surface structures [pili, OMPs (e.g., PorA, PorB, Opa, and Opc), LOS], and virulence factors associated with the genotype. The capsule, composed of sialic acid derivatives (with the exception of serogroup A), provides the organism with antiphagocytic, antibactericidal, and antiadherent properties enhancing its survival in the bloodstream or in the central nervous system (CNS). Meningococci that do not express capsular polysaccharides rarely cause invasive disease. LOS is in the family of lipopolysaccharide (LPS) or endotoxin expressed by many other gram-negative bacteria but lacks the repeating *O*-side chain of LPS of enteric gram-negative

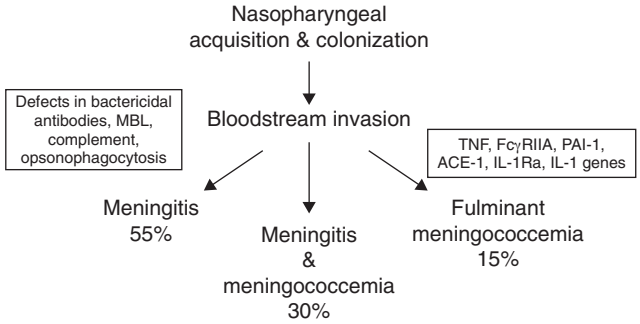

FIGURE 53.2 Pathogenesis of meningococcal disease. Acquisition of *N. meningitidis* in the upper respiratory tract may be asymptomatic, result in colonization, infrequently cause local inflammation or local disease (e.g., pneumonia), produce fulminant sepsis after access to the bloodstream, or seed secondary sites, particularly the CSF. In individuals who lack bactericidal antibodies, terminal or alternative pathway complement-deficiency states, and other genetic polymorphisms may influence the severity of the ensuing host response and the clinical presentation. Legend: MBL, mannose-binding lectin; TNF, tumor necrosis factor; FcγRIIA, FcγRIIA R131 allele; PAI-1, plasminogen activator inhibitor 1; ACE-1, angiotension-converting enzyme 1; IL, interleukin. [Adapted from Kasper et al. (2005) with permission of the McGraw-Hill Companies.]

bacilli. It plays a role in the adherence of the meningococcus (Kahler and Stephens, 1998) and activation of the innate immune system. The severity of meningococcal sepsis has been correlated with circulating levels of meningococcal LOS (Brandtzaeg et al., 1992). Other important virulence factors are pili (Stephens et al., 1985) and other OMPs (Virji et al., 1993) facilitating the adherence of the meningococcus to epithelial and endothelial surfaces. Importantly, meningococcal virulence is influenced by genetic mechanisms [transformation, slip-strand mispairing, insertion sequence (IS) element movement] that produce phase and antigenic variation and allow for genomic plasticity and adaptation (Stephens and Zimmer, 2002). The pathogen has also developed sophisticated pathways for iron acquisition, essential for colonization and infection, including an array of iron transport mechanisms (Schryvers and Stojiljkovic, 1999).

EPIDEMIOLOGY

Meningococcal infection is a global but nonuniform problem occurring as sporadic, hypersporadic, and epidemic disease. Disease patterns vary widely among regions, age groups, and serogroups, and in developing as well as developed countries (Fig. 53.3). In the last 60 years, large serogroup A epidemics have not occurred in industrialized countries for reasons not understood, but serogroup C and prolonged serogroup B outbreaks do occur. In the United States, the attack rate is less than 1 case per 100,000 per year while it is higher in Europe (Cartwright et al., 2001); in the United Kingdom, the attack rate was 5 cases per 100,000 per year prior to the introduction of the meningococcal C (MenC) conjugate vaccines. In the meningitis belt, rates vary between 20 and 600 and up to 1000 per 100,000 depending on the year and the presence or absence of epidemics. Meningococcal disease peak coincides with respiratory viral illnesses (Artenstein et al., 1967; Young et al., 1972) during winter months; in Africa, meningococcal disease occurs in the dry season (Greenwood et al., 1985).

Since the remarkable decline in disease due to the *Haemophilus influenzae* and pneumococcal polysaccharide–protein conjugate vaccines, the meningococcus is now the most common cause of bacterial meningitis in children and young adults in the United States (Harrison et al., 1999), mostly affecting children less than 2 years of age (Kaplan et al., 2006; Rosenstein et al., 1999). However, even though peak incidence occurs among infants and adolescents; one-third to one-half of the cases are seen in adults older than 18 years.

The epidemiology of meningococcal disease differs depending on the serogroup (Tzeng and Stephens, 2000). Six serogroups (A, B, C, Y, W-135, and recently X) (Boisier et al., 2007; Gagneux et al., 2002) constitute most of the cases of meningococcal disease worldwide. Serogroup A was the cause of most meningococcal disease in the first part of the 20th century and is now responsible for recurring epidemics in developing countries, particularly in sub-Saharan Africa (Hart and Cuevas, 1997). In the largest meningococcal epidemic outbreak recorded, an estimated 300,000 cases and 30,000 deaths occurred in sub-Saharan Africa during 1996–1997 due to serogroup A *N. meningitidis*. From 2000 to 2002, epidemics of serogroup W-135 occurred, related to spread during the hajj pilgrimage, affecting the health of these travelers and their contacts in countries throughout the world (Lingappa et al., 2003; Wilder-Smith et al., 2003; Hahne et al., 2002). In 2002, a large outbreak of W-135 occurred in Burkina Faso (Koumare et al., 2007; Traore et al.,

FIGURE 53.3 Serogroup distribution of invasive meningococcal disease worldwide. [Adapted from Stephens et al. (2007) with permission from Elsevier and from Caugant (1998) with permission from Wiley-Blackwell Publishing.]

2006; Decosas and Koama, 2002; Ouedraogo-Traore et al., 2002). Serogroup B is the most important cause of endemic disease in developed countries (30–40% and 80% of disease in the United States and European countries, respectively), and serogroup C has variable rates of endemic disease (currently around 30%) in industrialized countries (Jackson et al., 1995). Serogroup Y has emerged in the last decade in the United States and caused one-third of the disease related to meningococci in the country (Rosenstein et al., 1999), usually affecting older age groups. Interestingly, meningococcal pneumonia is usually due to serogroups Y and W-135.

CLINICAL DISEASE

The clinical spectrum of meningococcal disease can vary from transient bacteremia (Sullivan and LaScolea, 1987) to fulminant disease (Rosenstein et al., 2001). The predominant clinical syndrome is one of acute bacterial meningitis (Stephens et al., 1995; Thompson et al., 2006). Patients present with fever, headache, photophobia, neck stiffness, occasional seizures, altered mental status, nausea, vomiting, myalgia, and petechial or purpuric rash (28–77%) (Rosenstein et al., 2001). However, the rash may be absent or difficult to detect, and signs of sepsis (hypotension, organ failure, confusion) may be the presenting features. Approximately 30% of patients with meningococcal disease present with both meningitis and signs of meningococcemia. Up to 10–20% of patients will present with fulminant meningococcemia with severe sepsis leading to organ failure, disseminated intravascular coagulation (DIC), and death in up to 50% of these cases. The Waterhouse-Friderichsen syndrome, including adrenal hemorrhage in the setting of meningococcemia, is a dramatic example of microthrombosis from DIC, bleeding, and tissue injury. Up to 10–20% of patients with meningitis and meningococcemia will develop permanent sequelae (Erickson et al., 2001; Edwards and Baker, 1981). Complications are seen in meningitis in the form of different neurological deficits, especially hearing loss. In fulminant meningococcemia, loss of limb or digits from ischemia and necrosis can be observed.

Fifteen percent of patients present with pneumonia, frequently at an older age and more commonly in association with serogroup Y (Winstead et al., 2000). Other manifestations of meningococcal disease include conjunctivitis (Moraga et al., 1990; Newton and Wilson, 1977), pharyngitis (Mattila and Carlson, 1998; Pether et al., 1994; Wiesner et al., 1973), pericarditis (El Bashir et al., 2004; Morgan et al., 2002; Baevsky, 1999; Blaser et al., 1984; Chow et al., 1975), endocarditis (Benes et al., 2003; Joao et al., 2001), myocarditis (Garcia et al., 1999; Hardman and Earle, 1969), arthritis (Schaad, 1980; Bilavsky et al., 2006), urethritis (D'Antuono et al., 1999; Karolus et al., 1980; Miller et al., 1979), or cervicitis (Hagman et al., 1991; Odegaard and Gundersen, 1977). Rarely, chronic meningococcemia syndrome is reported. It is characterized by recurrent fever, skin rash, and headache (Nielsen, 1970) and may have a rheumatological presentation of weeks to months. Diagnosis is made by isolation of the meningococcus in sterile sites such as the blood or the CSF. Antigen detection assays can be used when cultures are negative and in developing settings where cultures are not available. PCR has rapidly gained acceptance in the diagnosis of meningococcal infection since it is capable of serogroup and strain typing, and its sensitivity is not affected by prior antibiotics (Ni et al., 1992; Newcombe et al., 1996; Bryant et al., 2004).

TREATMENT

Respiratory isolation of the patient is recommended for the first 24 h of hospital stay. For treatment, a third-generation cephalosporin (e.g., ceftriaxone) is recommended. Penicillin can also be given if susceptibility is confirmed. In patients with severe allergic reaction to beta-lactam drugs, fluoroquinolones or chloramphenicols are alternatives (McCrumb et al., 1951; Blondeau and Yaschuk, 1995). Several prognostic studies (Barquet et al., 1997; Niklasson et al., 1971) indicated that early administration of antibiotics results in decrease in mortality and morbidity (Cartwright et al., 1992), and prehospital antibiotic treatment is advocated in many countries. In meningococcal meningitis, steroid use is controversial (Weisfelt et al., 2006; Casella et al., 2004; Gupta and Tuladhar, 2004), but some experts recommend that they be given prior to, or simultaneously with, the first dose of antibiotics (van de Beek et al., 2004). For fulminant meningococcemia, often seen with serogroup C *N. meningitidis,* intensive care is required. The role of activated protein C for patients with meningococcemia is not clearly defined, with some studies showing promising results in subgroups (White et al., 2000; de Kleijn et al., 2003) while others did not show benefit (Nadel et al., 2007) and may suggest increase risks for side effects in patients with meningococcal disease (Vincent et al., 2005). Overall mortality from invasive meningococcal disease ranges from 10% to 15%; however, if purpura fulminans is present, mortality is increased to up to 50%. In the United Kingdom, the case-fatality rate of

meningococcal infections was unchanged from 1963 to 1998 (Goldacre et al., 2003), but use of aggressive supportive therapy has reduced mortality. In the United States, between 1994 and 2002, the case-fatality rate was increased during outbreaks compared to sporadic disease (Brooks et al., 2006).

POSTEXPOSURE IMMUNOPROPHYLAXIS

Chemoprophylaxis eradicates nasopharyngeal carriage and prevents secondary cases in close contacts. Chemoprophylaxis consists of rifampin twice daily for a total of four doses or a single dose of ciprofloxacin. Ceftriaxone as a single intramuscular dose can also be offered. Azithromycin has also shown efficacy (Girgis et al., 1998) among children but is not routinely recommended. Knowing that the attack rate among household or other close contacts of meningococcal cases is more than 400-fold greater than the general population (De Wals et al., 1981), chemoprophylaxis for individuals at risk should be offered (Fraser et al., 2006; Bilukha and Rosenstein, 2005). Close contacts include those living in the same household, day-care center contacts, and anyone directly exposed to oral secretions of the patient with meningococcal disease. Prophylaxis is not indicated if the exposure to the index case was brief (Gilmore et al., 2000). Chemoprophylaxis should be administered as soon as the index case is identified and up to 7 days following exposure; after 14 days, chemoprophylaxis is ineffective. Since treatment with penicillin alone is not reliable in eradicating nasopharyngeal carriage (Abramson and Spika, 1985), terminal prophylaxis should be given to index patients at hospital discharge. Vaccination rather than chemoprophylaxis is usually offered during outbreaks in large populations because of cost of chemoprophylaxis and the increased likelihood of antimicrobial resistance.

VACCINES

History

Early in the 20th century, attempts were made to develop meningococcal vaccines using killed whole cells (Sophian and Black, 1912; Gates, 1918). Those attempts failed due to uncertainty in the ability of the vaccines to confer protective immunity and high rates of observed side effects. In the 1930s, "inactivated toxin" was used as potential vaccine candidate (Ferry and Steele, 1935; Khuns et al., 1938). Though immunogenic, those vaccines carried the risk of side effects with other components of the meningococcal outer membrane. The successful introduction of sulfonamides in 1937 in both the treatment and the prevention of meningococcal disease somewhat dampened the enthusiasm for vaccine development. However, the emergence of antimicrobial resistance to sulfonamides in the 1960s led to renewed efforts in the development of a vaccine to prevent meningococcal disease. In 1969–1971, the purification of meningococcal capsular polysaccharides by Gotschlich et al. (1969a, 1969b) at the Walter Reed Army Institute of Research led to the discovery of meningococcal A and C polysaccharide vaccines. These vaccines were used to control serogroup C outbreaks in the U.S. military and serogroup A epidemics in Africa. In 1978, the quadrivalent (A, C, Y, and W-135) polysaccharide vaccine was approved. The main limitations of polysaccharide vaccines are their inability to induce a T-cell-dependent response limiting effectiveness in children and failure to induce long-term immunologic memory. The chemical conjugation to protein carriers converts the polysaccharide to a T-cell-mediated response. The successful introduction of the conjugate *H. influenzae* serotype b vaccine (Heath, 1998) preceded the first human trial with a MenA–MenC conjugate vaccine developed by Salvo Vaccines (Sienna) in 1991 (Costantino et al., 1992). In late 1999, the United Kingdom was the first country to introduce the conjugate serogroup C vaccines. In 2005, a tetravalent conjugate vaccine including serogroups A, C, Y, and W-135 was licensed in the United States.

Since 1980, researchers have been working on a vaccine for serogroup B, and to date, none of the vaccines has been shown to be broadly protective. Since the serogroup B polysaccharide is poorly immunogenic due to its identity with human glycoproteins [e.g., neural cell adhesion molecule (NCAM)] and carries a theoretical risk of inducing autoimmunity through molecular mimicry, other antigens are used as targets in vaccine development for serogroup B. The currently available serogroup B outer-membrane vesicle (OMV) vaccines protect against particular strains and have been used with success in outbreak settings. Since the sequencing of the serogroup B genome in 2000, recent advances in reverse vaccinology have revealed new molecules as potential serogroup B vaccine candidates.

Polysaccharide Vaccines

Polysaccharide vaccines are either monovalent or multivalent, containing one to four of the serogroup

TABLE 53.1 Meningococcal vaccines for serogroups A, C, Y, W-135, and B

Meningococcal polysaccharide vaccines	
Menomune® (Sanofi Pasteur)	A, C, Y, and W-135
ACWY Vax (GlaxoSmithKline)	A, C, Y, and W-135
Trivalent ACW vaccine (GlaxoSmithKline)	A, C, and W-135
AC Vax® (GlaxoSmithKline)	A and C
Mengiva A+C® (Sanofi Pasteur)	A and C
Meningococcal polysaccharide–protein conjugate vaccines	
Meningitec® (Wyeth)	C with CRM_{197}
Menjugate® (Novartis)	C with CRM_{197}
NeisVac-C® (Baxter)	C with tetanus toxoid
Menactra® (Sanofi Pasteur)	A, C, Y, and W-135 with CRM_{197}
Serogroup B meningococcal vaccines (in development)	
MonoMen®, HexaMen®, NonaMen® (Netherlands Vaccine Institute)	
Finlay Institute vaccine/VA-MENGOC-BC (Havana, Cuba)	
National Institute of Public Health vaccine (Oslo, Norway)	
B+OMV (Walter Reed Army Institute of Research, Washington, D.C., USA)	
MeNZB® (New Zealand)	

A, C, Y, and W-135 capsular polysaccharides (Table 53.1). A single subcutaneous injection of quadrivalent meningococcal polysaccharide vaccine containing 50μg of purified bacterial polysaccharide for serogroups A, C, Y, and W-135 [meningococcal polysaccharide vaccine (MPSV-4), Menomune®, Sanofi Pasteur, PA, USA] has been licensed in the United States since 1981. The vaccine is both safe and effective, inducing serum bactericidal immunity in 80–95% of adults (Bilukha and Rosenstein, 2005). Side effects are usually mild, with local reactions (4–46%) lasting 1–2 days. Severe side effects [systemic allergic reactions (0–0.1/100,000), infrequent neurological reactions] are rare (Lepow et al., 1986). The immunologic response to each of the four polysaccharides contained in the vaccine is serogroup specific and independent. In particular, the serogroup C capsular polysaccharide is poorly immunogenic in children less than 2 years of age (Gold et al., 1979), and SBA titers in adults decline markedly within 2 years of immunization (Zangwill et al., 1994). Serogroup A polysaccharide is capable of offering protection in children as young as 3 months (Gold et al., 1979); however, this protection is of short duration, and additional doses are required for longer protection. The duration of protection of the quadrivalent polysaccharide vaccine is therefore less than 5 years, and repeated doses of the vaccine may result in hyporesponsiveness, especially in the C component, among children and young adults (MacLennan et al., 1999). Polysaccharide vaccines do not confer long-term herd immunity. In a study from Gambia, immunization with the bivalent serogroup A/C vaccine had little effect on nasopharyngeal carriage of serogroup A meningococcus 6 months after vaccine administration (Hassan-King et al., 1988). Polysaccharide meningococcal vaccine is not recommended for routine use in the general population. It can be used in outbreak settings (Masterton et al., 1988) and high-risk populations. Since the introduction of meningococcal capsular polysaccharide vaccination for all recruits in the United States in 1972, epidemics in the military have not occurred (Brundage et al., 2002).

Conjugate Vaccines

The limitations of the polysaccharide vaccines, including lack of herd immunity and poor immunogenicity in young children, were the driving forces behind the development of protein–polysaccharide conjugate meningococcal vaccines (Zimmer and Stephens, 2004). The polysaccharide is covalently linked to a carrier protein and therefore converted to a thymus-dependent antigen enhancing memory B cells (Kelly et al., 2006) and IgG anticapsular antibody production in infants. In 1999, in an attempt to control hyperendemic serogroup C meningococcal disease, a campaign to vaccinate adolescents, children, and infants was launched in the United Kingdom, using serogroup C meningococcal polysaccharide–protein conjugate vaccines (MenC). The vaccination campaign was begun on the basis of safety and immunogenicity data, without prior studies demonstrating clinical efficacy. The vaccine program was a success, with dramatic reduction in invasive meningococcal serogroup C disease, and was replicated in other countries (Snape and Pollard, 2005). Major advantages to this vaccine over polysaccharide vaccines are the induction of herd immunity, memory responses, and better immunogenicity in infants and young children.

The vaccines used are conjugated either to CRM_{197} (a nontoxic mutant of diphtheria toxin) or to tetanus toxoid. The vaccines were developed from isolates containing *O*-acetyl group in their polysaccharides (OAC+ve). However, 12% (Borrow et al., 2000) of meningococcal serogroup C disease is caused by strains that lack the *O*-acetyl group (OAC−ve). Therefore, an alternative version of the monovalent MenC vaccine was developed conjugating an OAC−ve polysaccharide to tetanus toxoid (MenC-TT).

Currently, three vaccines are licensed: two OAC+ve–CRM_{197} conjugate vaccines (Meningitec® Wyeth, NJ, USA, and Menjugate® Novartis, Siena, Italy) and one OAC−ve–tetanus toxoid conjugate (NeisVac-C® Baxter Bioscience, MD, USA). All three vaccines are safe and immunogenic. Local (0.15%) and systemic reactions (seizure 1/60,000, anaphylaxis 1/500,000) are rare (2000). The efficacy of the vaccines is around 90% among all age groups (Snape and Pollard, 2005). In the United Kingdom, incidence of serogroup C disease declined by 81–87% among vaccinees (Balmer et al., 2002; Miller et al., 2001). In addition to the reduction in meningococcal disease, significant differences were seen in meningococcal carriage with a 66% reduction in serogroup C nasopharyngeal carriage in students 15–17 years of age (Maiden and Stuart, 2002). A herd immunity effect was noted with a 67% reduction in meningococcal disease reported for unvaccinated children (Ramsay et al., 2003). The use of the MenC conjugate vaccine was also effective in an outbreak setting (De Wals et al., 2004). Surveillance data after vaccine introduction have not demonstrated (Alonso et al., 2007), as of yet, significant capsule switching (Alcala et al., 2002; Diggle and Clarke, 2005) or serogroup replacement (Trotter et al., 2006). Although the duration of immunity is unknown, SBA titers wane rapidly after primary immunization (Trotter et al., 2004) but memory response persists (Richmond et al., 1999). However, in confirmed cases of vaccine failure (Auckland et al., 2006), this memory response alone did not provide protection against invasive disease. For this reason, a booster dose at 12–14 months should be considered after routine infant vaccination, and this change was made in the U.K. schedule. Other countries followed the successful U.K. example—Ireland (Dell et al., 2001) (2000), Spain (Salleras et al., 2003) (2000), Canada (De Wals et al., 2004) (Quebec) (2001), the Netherlands (Welte et al., 2004) (2002), Belgium (De Schrijver and Maes, 2003) (2002), Iceland (Bergthornorsson et al., 2004) (2002), Australia (Booy et al., 2007) (2003), Portugal (De Queiros et al., 2004) (2006), and Germany (Wiese-Posselt et al., 2006) (2006)—and a 54–96% reduction in invasive serogroup C meningococcal disease was noted (Snape and Pollard, 2005). Meningococcal conjugate vaccines are given as part of a routine childhood immunization program, but scheduling, dosing, and catch-up campaigns have varied among the countries (Trotter and Ramsay, 2007). The vaccine has been given as a two- or three-dose series in infancy or as one dose for toddlers at 12–14 months. Recent data suggest that while there is no clear difference if the immunization was given during infancy or in toddlers (Vu et al., 2006), a booster dose after 12 months is needed. In the United Kingdom, for instance, a booster dose is now given at 12 months after the two doses given in infancy. In addition to the childhood immunization program, all persons in the United Kingdom under 24 years of age were included in the initial catch-up campaign.

A new meningococcal quadrivalent conjugate vaccine (A, C, Y, and W-135 conjugated with diphtheria toxoid) [meningococcal conjugate vaccine (MCV-4), Menactra®, Aventis Pasteur, PA, USA] has been licensed in the United States since 2005 (Maiden and Spratt, 1999). Data comparing the immunogenicity and overall safety of Menactra to Menomune showed noninferiority (Bilukha and Rosenstein, 2005). Local reactions were more common in Menactra, likely due to the diphtheria toxoid component of the vaccine. Post licensure, a slight increase in cases of Guillain-Barré syndrome (GBS) was reported among Menactra recipients (2006), especially those over 15 years old. However, compared to the number of doses given and the impact on meningococcal disease incidence, those reports have not resulted in any change in vaccine recommendations. Duration of immunity to the vaccine is still unknown. A single intramuscular dose of vaccine is recommended as part of routine immunization for children aged 11–12 years, other adolescents, and groups at increased risk (2005). Vaccination is recommended in high-risk groups such as military recruits, microbiologists routinely exposed to meningococci (Sejvar et al., 2005), college freshmen living in dormitories, pilgrims to the hajj, travelers to sub-Saharan Africa during the dry months or to countries with known epidemics, and persons with increased susceptibility to meningococcal disease (terminal complement deficiency or anatomic/functional asplenia). MCV-4 has been recently licensed for children 2–11 years of age with risk factors (e.g., complement or antibody deficiency) for meningococcal disease. Recent data comparing MCV-4 to MPSV-4 in 2- to 10-year-olds showed a similar safety profile and elicited significantly higher and more persistent SBA responses (Pichichero et al., 2005). MCV-4 is contraindicated in persons with a history of GBS or an allergy to any component of the vaccine.

Serogroup B Vaccines

Development of a vaccine that can elicit broad protection against diverse serogroup B meningococcal strains presents several challenges (Zimmer and Stephens, 2006). The poor immunogenicity of the serogroup B polysaccharide is attributable to the fact that

this polysaccharide resembles host antigens (Finne et al., 1983). The capsule is of identical structure to polysialic structures expressed in fetal neural tissue. The development of a polysaccharide vaccine for serogroup B has been limited by the theoretical risk of inducing autoimmunity (Stein et al., 2006). Even though IgM against serogroup B polysaccharide can contribute to serum bactericidal activity, IgG antibodies to serogroup B polysaccharide are nonspecific and poorly protective in animal models (Granoff et al., 1995; Mandrell et al., 1995) as well as humans (Bruge et al., 2004). Recent data suggest that the meningococcal serogroup B capsular polysaccharide may be engineered to express unique bactericidal epitopes suitable as vaccine targets (Moe et al., 2006; Granoff et al., 1998).

Other noncapsular antigens such as OMVs, containing OMPs and LOS, are therefore important vaccine candidates for serogroup B. The challenge of developing an effective vaccine against meningococcal serogroup B disease is of regional importance. In the late 1980s and in the 1990s, several trials of serogroup B OMV vaccines were undertaken in Cuba, Brazil, Chile, and Norway, which showed efficacy between 50% and 80%. Similar to the polysaccharide vaccines, serogroup B OMV vaccines have limited efficacy in infants and very young children, and the single-strain OMV vaccines may not provide cross-protection against a variety of heterologous meningococcal isolates. Usually, the protection is of short duration, and nasopharyngeal carriage is not affected.

Norway has had high rates of meningococcal disease, up to 80%, due to serogroup B. Between 1988 and 1991, the Norwegian Institute of Public Health (NIPH) enrolled 171,800 students in a double-blind, placebo-controlled, efficacy trial to evaluate the effect of OMV vaccine against serogroup B meningococci (MenBvac) (Bjune et al., 1991). Efficacy was around 50%. The Finlay Institute in collaboration with GlaxoSmithKline produced a purified OMP vaccine (VA-MENGOC-BC™) that was tested in Cuba (106,000 vaccinees) with great success (Sierra et al., 1991). The vaccine has been licensed in many Latin American countries. However, the high efficacy observed in the original Cuban trial was not replicated in case control studies in Brazil including 4 million vaccinees from Sao Paolo and Rio de Janeiro (Noronha et al., 1995; de Moraes et al., 1992). Two other OMV vaccines developed by the Walter Reed Army Institute of Research (Boslego et al., 1995) and the NIPH/Chiron (Tappero et al., 1999) (VA-MENGOC-BC) were tested in Chile. Because of the geographical and temporal diversity of OMPs, the OMP-based approach may be best suited for the development of vaccines for specific outbreaks and is best illustrated by the New Zealand experience. In New Zealand, in 1997, the rate of meningococcal disease rose to 16.9 cases per 100,000 with more than 90% of the disease due to serogroup B (Baker et al., 2001). As this is typical of serogroup B outbreaks, this epidemic has persisted for a decade. The stability of OMVs from serogroup B isolates during this meningococcal outbreak supported the use of a strain-specific OMV vaccine to control the epidemic (Dyet and Martin, 2005; Devoy et al., 2005). MeNZB™ was produced as a result of collaboration between the New Zealand government, the University of Auckland, and Chiron (now Novartis) (O'Hallahan et al., 2004). A three-dose regimen of the vaccine containing PorA, PorB, and LOS was safe and immunogenic in 75 healthy adults (Thornton et al., 2006) and children (Wong et al., 2007) (16–24 months). New Zealand's regulatory authority granted licensure to deliver MeNZB™, and 1 million individuals under age 20 received the vaccine (Sexton et al., 2004), which has diminished the outbreak.

An estimation of potential coverage by current OMP vaccines to European serogroup B strains was performed (Trotter and Ramsay, 2007). The Cuban, Norwegian, and New Zealand vaccines cover less than one-third of the strains circulating in Europe between 1999 and 2004, and multivalent OMP vaccines such as those used in the Netherlands can cover more than 70% of the strains. Both a hexavalent OMV vaccine (HexaMen™) containing two OMVs with three PorA subtypes each and a monovalent OMV vaccine (MonoMen™) have been studied in infants, toddlers, and children. These vaccines showed promise but limited cross-protection to other serosubtypes not contained in the vaccine (de Kleijn et al., 2000a, 2000b). Three additional vesicles have been added to a new nonavalent formulation (NonaMen™), and trials are underway. In the United States, it has been estimated that 20 different PorA proteins need to be incorporated in the serogroup B vaccine to cover 80% of circulating strains (Tondella et al., 2000).

Vaccines in Development

Other Serogroup B Vaccines

The lack of broad efficacy provided by PorA-based serogroup B vaccines suggests that other vaccine strategies should be further investigated. The challenge is to identify proteins that are exposed at the surface, conserved across various strains, and consistently expressed. Those proteins should be immunogenic and capable of inducing bactericidal antibodies and long-lasting immunity (Ruggeberg and Pollard, 2004).

Proteins involved in the meningococcal iron metabolism have been evaluated as potential vaccine candidates (Johnson et al., 1999; Gomez et al., 1998; Thompson et al., 2003; West et al., 2001; Lehmann et al., 1999). Among these proteins are the transferrin-binding proteins. Opsonins are recovered in humans during the convalescence (Lehmann et al., 1999) period, and there is protection in animal models (West et al., 2001). However, phase I human trials led to disappointing results (Ruggeberg and Pollard, 2004). Neisserial surface protein A (NspA) is highly conserved among meningococcal strains, although the function of the protein is unknown. Active and passive immunizations confer protection in mice (Martin et al., 1997). However, focusing on meningococcal serogroup B vaccines, other researchers were not able to fully replicate these results (Moe et al., 2001). A vaccine based on purified NspA has been developed by Shire Pharmaceuticals and evaluated in phase I trials. Though protective in the mouse model and safe in humans, the vaccine did not induce SBA in a phase I trial (Halperin et al., 2007). Other OMVs have also been considered as vaccine candidates (e.g., Opa, Opc, App, pilin, Rmp, PorB, and NadA) (Stephens et al., 1985; Wright et al., 2002; Hadi et al., 2001; de Jonge et al., 2003, 2004; Rosenqvist et al., 1999; Comanducci et al., 2002; Bowe et al., 2004) (Table 53.2).

The range of novel antigens is not restricted to proteins. Lipoprotein LP2086, displayed on the surface of 91% meningococcal strains, has been shown to induce serum bactericidal activity against a broad variety of meningococcal strains and prevent colonization in animal models (Pillai et al., 2005; Zhu et al., 2005, 2006). LPS is a key player in pathogenesis and may be useful as vaccine adjuvant. Even though it is highly conserved among meningococci, complete lack of protection among certain strains has been shown (Plested et al., 2003).

Other approaches such as use of commensal neisserial species or a genomic approach are being considered in the quest for a broader vaccine against serogroup B meningococcal disease. *Neisseria lactamica* is a commensal of the upper respiratory tract, is often carried by infants and young children, and shares many common antigens with *N. meningitidis*. Epidemiologic data suggest that colonization with *N. lactamica* confers some protection against invasive meningococcal disease (Olsen et al., 1991). Vaccines based of the OMVs of *N. lactamica* have been tested in animals and were found to induce cross-protection (Gorringe, 2005; Li et al., 2006).

Finally, in recent years, with the completion of meningococcal genomes, the use of reverse vaccinology has led to the discovery of new meningococcal

TABLE 53.2 Selected outer-membrane protein meningococcal vaccine candidates

OMP	References	Comments
Transferrin-binding protein (TbpA/TbpB)	Dyet et al., 2005	TbpB is better exposed and more immunogenic, but TbpA is more conserved, providing better protection in an animal model
Ferric enterobactin receptor (FetA)	Baker et al., 2001	Protein diversity and poor expression of cross-reactive epitopes limit the use as vaccine candidate
Lactoferrin-binding protein (LbpA/LbpB)	Boslego et al., 1995	Poorly immunogenic
Ferric-binding protein (FbpA)	Tappero et al., 1999	Well-conserved and -exposed protein but induces low bactericidal activity
Adhesion penetration protein (App)	De Kleijn et al., 2000	Conserved protein with presence of antibodies during human convalescence as well as bactericidal rabbit anti-App
Opacity-associated protein (Opa/Opc)	De Kleijn et al., 2000 Tondella et al., 2000	Anti-Opa interference with colonization and intranasal vaccine in mice induce IgA and IgG responses
Pilin	Kahler et al., 1998	High degree of variability but potential for antibodies to block pathogen adhesion
Porin B (PorB)	Sexton et al., 2004	Antibody to PorB mediates serotype-specific complement-mediated killing
Neisserial surface protein (NspA)	O'Hallahon et al., 2004 Wong et al., 2007	Highly conserved protein. Passive and active immunization conferring protection in mice. Vaccines in phase I trial show safety and immunogenicity but absence of bactericidal antibodies
NadA	Thompson et al., 2003	Intranasal vaccine provides protection in rats
Reduction-modifiable protein (Rmp)	Ruggeberg et al., 2004	No bactericidal or opsonic activity

Source: Adapted from Ruggeberg and Pollard (2004) with permission from the publisher.

serogroup B vaccine candidates (Pizza et al., 2000). Five antigens with aluminum hydroxide adjuvants induced SBA in mice against 78% of a large panel of meningococcal serogroup B isolates representative of global strains (Giuliani et al., 2006). Coverage could reach 90% if additional antigens or different adjuvants are used. Another promising vaccine candidate based on genome-derived neisserial antigen 1870 (recently renamed factor H-binding protein, FHBP) provides protection in rats and induces SBA in mice (Beernink et al., 2006).

Vaccines for Africa

The current approach in controlling meningococcal epidemics in sub-Saharan Africa is based on early detection of disease and mass vaccination with meningococcal polysaccharide vaccine once a weekly incidence threshold has been crossed (Lewis et al., 2001). A conjugate A/C vaccine has been studied in the African "meningitis belt" in the Gambia and Niger, and the safety and the immunogenicity of the vaccine were demonstrated (Campagne et al., 2000; Leach et al., 1997; Twumasi et al., 1995). However, the response of the serogroup A conjugate component was not as robust as the response to the serogroup C conjugate component. Currently, efforts are underway to develop conjugate vaccines against serogroup A since it is the most prevalent serogroup in the African meningitis belt.

In 2001, a partnership between the Program for Appropriate Technology in Health (PATH) and the World Health Organization (WHO) resulted in the creation of the Meningitis Vaccine Project (MVP) (Laforce et al., 2007) with the goal of eliminating meningococcal epidemics in Africa, through the development, licensure, introduction, and widespread use of an affordable (US$0.40 per dose) MenA conjugate vaccine. The MVP has identified a European manufacturer (SynCo Bio Partners, Amsterdam, Netherlands) for polysaccharide serogroup A, a developing-country manufacturer of high-quality tetanus toxoid used as a carrier (Serum Institute of India), and a U.S. public biological research center (CBER/FDA) to provide expertise in the design of conjugate vaccines. A phase I study of the vaccine in India has shown that the vaccine is both safe and immunogenic. Phase II studies have begun in Gambia and Mali, and a large demonstration study of the conjugate vaccine is envisioned for 2008–2009. After consultations with African public health officials, a vaccine introduction plan will aim at including the MenA conjugate vaccine into standard immunization schedules. Emphasis should be put on vaccination of 1- to 29-year-olds to induce herd immunity, a strategy shown to be highly effective when the MenC conjugate vaccine was introduced in several European countries.

Correlates of Protection

The standardization of the laboratory evaluation of meningococcal vaccines remains a challenge. The definition and harmonization of surrogate endpoints of efficacy, the reference strains, and the reagents to be utilized in assays and the applicability of such methodologies across all classes of vaccines and meningococcal subtypes responsible for widespread epidemic outbreaks must be established.

The currently accepted serological correlate of protection is SBA using either a rabbit or human as source of complement (Borrow et al., 2005). SBA titers greater than four using human complement and greater than eight using rabbit complement are current standards of protection. Also, data suggest that the absence of serum bactericidal activity is not necessarily associated with susceptibility to meningococcal disease. A different approach consists of assessment of a greater than fourfold rise in antibody titer after immunization. Other correlates of protection, such as a whole-blood assay that may be more sensitive than the SBA but is difficult to standardize, can be used. The serological correlates of long-term protection are not well defined. Standardization of assays to assess immunologic memory is also needed. Memory alone may be insufficient for protection since it takes at least 4–7 days for a vaccinated primed adult to mount a memory anticapsular response, and the time between acquisition of the meningococcus and development of invasive disease can be less. Memory can be assessed by the immune response to polysaccharide challenge or an increase in antibody avidity over time (Snape and Pollard, 2005). The important herd immunity features of conjugate vaccines are not easily predicted or quantified.

PROSPECTS FOR THE FUTURE

Global elimination of meningococcal disease could be an achievable target when potent and affordable vaccines against meningococcal A, C, Y, and W-135 conjugate vaccines and a broadly effective serogroup B vaccine are available. The introduction of conjugate vaccines for encapsulated organisms such as *H. influenzae*, *Streptococcus pneumoniae,* and *N. meningitidis* offer protection to the pediatric populations and herd immunity to the overall population, drastically decreasing the number of bacterial meningitis cases worldwide. Because of the rapid increase in the number of vaccines given during infancy, there is a

need to develop combination vaccines that will protect against meningococcal disease without creating immunological interference (Southern et al., 2006; Tejedor et al., 2007; Buttery et al., 2005). Standardization of correlates of protection is important for the comparison among the different future vaccine candidates.

KEY ISSUES

- Meningococci cause meningitis/septicemia with worldwide epidemic and endemic disease, leading to high morbidity and morbidity.
- Vaccination remains the mainstay for disease prevention.
- Polysaccharide vaccines to serogroups A, C, Y, and W-135 are safe and effective; however, they do not produce herd immunity, memory responses, or immunogenicity in infants and young children. Now, available conjugate vaccines are able to overcome these limitations.
- No serogroup B polysaccharide vaccine is available due to the lack of immunogenicity and the theoretical risk of inducing autoantibodies to the polysaccharide. Serogroup B vaccines based on OMV can be used in epidemic settings but do not provide cross-protection in some age groups.
- Control of meningococcal disease relies on the development of an affordable conjugate vaccine for Africa and a broadly effective vaccine against serogroup B, using new vaccine candidates.

CHAPTER

54

Plague

Diane E. Williamson
DSTL Porton Down, Salisbury, Wiltshire, UK

OUTLINE

ABSTRACT

Killed whole cell vaccines for plague were first produced as long ago as the late 1890s and modified versions of these are still used, with evidence that they are efficacious against bubonic plague. Renewed efforts with modern technology have yielded new candidate vaccines that are less reactogenic, can be produced in a conventional pharmaceutical manufacturing plant, and are protective against the life-threatening pneumonic form of the disease. This chapter reviews the threat still posed by plague in the world today, the rationale for the research and development of new vaccine formulations and assesses the likely impact of a prophylactic vaccine for pneumonic plague.

INTRODUCTION

Plague is an ancient disease which has not been eradicated from the modern world. During the last two millennia, the causative bacterium *Yersinia pestis* has been responsible for social and economic devastation on a scale unmatched by other infectious diseases or armed conflicts. In the modern era, bubonic plague is primarily a disease of small rodents and mammals that is spread by fleas in endemic areas, establishing enzootic foci which occasionally erupt as an epizootic outbreak. Humans can be infected either by flea bite or by inhalational exposure through a secondary host, e.g., wild rabbit or prairie dog, or domestic cat. Endemic areas for the disease include China, southern Africa, vast areas of Asia and South America and the southwest portion of the United States (Perry and Fetherston, 1997) while an antibiotic-resistant strain of plague emerged in Madagascar in 1995 (Guiyoule et al., 1997, 2001).

Each year there are several thousand reported cases of the disease worldwide (Dennis et al., 1999) with a fatality rate between 5 and 15% (Anon, 1996, 2000), and plague has been classified as a re-emerging disease by the World Health Organization. In the United States, an average of 18 cases is reported each year with a death rate of 1 in 7. In 2003, two individuals infected in New Mexico, traveled to New York where they developed feverish symptoms, later diagnosed as plague (reported in the *Sunday Telegraph*, London, UK, 11 May 2003). Antibiotic therapy was started in time to save their lives, but this case history indicates the insidious threat that the infection causes to individuals and to the wider population. Additional threats to modern human life posed by plague include the emergence of strains resistant to multiple drugs (Gallimand et al., 1997) and the potential use of plague as an agent of biological warfare.

The consequences of infection with plague in humans are serious and the infection needs to be detected and treated promptly to prevent serious morbidity leading to death. Transmission to humans by feeding fleas leads to the swelling of the draining lymph nodes, followed by a septicemic illness, characteristic of bubonic plague (Perry and Fetherston, 1997). However, animal-to-human or human-to-human transmission can occur via droplet nuclei spread by the coughing of individuals with bubonic or septicemic plague who have developed pulmonary lesions (Meyer, 1961; Poland and Barnes, 1979). Protection against pneumonic plague is the paramount requirement to prevent epidemic spread.

In the long term, comprehensive vaccination against this disease holds the brightest prospect for prevention and control. Killed whole cell (KWC) vaccines for plague have been used in humans since the late 1890s and although evidence from the 20th century indicates that these formulations have reduced the incidence of bubonic plague (Cavanaugh et al., 1974), there is no evidence to suggest that they are effective against pneumonic plague (Anderson et al., 1996; Andrews et al., 1996; Reisman, 1970; Williamson et al., 1995, 2001). In the late 1990s renewed efforts led to recombinant vaccine candidates with potential to protect against the virulent pneumonic form of plague and progress toward the development and licensing of these formulations for human use is reported below.

SHORT HISTORY OF THE DISEASE

The first major epidemic of plague probably occurred in China around 224 BC. Credible sources suggest that the Justinian plague (AD 541–750) killed an estimated 100 million people. This originated in central Africa and rapidly spread along the trading routes from Egypt's main port, Alexandria, to Central and South Asia, Arabia, North Africa, and much of Southern Europe. By the end of 544, it is estimated that 20–25% of the population of Europe south of the Alps had been killed by the plague (Sodeinde et al., 1992).

The most well-known epidemic of the plague, the Black Death, occurred during the 14th century (Table 54.1). This epidemic probably began in China about AD 1338 and 1351, killing an estimated 60% of the population (Dols, 1977) and may have been associated with natural disasters such as floods and earthquakes which destroyed the habitats of the plague-bearing rodents, forcing them into contact with other rodent

TABLE 54.1 Transmission of the Black Death along trading routes during the second plague pandemic

Major trading region	Year of first arrival
Central Asia	1338
Volga River	1345
Anatolia	1347
Lower Egypt	
Southern Italy	
Palestine	1348
Arabia	
Tunisia	
Northern Italy	
Iberia	
France	
England	1348
Northern Germany

populations and thus spreading their fleas (Gottfried, 1983). From China, the plague spread along the trade route known as the Silk Road into Central Asia and throughout the Caucasus. The northern and eastern shores of the Black Sea became ridden with plague, from where infected rats and fleas were picked up in merchant ships on the spice-trading sea routes and carried south (Gottfried, 1983). Thus, the plague eventually reached the Mediterranean and Southern Europe. By 1350, the plague had run its course through the Mediterranean Basin, killing 35–40% of the population in the region. However, following the sea lanes and rivers, the disease had moved north, into France, reaching Paris in 1348, where the population was decimated (Gottfried, 1983). The plague continued northward, killing an estimated 45–55% of the Scandinavian population, and along the trade routes to Iceland, where it killed 60% of the population, and then onto Greenland, reaching there probably in the winter of 1350 and annihilating the small population (Gottfried, 1983).

The Black Death is best documented in Britain, where it is believed to have arrived on Gascon ships to the port of Melcombe Regis, in 1348. Other outbreaks followed across southwest England. It reached London in September 1348 and Ireland the following year. The plague ravaged London until the spring of 1350, killing an estimated 20,000 people. There is evidence that the port of Bristol and city of Winchester were also severely affected (Gottfried, 1983).

Plague persisted on the European continental land mass for several centuries, and culminated in an epidemic of bubonic plague, known as the Great Plague of London. This started in London in the summer of 1665 killing more than 30,000 people in the city and spread to many parts of England, and was curtailed by the killing of the infected fleas with the arrival of winter.

The third plague pandemic started in China in the middle of the 19th century, and spread east and west, causing 10 million deaths in India alone. In the 1890s, plague finally made its way to North America. Rats infected with the disease arrived in San Francisco in 1900 aboard ships which had sailed from Asia. In the 20th century, outbreaks of plague in Asia, prevalent during the 1960s and 1970s, were attributed to the ecological disruption caused by the Vietnam War and consequently increased contact between the animal reservoir of the disease and humans. Credible estimates indicate that in total almost 200 million deaths can be attributed to plague, which swept across Europe in the three major epidemics (Duplaix, 1998; Perry and Fetherston, 1997).

ETIOLOGIC AGENT

Classification

The etiological agent of plague is *Y. pestis*, a gram-negative bacterium which is a member of the Enterobacteriacae family. *Y. pestis* is closely related to the other human pathogenic Yersiniae. However, unlike *Yersinia enterocolitica* and *Yersinia pseudotuberculosis, Y. pestis* does not infect the host by the enteric route. Some of the genes that are required for invasion by this route in *Y. pseudotuberculosis* and *Y. enterocolitica*, such as the *inv* and *yadA*, are present in *Y. pestis* but are not expressed as a consequence of mutations (Brubaker, 1991; Perry and Fetherston, 1997). Another major difference is that *Y. pestis* is unable to survive outside an animal host, whereas *Y. enterocolitica* and *Y. pseudotuberculosis* can survive in the environment. These findings suggest that *Y. pestis* might have evolved from the other human pathogenic Yersiniae. This suggestion is supported by a comparison of the genetic diversity of several housekeeping genes in *Y. pestis* and *Y. pseudotuberculosis* which indicates that *Y. pestis* likely evolved from *Y. pseudotuberculosis* 1500–20,000 years ago (Achtman et al., 1999).

The recent genome sequencing of the CO92 strain of *Y. pestis* (Parkhill et al., 2001) has allowed comparison with the genome sequence of *Y. pseudotuberculosis* and has revealed numerous genetic differences reflecting changes in virulence and niche (Wren, 2003). In the transition from an enteropathogen to an arthropod-vectored systemic pathogen, *Y. pestis* has acquired, inactivated, and rearranged genes (Parkhill et al., 2001;

Wren, 2003). In addition to the 70 kb virulence plasmid (pYV/pCD1) common to all the pathogenic yersiniae, *Y. pestis* possesses two unique plasmids, a 100–110 kb plasmid denoted pFra/pMT1 and a small pPST/pPCP1 plasmid of 9.5 kb. These plasmids encode a number of virulence determinants, described below. A total of 149 pseudogenes has been identified in the genome of the fully virulent *Y. pestis* strain CO92 (Parkhill et al., 2001) indicating the genetic evolution undertaken by the organism to adapt from being an enteropathogen to a flea-vectored pathogen (Oyston and Isherwood, 2005), with genome reduction.

Because of its evolution to a flea-vectored lifecycle, environmental temperature would be expected to be influential in the regulation of virulence in *Y. pestis*. In the flea where the temperature does not exceed 28°C, the *caf1* and the pCD1 Type three secretion TTS operons are repressed so that the bacterium does not have a capsule or secrete yersinia outer proteins (YOPs). The evidence that the two-component response regulatory system, PhoPQ, may have a role in the survival of *Y. pestis* in the flea, comes from a study where inactivation of the *phoP* gene allowed the expression of a number of Pho-regulated proteins, usually at 28°C, to occur at 37°C (Oyston et al., 2000). The *PhoP*$^{-}$ *Y. pestis* was more susceptible to macrophage killing and less virulent in the mouse model (Oyston et al., 2000). However, the mutation of a high temperature response gene, *HtrA*, did not significantly attenuate *Y. pestis* in the mouse model, although the mutant could not grow *in vitro* at 39°C (Williams et al., 2000).

ANTIGENS

The three plasmids borne by *Y. pestis* encode an array of virulence factors which are active at different stages in the life cycle of the bacterium. These virulence factors are also potential antigens for isolation, toxoiding if necessary and inclusion in a potential new vaccine for plague. To have protective potential, the antigens must be secreted from the bacterium in a niche accessible to the host immune system which could then be primed by vaccination to neutralize them. In this context, therefore, it is helpful to review the virulence factors associated with the stages in the life cycle of the plague bacterium.

Y. pestis, present in a blood meal ingested by the flea from an infected mammal, is protected by an intracellular phospholipase D, encoded by pFra/pMT1 (Hinnebusch et al., 2000), from lysis by plasma components. The ability of the bacteria to aggregate in the flea and block the midgut is now known to be due to their ability to form a biofilm which in turn is dependent on the *hms* locus (Hinnebusch et al, 1996). *Y. pestis* uses additional complex regulatory mechanisms to survive within the flea, which are influenced by environmental temperature and which include changes to the surface structure of the bacteria. The small pPST/pPCP1 plasmid encodes plasminogen activator (Pla), a surface protease, which is required for dissemination of the bacteria from the initial site of infection by promoting the cleavage of fibrin clots (Sodeinde et al., 1992) through the activation of plasminogen to plasmin and by facilitating adhesion to extracellular matrices and the invasion of mammalian endothelial cells (Lahteenmaki et al., 1998, 2001).

Once in the mammalian host, the bacteria are phagocytosed in macrophages and likely transported to a draining lymph node. There is controversial evidence that phagocytosis may be facilitated by the chemokine receptor CCR5 (Elvin et al., 2004; Mecsas et al., 2004; Stephens et al., 1998), prevalent on macrophages and dendritic cells, but not on neutrophils. *Y. pestis* can survive and multiply in the phagolysosome (Straley and Harmon, 1984a, 1984b), eventually killing the macrophage (Straley and Harmon, 1984b). While intracellular and at 37°C, additional temperature and calcium-regulated virulence factors are expressed. One of these is the Fraction 1 antigen (F1) which becomes surface expressed in the capsule surrounding the bacterium, preventing further phagocytosis and aiding the eventual establishment of an extracellular infection (Titball et al., 2003). Also important in this process is the pCD1/pYV-encoded type III secretion system, the function of which is to secrete an array of YOPs with cytotoxic or anti-phagocytic activity into the host cell in a highly regulated manner (Cornelis, 2002). A key regulatory antigen in this system is the low calcium response virulence or lcrV antigen (Burrows, 1963) which has been visualized on the bacterial cell surface (Petterson et al., 1999) and is important in establishing host cell contact and initiating TTS. In addition, the *psa* operon of *Y. pestis* encodes the pH6 antigen adhesin which appears as surface fimbriae on the bacteria on release from the macrophage and which may be involved in adhesion (Payne et al., 1998) to secondary targets *in vivo*. Although, *Y. pestis* has a rough LPS phenotype, with lipid A and core components, it has no O antigen (Prior et al., 2001a, 2001b; Skurnik et al., 2000) to confer resistance to complement. It may be that surface proteases such as Pla are able to confer serum resistance by cleaving complement components (Sodeinde et al., 1992).

Many of the *Y. pestis* virulence factors have been isolated in native or recombinant forms and screened as immunogens, including LPS (Prior et al., 2001a),

TABLE 54.2 Immunogenicity and protective efficacy of subunit antigens of *Yersinia pestis* in the mouse model

Subunit	Description	Immunogenic	Protective (references)
Pla	Surface plasminogen activator protease	Y	Not tested
PH6 antigen	Putative surface adhesin	Y	Bubonic—not protective (Unpublished data, Payne et al., 1998)
LPS	Lipopolysaccharide	Y	Bubonic—not protective (Prior et al., 2001a)
F1 antigen	Surface capsule	Y	Bubonic & pneumonic—protective (Andrews et al., 1996; Lawton et al., 1963; Miller et al., 1998; Simpson et al., 1990; Williamson et al., 1995)
YopD	Type III system—translocation Yop	Y	Bubonic—partially protective (Andrews et al., 1999; Leary et al., 1999)
YopH	Type III system—PTPase effector Yop	Y	Bubonic—minimally protective (Andrews et al., 1999)
YopE	Type III system—cytotoxin effector Yop	Y	Bubonic—not protective (Leary et al., 1999)
YopN	Type III system—regulates Yop release?	Y	Bubonic—not protective (Andrews et al., 1999; Leary et al., 1999)
YopK	Type III system—regulates Yop release?	Y	Bubonic—not protective (Andrews et al., 1999; Leary et al., 1999)
YopM	Type III system—effector Yop	Y	Bubonic—not protective (Andrews et al., 1999; Leary et al., 1999)
Ypk A	Type III system—Ser/Thr kinase effector Yop	Y	Bubonic—delayed time to death (Andrews et al., 1999)
YscF	Type III system—part of injection needle structure	Y	Bubonic—protective (Matson et al., 2005)
V antigen	Type III system—part of the injectosome	Y	Bubonic & pneumonic—protective (Anderson et al., 1996; Lawton et al., 1963; Leary et al., 1995; Williamson et al., 1995)

YOPs (Andrews et al., 1999; Leary et al., 1999; Matson et al., 2005), pH6 antigen (unpublished data), Pla (unpublished data) and F1 and V (Heath et al., 1998; Lawton et al., 1963; Williamson et al., 1995), (Table 54.2). Only the F1 and V proteins have been demonstrated to have significant protective efficacy in animal models as either individual proteins, or when coadministered or fused (Heath et al., 1998; Lawton et al., 1963; Simpson et al., 1990; Williamson et al., 1995).

PROTECTIVE IMMUNE RESPONSE

Much effort has been made in understanding the mechanism of protective immunity in plague, with early work identifying the F1 and V (VW) proteins as protective antigens (Burrows, 1963; Lawton et al., 1963). A significant amount of work has been carried out in the mouse (Williamson, 2001), guinea pig (Jones et al., 2003), and in nonhuman primate models (Williamson, 2004) from which immune correlates have been proposed. Although a titer of neutralizing antibody provides protection against exposure, it is clear that the development of cell-mediated immunity (CMI) is also critical to full protection and eventual clearance of the bacterial challenge from the host (Elvin et al., 2004).

ANTIBODY

Mice immunized with antigens derived from *Y. pestis* or in recombinant form have been observed to develop specific antibody titers to the YOPs (Leary et al., 1999; Matson et al., 2005) and to recombinant F1 (rF1) and rV (Heath et al., 1998; Williamson et al., 1995). The major research effort in recent years has focused on the rF1 and rV antigens and these have been found to be immunogenic individually (Anderson et al., 1996; Andrews et al., 1996; Lawton et al., 1963; Leary et al., 1995; Miller et al., 1998; Simpson et al., 1990; Williamson et al., 1995) in different strains of mice (Elvin and Williamson, 2000, 2004; Heath et al., 1998; Williamson et al., 2001) and when tested in different laboratories (Heath et al., 1998; Lawton et al., 1963; Williamson et al., 1995). A systematic study in which mice of four different haplotypes

and each gender was used, showed that all responded to immunization with the rF1 and rV antigens with high antibody titers (Jones et al., 2001). The response to either antigen is affected by the conformation of the protein (Williamson et al., 1999) and an optimum combination of rF1 to rV was found to be when rF1 was in a twofold molar excess to rV. However, mice can also mount an antibody response to these antigens when the C-terminal of the F1 antigen is genetically fused to the N-terminus of the V antigen (Heath et al., 1998). In immunized Balb/c mice, the titer of IgG1 directed toward the combined antigens correlated significantly ($P < 0.005$) with protection against challenge (Williamson et al., 1999). Antibody titer to rF1 + rV in guinea pigs also correlated with protection and passive transfer of specific antibody (IgG) from the guinea pig into naïve mice, protecting the latter against challenge (Jones et al., 2003). Cynomolgus macaques immunized with rF1 and rV antigens produced high titers of specific antibody which also passively protected naïve mice against challenge, when used as a reference serum (Williamson et al., 2005). A murine monoclonal antibody (Mab7.3) specific for the V antigen, has been identified to passively protect naïve mice against live organism challenge (Hill et al., 1997) and also to compete with mouse, macaque, and human serum, derived from rF1 + rV immunized subjects, for binding to V antigen *in vitro* (Williamson et al., 2005) indicating the existence of a B-cell epitope in the V antigen which is highly conserved and protective. In addition, a monoclonal antibody to F1 is synergistic in effect with Mab 7.3 in conferring protection by passive transfer in the mouse against plague challenge (Hill et al., 2003).

However, the protection conferred by passive transfer is not infinite and as the mass of delivered antibody decays with time, breakthrough can occur in protection (Green et al., 1999), indicating the importance of inducing a CMI response by immunization.

CMI

CMI has traditionally been much more difficult than antibody to evaluate satisfactorily. However, the induction of CMI has been detected in mice immunized with a combination of rF1 and rV antigens by measurement of the recall response of lymphocytes isolated from the vaccinees to the antigens *in vitro* (Williamson et al., 1996, 1999). Moreover, mice immunized with the rF1 + rV antigens by the nasal or transdermal routes have been found to have splenic recall responses, when splenocytes have been isolated and restimulated *in vitro* (Eyles et al., 2004). Attempts to measure changes in cellular activation by flow cytometry following immunization of individuals in a Phase I clinical trial of the rF1 + rV vaccine, failed to discern measurable trends (Williamson et al., 2005), possibly due to the inherent variation present in a genetically diverse target population. A simplified *in vitro* assay in which peripheral blood mononuclear cells (PBMCs) from clinical trial vaccinees are restimulated with rF1 and rV has also not been sufficiently sensitive to detect a significant activation signal for these cells over background noise.

However, CMI is clearly of importance in the survival of immunized animals following live organism challenge. This conclusion has been reached by the testing of the vaccine in mice with targeted gene deletions which impair either the antibody or cell-mediated axes of the immune response. IL4 was found not to be essential for protective efficacy, in that IL4 knockout mice were able to respond to the vaccine with measurable antibody and were protected against challenge (Elvin and Williamson, 2000). However, a targeted gene deletion in the Stat4 signaling pathway (preventing the ligation of the Stat4 receptor with IL12 signaling) and abrogating a Th1 response, resulted in reduced protection, whereas mice with a targeted gene deletion in the Stat 6 pathway and no Th2 activity, were fully protected against challenge (Elvin and Williamson, 2004). In general terms, antibody is highly protective against this predominantly extracellular infection. Supplementation of the specific antibody responses with a balanced Th1/Th2 activity (Elvin and Williamson, 2004) appears to provide an optimum strategy for protection.

EPIDEMIOLOGY

In the modern world, plague is maintained in endemic areas by enzootic foci which occasionally erupt in an epizootic outbreak (Fig. 54.1). In these areas, *Y. pestis* cycles through populations of rodents and is transmitted to and between mammals by the bite of infected fleas. Infected fleas can survive for long periods in close association with infected animals (Engelthaler and Gage, 2000; Kir'iakova, 1973) and periodically there is an epizootic outbreak, sometimes associated with major environmental change, e.g., an earthquake, but often unattributable (Oyston and Isherwood, 2005). In this complex life cycle maintained by the bacterium, human is an accidental host, either through close contact with infected rodents and their fleas or following exposure to an infected wild

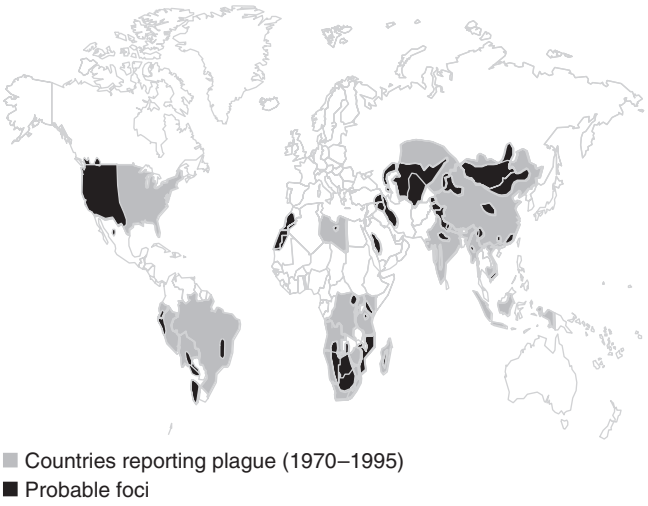

FIGURE 54.1 Occurrence of plague in the modern world. The map depicts the probable foci of plague in red, with countries reporting plague (1975–1995) in ocher.

animal or to an aerosol of bacteria from an infected domestic cat (Doll et al., 1994). In these instances, subsequent spread of plague bacilli to the lungs leads to the development of the pneumonic form of the disease; person-to-person transmission by respiratory droplets (Poland and Barnes, 1979) can result in rapid epidemic spread of the disease (Meyer, 1961). It is the pneumonic form of the disease that is most feared and associated with a mortality rate approaching 100% when untreated (Christie and Corbel, 1990; Parkhill et al., 2001; Poland and Barnes, 1979).

SIGNIFICANCE AS PUBLIC HEALTH PROBLEM

Plague continues to affect people all over the world. Plague returned to Madagascar in 1997, having been absent from the country since the 1930s. The recurrence has been attributed mainly to a reduction in rat control measures and control over the disease is still trying to be regained, complicated by the identification of a multi-drug-resistant isolate (Gallimand et al., 1997; Guiyoule et al., 1997, 2001). An outbreak of plague in the Surat region of India in 1994 caused 876 presumptive cases of plague and 54 fatalities (Anon, 1995). In 2005, an outbreak of pneumonic plague at a diamond mine in Northern Congo in January–February 2005, caused 114 confirmed infections among the miners, 54 of whom died. The outbreak was limited only by the dispersal of miners fleeing in panic from the area (WHO, 2005).

POTENTIAL AS BIOTHREAT AGENT

Due to its propensity to cause epidemic disease, plague is a potential biothreat agent. The development of vaccines with comprehensive efficacy against both the bubonic and pneumonic forms of plague provides a robust defense against the risk of the deliberate use of this serious pathogen as a biothreat agent.

CLINICAL DISEASE

There are three recognized forms of plague in human. Bubonic plague is the most common form of disease and arises following a bite from a flea that has previously fed on an infected animal (Poland and Barnes, 1979). The bacteria are disseminated from the initial site of infection to the draining lymph nodes, which become swollen and tender, forming a bubo. The bubo can reach the size of a hen's egg and is the classical feature of bubonic plague. A bacteremia may develop with blood culture counts in the range $<10–4 \times 10^7$ cfu/ml (Perry and Fetherston, 1997). Symptoms usually begin within a week of a person's exposure to the bacteria. The typical presentation involves fever of sudden onset, chills, and acutely swollen and extremely tender lymph nodes, or buboes, usually in the groin or axilla. As the disease progresses, sepsis may develop along with disseminated intravascular coagulation (DIC) and purpuric skin lesions, eventually producing necrosis of the digits or nose (hence the name Black Death).

In a small percentage of patients, a septicemic form of plague will develop, in which the buboes are not noticeable but which is characterized by an elevated temperature, chills, headache, malaise, and gastrointestinal disturbances (Poland and Barnes, 1979). Septicemic plague can be primary or secondary to pneumonic or bubonic plague and can result in DIC, purpura, meningitis, and pneumonia. Thrombosis of acral blood vessels can result in gangrene of the fingers and nose. Survival rates are good if plague is diagnosed and treatment is started promptly but because of the generalized nature of these symptoms a diagnosis is often delayed, and if this is the case, even with medical intervention, 50% of patients may die, probably as a result of the induction of the systemic inflammatory response syndrome (Perry and Fetherston, 1997). Some patients may also have secondary pneumonia caused by hematogenous spreading of bacteria to the lungs (Poland and Barnes, 1979). Pneumonic plague results in the production of highly infectious bloody sputum. Coughing results in the

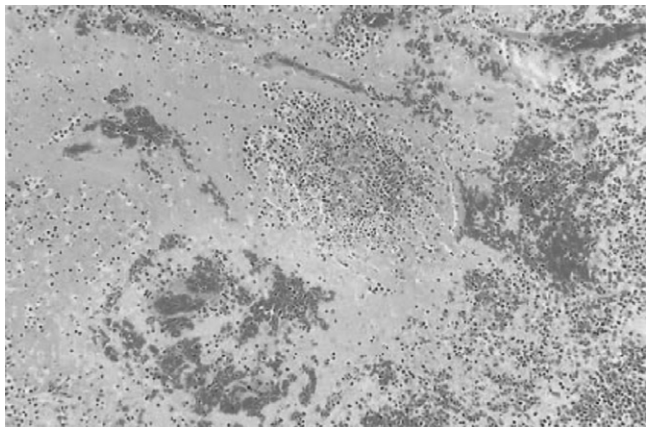

FIGURE 54.3 Evidence of plague in the lymph nodes. In this image, medullary necrosis with fluid and *Yersinia pestis* bacteria are evident. Image (PHIL ID NO. 731) courtesy of Dr. Marshall Fox/CDC; available at http://phil.cdc.gov/phil/ (see color plate section).

production of airborne droplets containing bacteria, which can be inhaled by susceptible individuals, causing a primary pneumonic plague (Meyer, 1961; Poland and Barnes, 1979). The infectious dose by inhalation is estimated to be 100–500 organisms (Franz et al., 1997). The pneumonic form of the disease is feared because of the rapidity with which the disease develops (1–3 days), infected persons having fever, cough, and dyspnea. Respiratory symptoms include pleuritic chest pain, dyspnea, cyanosis, and a productive cough (hemoptysis). Gastrointestinal symptoms (nausea, vomiting, abdominal pain, and diarrhea) may be present. Meningitis, septicemia, and DIC can also occur. There is a high mortality rate in infected individuals (approximately 100%) and potential for rapid spread of disease from human to human (Poland and Barnes, 1979). The clinical course follows that of a severe and rapidly progressive pneumonia. Marked intra-alveolar edema and congestion of the lungs are common (Centers for Disease Control; Bioterrorism preparedness website) (Fig. 54.2). Pulmonary lesions include areas of central exudate with peripheral congestion. This pattern initially is lobular, but usually progresses to lobar consolidation (Dennis and Meier, 1997). Distinguishing primary pneumonic plague from secondary hematogenous spread to the lungs can be difficult. Features that occur more commonly with primary pneumonic plague include the following: tracheal and bronchial mucosal hemorrhages, fibrinous pleuritis and subpleural hemorrhages overlying areas of exudative pneumonia, less inflammation and necrosis and more exudation in lobular foci of the parenchyma, foci of pneumonia along medium and large bronchi, and more involvement of hilar lymph nodes (Dennis and Meier, 1997) (Fig. 54.3). There is less evidence of severe disease in organs other than the lungs, if such evidence is present. Symptoms may progress rapidly to respiratory failure and full-blown sepsis with DIC. Chest films commonly show bilateral infiltrates or consolidation. The results of laboratory studies of seriously ill patients usually reveal what would be expected to accompany sepsis and end organ failure—leukocytosis, coagulation abnormalities, elevated transaminase levels, and azotemia.

DIAGNOSIS

Plague would probably be detected through the usual microbiologic investigations performed for patients with severe pneumonia, and DIC. A Gram's stain of blood, sputum, or node aspirate may reveal gram-negative coccobacilli. A Wright, Giemsa, or Wayson stain may show a characteristic bipolar pattern. Cultures of sputum, blood, or node aspirate will show growth in about 24–48h. Where available, specialist assays may be deployed to identify plague antigens by ELISA for IgM, or fluorescent antibody staining of sputum or blood specimens, or polymerase chain reaction. Chest radiograph findings in pneumonic plague are nonspecific and include infiltrates and consolidation.

TREATMENT

Although study data are very limited regarding the success of treatment targeted against plague, *Y. pestis* is susceptible to a number of antibiotics. Historically, streptomycin has been the preferred treatment,

although it is not commonly used now and its availability is limited. Other options include gentamicin, doxycycline, ciprofloxacin, levofloxacin, and chloramphenicol (Centers for Disease Control; Bioterrorism preparedness website). The same antibiotics are administered to adults and children alike, with dosage scaled down for body weight for children. Intravenous therapy is usually recommended for seriously ill patients. In the case of an epidemic, during which resources may be limited, oral therapy with ciprofloxacin or doxycycline could be effective. Once exposure to plague has been established, prompt antibiotic therapy should be administered to any patient who presents with fever or cough, because to delay such treatment before confirmatory test results are obtained would threaten a patient's chance of survival.

While the mortality of untreated bubonic plague is estimated to be 60%, antibiotic therapy should reduce this to less than 5%. In pneumonic plague, the disease progresses rapidly to shock and death if not treated with antibiotics within 24 h of onset. In septicemic plague the overall case-fatality rate is 30–50% but approaches 100% without therapy.

PROPHYLACTIC VACCINATION

Prophylactic vaccination should hold the best prospect for disease prevention. The availability of vaccines is reviewed below. Primarily, these have been suspensions of killed whole organisms and there is evidence that their use, e.g., during the Vietnam War, did reduce the incidence of bubonic plague in military personnel in this endemic region of the world. However, there is also evidence that these formulations are ineffective against the life-threatening pneumonic plague, a fact that has accelerated the search in the last 20 years for improved vaccine(s).

VACCINES

History

KWC vaccines for plague have been used in humans since 1897, when Waldemar Haffkine introduced a KWC vaccine, following an outbreak of plague in Bombay in 1896. Subsequently a number of iterations of the Haffkine vaccine were produced including the Army Vaccine in 1946, the Cutter USP vaccine in 1994, and the Greer vaccine (1994–1999). These KWC vaccine formulations were sterile suspensions of killed *Y. pestis* ($1.8–2.2 \times 10^9$ organisms per ml), suspended in aqueous medium incorporating a preservative such as phenol. The plague bacilli were killed by formaldehyde exposure. These vaccines were generally rather reactogenic, inducing local and systemic side effects, which although transient, could be incapacitating. Despite these limitations, there is evidence to suggest that the KWC vaccines did provide some protection against bubonic plague, principally from KWC-vaccinated U.S. servicemen in Vietnam in whom the incidence of disease was 1 case/10^6 people whereas the incidence in unvaccinated Vietnamese was 333 cases/10^6 people (Anon, 1996; Cavanaugh et al., 1974). There is, however, experimental evidence that protection against the pneumonic form of the disease was negligible (Williamson et al., 2001).

A series of live attenuated vaccines, the EV series, has also been used, mainly in the former Soviet Union and French colonies, e.g., Madagascar. EV76 (in use since 1908), EV Saigon, and EV Madagascar have questionable efficacy in evoking an immune response in humans and some severe side effects (Meyer et al., 1974; Naumov et al., 1992). It was reported that 12/12 human volunteers administered EV76 developed severe systemic reactions including febrile responses with headache, weakness, and malaise of sufficient severity to warrant the hospitalization of some vaccinees (Meyer, 1970). Moreover, there is experimental evidence that EV76 protects mice against bubonic and pneumonic plague (Russell et al., 1995). However, the EV vaccines are not licensed for clinical use in Europe/United States, possibly for reasons of reactogenicity and instability. EV76 is a pigmentation mutant of *Y. pestis* in which the *pgm* locus, affecting not only pigmentation but also iron aquisition and siderophore production, was spontaneously deleted but in which there is also evidence for the insertional activation of some genes.

Current Vaccine

The only currently available vaccine for plague is a KWC formulation, made by the Commonwealth Serum Laboratories (CSL) in Australia and comprises heat-killed agar-grown *Y. pestis* organisms (3×10^9 organisms per ml) in a saline suspension containing 0.5% w/v phenol. The strains used in the preparation of the vaccine were derived from the Haffkine Institute, India. This vaccine is a prescription medicine. The primary immunization schedule comprises an initial subcutaneous 0.5 ml dose, followed by a 0.5 ml booster dose at 1–4 weeks and every 6 months thereafter. The recommended dosage for children is scaled down from the adult dose, depending on age (Table 54.3).

TABLE 54.3 Recommended dosage (ml) for CSL plague vaccine

Age	1st dose	2nd dose	3rd dose	Booster dose
6 months–2 years	0.1	0.1	0.1	0.1
3–6 years	0.2	0.2	0.2	0.2
7–11 years	0.3	0.3	0.3	0.3
Over 12 years	0.5	0.5	–	0.5

TABLE 54.4 Recommendations for the use of plague vaccines

Situation
Vaccination recommended
1. Following natural disaster and/or at times when regular sanitary practices are disrupted
2. All laboratory and field personnel who are working with *Y. pestis* organisms resistant to antibiotics
3. Persons engaged in aerosol experiments with *Y. pestis*
4. Persons engaged in field operations in plague enzootic areas where prevention of exposure is not possible (e.g., some disaster areas)
Selective vaccination recommended
1. Laboratory personnel regularly working with *Y. pestis* or plague-infected rodents
2. Workers (e.g., Peace Corps volunteers or agricultural advisers) who reside in plague enzootic areas or plague epidemic rural areas where avoidance of rodents or fleas is impossible
3. Persons whose vocation brings them into regular contact with wild rodents or rabbits in plague enzootic areas

Booster doses every 6 months are recommended for persons living in areas where plague is prevalent. If booster doses are required for people who have had reactions to this vaccine previously, it is recommended to give a reduced dose (0.1 ml) by intradermal injection.

Indications for Vaccination and Target Populations

The indication for the current licensed vaccine is to protect against risk of exposure to plague (Table 54.4). Currently such a risk could arise from environmental exposure of individuals in high-risk areas in countries in which the disease is endemic, including the rural mountains or upland areas of South America, Asia, and Africa. Routine vaccination is not necessary however for persons residing in plague enzootic areas (such as those living in the Western United States) nor for travelers in countries where cases have been reported, particularly if travel is limited to urban areas. It is generally believed that the use of plague vaccine greatly increases the chances of recovery in those vaccinated individuals who may develop the bubonic form of infection. The degree of protection afforded against the pneumonic form is unknown and vaccinated persons exposed to the pneumonic form should be given daily, adequate doses of a suitable antibiotic over a 7–10-day period (Centers for Disease Control; Bioterrorism preparedness website).

Contraindications of Vaccination

There are no particular contraindications to the use of the vaccine. It is advisable not to give any injections during upper respiratory tract infections, because more severe reactions may ensue. In general, inactivated vaccines can be administered simultaneously at different sites. It should be noted however that when vaccines commonly associated with local or systemic side effects (such as cholera, typhoid, and plague vaccines) are given simultaneously, it is possible that the side effects may be accentuated. When practical, therefore, it is recommended that these vaccines should be given on separate occasions.

Duration of Immunity

The duration of protection against infection following administration of the primary series of injections of plague vaccine is thought to be brief (i.e., 6–12 months) and booster doses in approximately 6 monthly intervals are required for continued protection.

Adverse Events

Local and general reactions to the plague vaccine are usually mild and infrequent. They will generally become more frequent with increasing numbers of booster injections. The adverse events reported include injection site reaction, rigors, fever, increased sweating, neuropathy, paresthesia, paresis, dizziness, syncope, abnormal coordination, speech disorder, muscle atrophy, and anorexia. As with other injectable vaccines, appropriate medical treatment and supervision should always be available in case of anaphylactic reactions. Adrenalin should always be readily available whenever the injection is given.

IMPROVED VACCINES

Rationale for Second-Generation Vaccines

The limitations of the live attenuated and KWC vaccines detailed above have prompted significant efforts in recent years to devise improved vaccines against plague.

Evidence that the existing KWC vaccines provided some protection against bubonic plague and the predominant protective immunogen in these vaccines was the F1-antigen (Williams et al., 1986) provided a rationale for inclusion of this antigen in next-generation vaccines. In addition, KWC-vaccinated animals had serum antibody to F1-antigen which appeared to correlate with the level of protection against a subcutaneous challenge with *Y. pestis* (Meyer, 1970). Although the EV series of live attenuated vaccines have some disadvantages, they have been observed to be protective in animal models and this was attributed partly to their content of both F1 and V antigens (Williamson et al., 1995). Subsequently, it was observed that immunization of mice with either the F1-capsular antigen or the LcrV (V-antigen) component of the TTS alone provides protection against plague (Anderson et al., 1996; Leary et al., 1995; Miller et al., 1998). Combining these subunits together significantly enhanced the protective efficacy of the vaccine (Williamson et al., 1995). The use of the F1 antigen alone in a subunit vaccine is not desirable since, as noted above, virulent but F1-negative strains of *Y. pestis* have been reported (Friedlander et al., 1995).

The production of the F1 and V antigens has been greatly facilitated by the development of recombinant systems for the over-expression of the encoding genes in *Escherichia coli* (Leary et al., 1995; Titball et al., 1997). Formulations incorporating the individual subunits or a recombinant F1/V-antigen fusion protein have been reported (Heath et al., 1998); the use of individual subunits allows the optimal molar ratio of rF1: rV of 2:1 to be achieved in the final vaccine formulation (Williamson et al., 1999). In addition, the use of the rF1-antigen subunit may allow oligomerization which appears to enhance the immunogenicity of the protein (Miller et al., 1998). A vaccine based on rF1 and rV antigens, and formulated with an alhydrogel adjuvant, has been shown to be efficacious in a range of animal models (Anderson et al., 1996; Andrews et al., 1996; Jones et al., 2001, 2003). Importantly, unlike the KWC vaccines, in mice this vaccine provides good protection against an airborne challenge with *Y. pestis* (Heath et al., 1998; Williamson et al., 2001) suggesting that it can be developed as a new prophylactic for pneumonic as well as bubonic plague in humans. Although a single dose of this vaccine has been shown to induce good protective responses in animals (Williamson et al., 2001), the immunization schedule trial in humans for safety and immunogenicity entailed two doses of the rF1 + rV vaccine given on days 1 and 21 (Williamson et al., 2005).

The basis of protection afforded by the rF1 + rV vaccine is not fully elucidated. However, the passive transfer of immune sera into naive mice provides protection against a subsequent challenge (Green et al., 1999), and it has been shown that IgG1 subclass antibody correlates with protection (Williamson et al., 1999). Therefore, it seems likely that the antibody plays a significant role in protection. However, CMI is also important in the development of protective immunity and evidence for induction of a CMI response has been derived from animal studies (Williamson et al., 1995). The concerted immune response to the rF1 + rV vaccine has been shown to be protective in animal species tested and has led to the clearance of *Y. pestis* from the spleens, livers, and lungs of immunized animals 14 days after challenge (Jones et al., 2001).

In addition, the observation that Mab7.3, previously shown to protect mice by passive immunization against plague (Hill et al., 1997) competes with rV-immune macaque and human serum for binding to rV *in vitro*, indicates that this B cell epitope in rV is conserved across the species (Williamson et al., 2005). Work is also in progress to map murine T-cell epitopes in rF1 and rV in order to estimate the degree of conservation of CMI responses between animal species and man (Parent et al., 2005; Williamson, 2004).

ALTERNATIVE VACCINE APPROACHES: RATIONALLY ATTENUATED MUTANTS AND DNA VACCINES

There are several reports that immunization with naked DNA vaccines encoding either the F1 or V antigens is able to provide protection against plague (Garmory et al., 2004; Grosfield et al., 2003; Williamson et al., 2002). Multiple vaccinations with naked DNA are required and, at least in the case of a naked DNA construct expressing rF1, protection appears to be antibody mediated (Grosfield et al., 2003). In some studies a prime-boost strategy, where naked DNA-immunized mice were boosted with purified protein, was necessary to provide good protection (Garmory et al., 2004; Williamson et al., 2002), while gene gun–mediated vaccination was significantly

more efficient than manual immunization with a DNA vaccine (Bennett et al., 2000).

Rationally attenuated mutants of *Y. pestis* have also been derived and tested as candidate vaccines. The findings that immunization with *Y. pestis* mutants, such as strain EV76, results in protection against subcutaneous and inhalation challenges indicate the feasibility of a live attenuated vaccine. The main limitations of the EV76 vaccine are the lack of detailed knowledge on the basis of attenuation and a partial retention of virulence. In other bacterial pathogens, such as *Salmonella enterica*, rationally attenuated mutants have proven to be highly effective vaccines. Therefore, some workers have applied the technologies developed with *S. enterica* to *Y. pestis*. In general, the results of this work have been disappointing. Mutations in the *aroA*, *phoP,* and *htrA* genes, which markedly attenuate other pathogens, have only a limited effect on the virulence of *Y. pestis* (Oyston et al., 1996, 2000; Williams et al., 2000). However, the exposure of mice to sublethal doses of these mutants can result in the induction of protective immunity (Oyston et al., 1996, 2000).

An alternative approach is to use a live attenuated salmonella as a vaccine vector from which to express plague antigens. Both the F1 and V antigens have been expressed from *S. enterica* serovar *typhimurium* (Garmory et al., 2005; Morton et al., 2004; Titball et al., 1997) which has then been used to dose mice orally or intranasally. The salmonella F1 construct, derived by cloning the entire *caf* operon from *Y. pestis* in plasmid form into *Salmonella typhimurium*, induced full protective immunity in Balb/c mice after two oral doses (Titball et al., 1997) while a similar construct conferred some protection against aerosol challenge with plague after only a single oral dose (Garmory et al., 2005). Unusually for an attenuated live vaccine, the recombinant plasmid in this *S. typhimurium* did not incorporate any antibiotic resistance markers (Garmory et al., 2005). Stable maintenance of the recombinant plasmid in the salmonella vector was achieved alternatively by means of Ortho-repressor titration (Cranenburgh et al., 2001) in which a gene product from the plasmid was essential for growth and survival of the attenuated salmonella vector (Garmory et al., 2005).

VACCINES IN DEVELOPMENT

A fully recombinant subunit vaccine for plague has been identified (Williamson et al., 1995), which in animal models of both bubonic and pneumonic infections, provides enhanced protection and which represents a new candidate human vaccine (Williamson et al., 2005).

Much effort is being expended in the development of the combination of rF1 and rV as a second-generation plague vaccine (Williamson, 2001).

DISCOVERY/BASIC SCIENCE

Preclinical Development, Including Relevant Animal Models

Mouse

The immunogenicity and efficacy of the rF1 and rV immunogens have been extensively studied in the mouse in which the synergistic effect of these proteins was first reported (Heath et al., 1998; Williamson et al., 1995). Subsequently, regions of the V antigen associated with protection were identified in the mouse model and Mab 7.3, derived against V135-275, was found to passively protect mice against live plague organism challenge (Hill et al., 1997). Recombinant F1 antigen protected Balb/c mice optimally when allowed to naturally aggregate, although attempts to denature this protein reduced, but did not abolish, efficacy (Miller et al., 1998). The development of an IgG1 titer to the rF1 + rV antigens in the Balb/c mouse correlated with protection against challenge (Williamson et al., 1999), although evidence for the existence of CMI responses has also been found (Williamson et al., 1995, 1996). Mouse haplotype and gender did not significantly influence the response to the F1 + V vaccine so that CBA(H-2k), C57Bl6 (H-2b), Balb/c (H-2d), and the CB57Bl6 x Balb/c strain (CB6F1) all responded and were protected to a similar high level against either subcutaneous or aerosol challenge with plague (Jones et al., 2001). Similar levels of immunogenicity and efficacy have been observed in outbred mouse strains immunized with the rF1 and rV proteins, either in combination (Williamson et al., 2001) or as a genetic fusion (Heath et al., 1998). Passive transfer of antiserum to rF1 + rV from the Balb/c mouse into the servere combined immunodeficient with Beige mutation (Scid/Bge) mouse fully protected the latter against plague challenge, again indicating the importance of high titer-specific antibody in protection (Green et al., 1999).

Guinea Pig

Although the guinea pig is susceptible to plague, it has been much less used to evaluate subunit vaccines incorporating the rF1 and rV antigens. However, in a single study Jones et al. (2003) reported that guinea pigs responded with specific antibody to each antigen,

although the response to rF1 was more variable than the response to rV. Actively immunized guinea pigs were also fully protected against subcutaneous challenge with 10^5 colony-forming units (cfu) of *Y. pestis* (equivalent to at least 10 lethal doses). Moreover, antiserum raised in the guinea pig and specific for rF1 + rV passively protected naive Balb/c mice from challenge with plague, indicating a conservation of B cell epitopes in F1 and V between the two species.

Macaque

Cynomolgus macaques, immunized with the rF1 + rV vaccine in alhydrogel have responded with high titer antibody to each subunit antigen (Williamson, 2004). The positive reference macaque antiserum raised (Williamson et al., 2005) has been demonstrated to protect mice in a dose-related manner against challenge by passive transfer and to compete *in vitro* with murine Mab7.3 for binding to rV antigen on a solid phase, in a competitive ELISA (Williamson et al., 2005). These data indicate that cynomolgus macaques immunized with rF1 + rV in alhydrogel, responded with protective antibody and again indicates the conservation of B-cell epitopes between the macaque and the mouse.

CLINICAL TRIALS

Phase I

The human immune response to the recombinant plague vaccine, comprising rF1 and rV antigens in alhydrogel, has been assessed during a Phase 1 safety and immunogenicity trial in 32 healthy male volunteers in Europe in 2001 (Williamson et al., 2005). The vaccine was found to be safe with no vaccine-related serious adverse events reported. All the subjects produced specific IgG in serum after the priming dose, which peaked in value after the booster dose (day 21), with the exception of one individual in the lowest dose-level group, who responded to rF1 only. Three subjects, found to have an anti-rV titer at screening, were excluded from the overall analysis. Human antibody functionality was assessed by quantification of antibody competing for binding to rV *in vitro* and also by the transfer of protective immunity in human serum into the naïve mouse. Human and macaque IgG competed for binding to rV *in vitro* with Mab7.3, previously shown to protect mice against challenge with plague, suggesting that this protective B-cell epitope on rV is conserved between these three species. Total IgG to rV in individuals and the titer of IgG competing for binding to rV, correlated significantly at days 21 ($r = 0.72$; $p < 0.001$) and 28 ($r = 0.82$; $p < 0.001$). Passive transfer of protective immunity into mice also correlated significantly with total IgG titer to rF1 plus rV at days 21 ($r^2 = 98.6\%$; $p < 0.001$) and 28 ($r^2 = 76.8\%$; $p < 0.03$). However, no significant vaccination-related change in the activation of PBMC was detected at any point of time. Potential serological immune correlates of protection were identified, but no trends specific to vaccination could be detected in cellular markers.

Phase II

Expanded clinical trials have been conducted to further address issues of safety and immunogenicity in male and female volunteers together with vaccine dose ranging studies. The ultimate aim of these studies is to arrive at a final formulation and regimen for licensure of the vaccine.

Phase III

In Europe, Phase III post-marketing safety studies may be conducted after marketing authorization has been received for the vaccine, in a sufficient number of individuals to provide a statistically sound evaluation of vaccine safety. In North America, Phase III studies to evaluate vaccine safety in an expanded population are normally required prior to the application for Biologic Licensing Authorization (BLA).

Postexposure Immunoprophylaxis

It is possible that a recombinant subunit vaccine with enhanced immunogenicity could provide some benefit in conjunction with antibiotic, in a postexposure scenario. In mouse studies, the earliest protective response against aerosol challenge, induced to a single high dose vaccination with rF1 + rV was observed at approximately day 6 (Fig. 54.4) and so by extrapolation, postexposure vaccination in man with an enhanced formulation could be beneficial.

Third-Generation Vaccines

Third-generation vaccines comprising rF1 + rV delivered in association with different adjuvants and/or by a non-parenteral route, or alternative physical formulations or rF1 + rV and rF1-V are also being researched. For this first option, rF1 + rV simply coadministered with a mucosal adjuvant such as cholera toxin B subunit (CTB), induced a high level of

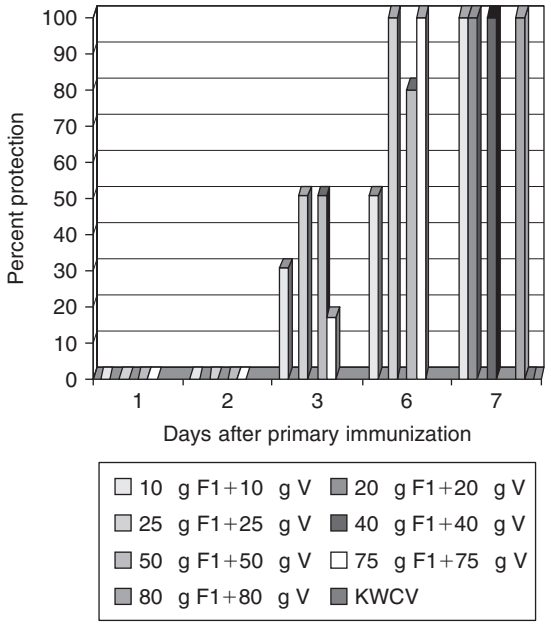

FIGURE 54.4 Time to immunity against pneumonic plague in the Balb/c mouse model; groups of five mice received a single immunizing dose of the rF1 + rV vaccine on day zero at escalating dose-levels of each subunit, followed by inhalational challenge with >300 MLD (3×10^5cfu) *Y. pestis* strain GB on days 1–7. The figure shows percent protection at 14 days post-challenge (see color plate section).

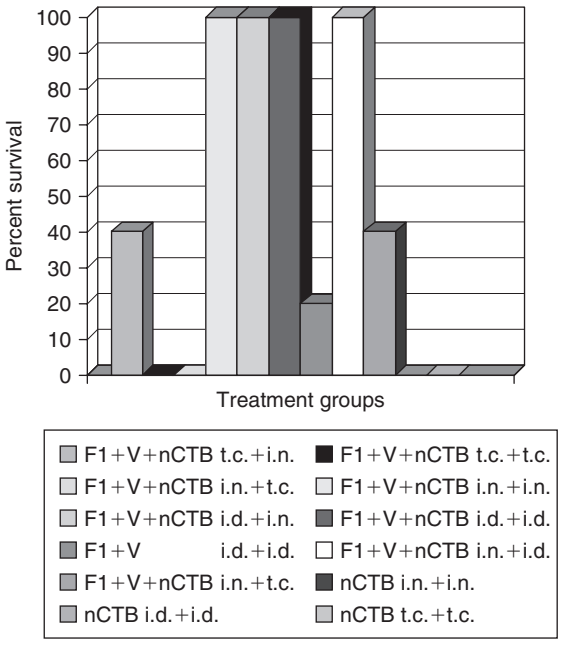

FIGURE 54.5 The protective efficacy of rF1 + rV coadministered with CTB by the transcutaneous, intradermal, or intranasal routes, or combinations of these. The figure shows the percentage survival for groups of 5 Balb/c mice immunized by the routes indicated (1 bar per group) on two occasions (days 1 and 21) with 10μg rF1 + 40μg rV, with or without 10μg CTB (Sigma, Poole, United Kingdom) in 50μl phosphate-buffered saline per mouse. All groups were challenged subcutaneously at day 90 with 5×106 MLD *Y. pestis* (GB strain) (Somavarapu et al., 2001) (see color plate section).

protective immunity in Balb/c mice when delivered intranasally (i.n.) or intradermally (i.d.) (Fig. 54.5). Interestingly, the primary immune response induced by this formulation given i.d. could be boosted by i.n. dosing and the primary response induced to i.n. dosing, could be boosted i.d., either of these combinations leading to full protective immunity, and indicating that there is significant cross talk between the nasal-associated lymphoid tissue and the skin. Moreover, transcutaneous (t.c.) priming and boosting with this formulation did not induce protective immunity although 40% protection was achieved when t.c.-primed mice were boosted i.n. However, the substitution of cholera holotoxin (CT) for CTB in the formulation and the use of three t.c. immunizations, did lead to protective immunity in Balb/c mice against 10^2 median lethal doses of *Y. pestis* and t.c. priming with this formulation could be effectively boosted i.n. or i.d (Eyles et al., 2004). T.c. immunization with this formulation induced CMI responses in the spleens of immunized mice.

Significant progress has also been made using formulations in which the rF1 and rV proteins are encapsulated in polymeric microspheres which further enhances their immunogenicity and facilitates their delivery by mucosal routes such as nasal (Eyles et al., 1998), or inhalational (Eyles et al., 2000). Some of these formulations are in early stage of development and represent potential vaccine formulations for the future. These formulation types have the advantage that they are generally more stable than liquid formulations, do not require cold chain storage, and *in vivo* act as effective depot release systems, so that they are expected to need less boosting. These are particularly ideal qualities for a biodefense vaccine which may be required for use in the field or on an intermittent basis, depending on an assessment of risk. Microencapsulated formulations of rF1 + rV have been extensively studied (Williamson et al., 1996) and optimized (Eyles et al., 2003) so that in the mouse model a single dose provides slow release sufficient to prime and boost the immune system (Elvin and Williamson, 2006), to induce substantial antibody titers and CMI which confers protection against virulent plague challenge (Eyles et al., 2000; Williamson et al., 2001).

PROSPECTS FOR THE FUTURE

For a number of reasons it is clear that the existing KWC or live attenuated vaccines are not suitable for

the immunization of populations to protect against pneumonic plague. However, until improved vaccines become available the KWC vaccine has a role to play in the immunization of individuals who might contract bubonic plague.

A number of approaches to the development of an improved vaccine have been reported. Live attenuated vaccines offer some advantages but a suitable candidate has yet to be identified and the licensing of such a vaccine could be difficult. Naked DNA vaccines do not appear to offer any significant benefits over subunit vaccines, especially since there is no evidence of the need for cytotoxic T cell responses to control infection. The most likely candidate vaccine, which could provide protection against bubonic and pneumonic plague, is an injected subunit vaccine. Most effort to date has focused on recombinant *Y. pestis* proteins, which are produced in *E. coli*, and this seems to be the simplest strategy for the development of an improved vaccine. A work has already shown that a vaccine based on rF1 and rV is effective and this vaccine is currently undergoing clinical trials in humans. Such a vaccine could therefore be licensed for use within the next few years. However, the identification of additional protective subunits could be used to provide alternative vaccine formulations for the future.

In the long term, the licensing of a recombinant subunit vaccine would support ongoing studies to devise plague vaccine formulations which could be given noninvasively. Such vaccines would be ideally suited to the large-scale immunization of populations. Licensed vaccines based on attenuated *S. enterica* (or other vaccine vectors), which can be given orally and in which the maintenance of recombinant plasmids *in vivo* does not require antibiotic resistance, or microencapsulated subunit protein vaccines which may be delivered by a mucosal or parenteral route, appear to be a realizable prospect within the next decade.

KEY ISSUES

- Plague is an ancient life-threatening disease which still exists in some parts of the modern world, with the potential for epidemic spread.
- The only vaccine available for human use in the Western world is a KWC formulation which provides some protection against the bubonic form of the disease, but probably provides little or no protection against the more serious pneumonic plague syndrome.
- A live attenuated mutant strain of plague, EV76, has been used in human but can cause serious side effects.
- A number of alternative vaccines have been researched to include live rationally attenuated strains, a live vaccine vector expressing plague subunit proteins, DNA vaccines, and a fully recombinant subunit vaccine.
- The subunit proteins F1 and V, which occur naturally in the causative organism, are protective immunogens which are synergistic in effect and protective against pneumonic plague in an experimental model.
- Fully recombinant subunit vaccines, comprising the F1 and V antigens in an alhydrogel vehicle, are in development and have been shown to be immunogenic in a range of species as well as in human.
- A Phase I clinical trial has shown that the vaccine is safe and well tolerated and Phase II trials are ongoing.
- The future application of the rF1 + rV vaccine is expected to provide the capability to protect people against pneumonic plague.

OUTLINE

ABSTRACT

Ricin is a plant cytotoxin that poses a significant risk as a biothreat, primarily as a toxin that could be delivered by aerosolization in acts of bioterrorism and biological warfare. Ricin is a type II ribotoxin that is closely related in the mechanism of action to other plant toxins and several bacterial toxins, including the family of Shiga toxins, a cause of diarrhea-associated hemolytic uremia syndrome. There has been a huge amount of research directed at understanding the molecular basis of toxicity of ricin and related toxins and the use of those toxins in targeted immunotoxins for therapeutics. Lately, because of the interest in developing countermeasures and vaccines for

category A and B biothreats, this research has culminated in the development of subunit vaccines for ricin that are now in advanced preclinical and clinical studies. Depending on dose and route, ricin exposure results in three separately identifiable pathways of toxicity: direct cytotoxicity through the inhibition of protein synthesis resulting in necrosis, yet-unresolved signaling of programmed cell death (apoptosis), and upregulation of inflammatory cascades regulated by a variety of mitogen-activated protein kinases (MAPK) and transcription factors. Both tissue damage and organ damage are a result of direct cytotoxicity, highest in those mucosal regions directly exposed to toxin, and inflammation. Antibodies to ricin holotoxin have historically been shown to confer protection to naive animals by passive transfer. Antibodies to ricin can rescue exposed animals, but only if given shortly after exposure. Several recombinant vaccine immunogens have been developed in the past several years, the most promising ones being derived by mutation or deletion from the ricin toxin A (RTA) chain. The RTA mutant vaccines induce protection from systemic toxin exposure in animal models and neutralizing antibodies that are correlated to protection. RTA vaccines also induce protection from oral and aerosol toxin exposure and largely protect against mucosal damage. The role of local and systemic antibodies in animal models is being studied as part of the program to correlate human immune responses to protective efficacy in animal models.

INTRODUCTION

Protein toxins are principal determinants of pathogenicity for a large number of bacterial diseases of animals and humans. In many cases, toxins are logical targets for vaccine development since inactivation of the toxins by specific circulating antibodies that participate in toxin neutralization or clearance prevents the toxins from reaching intracellular targets. For several bacteria that manifest toxins as their principal virulence determinants, passive immunization with antitoxins had been a means to treat or prevent human disease before the availability of vaccines. It is well known that several of the most successful vaccines used, since the first quarter of the 20th century, as public health tools are based on the chemical inactivation of bacterial toxins secreted into culture supernatants and the fact that such toxoids induce antibodies that recognize and neutralize the native toxins. The most notable examples of antitoxin vaccines are diphtheria and tetanus toxoids that are usually given as a pediatric series in combination with whole-cell pertussis (DTP) or acellular pertussis components (DTaP), and the principal component of anthrax vaccines. Although antitoxic immunity would not be expected to inhibit initial infections, induction of antitoxic antibodies by vaccination can control morbidity and mortality due to downstream elaboration of toxins from these infections. Just as the development of effective and safe toxoids had been successful for controlling diphtheria and tetanus epidemics, new vaccines can be generated from toxin targets of bacterial pathogens that are emerging as public health threats and toxins of plant and fungal origin that could be used in biowarfare or bioterrorism.

Over the last several decades, elucidation of the molecular mechanisms of toxin action across the spectrum of potential pathogens has led to the greater understanding of how toxins interact with animal and human hosts. This fundamental knowledge has been crucial to the development of new vaccine candidates and therapies for emerging pathogens that express toxins that determine pathogenicity.

This chapter focuses on the progress of vaccine development against ricin toxin as a paradigm for vaccines against other ribosome-inactivating toxins. Although this subject has been recently reviewed (Marsden et al., 2005; Mantis, 2005), an update is warranted as there has been significant progress over the past 3 years in both the advancement of several vaccine candidates and knowledge of toxin pathogenesis. In this chapter, we will highlight the recent advances in our understanding of ricin toxicity, pathology, and immunity and relate these to vaccines. Ordinarily, the subject of ricin intoxication and vaccine development would not be the subject of discussion in the context of emerging infectious diseases. However, ricin bears striking similarities to bacterial toxins, notably the Shiga family of toxins (Stx1 and Stx2, formerly called verotoxins), which cause human and animal diseases of public health significance. It is becoming increasingly apparent that the lessons learned with respect to ricin will have direct implication for countermeasures against these related bacterial toxins.

Considering that ricin intoxication is relatively rare [e.g., there have been less than 1000 cases of known ricin intoxication documented during the 1900s (Rauber and Heard, 1985], one is tempted to ask whether efforts to develop vaccines against ricin are truly necessary. Historically, efforts to understand immunity to ricin have been associated with the potential use of ricin, or more specifically the ricin enzymatic subunit, to create engineered immunotoxins for targeted therapy of cancers and select infectious diseases (Olsnes et al., 1989; Vitetta and Thorpe, 1991; Thrush et al., 1996). While these efforts are ongoing, the resurgence in ricin-related research has been driven by the proven potential of the toxin to be used as an agent of bioterrorism.

RICIN AS A CATEGORY B BIOTHREAT

Ricin toxin is a natural product of the castor bean plant, *Ricinis communis*, which is cultivated on industrial levels around the world for the production of castor oil. Recent economic surveys have shown that over 1 million tons of castor beans are produced in the world annually, with approximately 800,000 tons originating from India and around 100,000 tons from Brazil. Ricin toxin can constitute up to 5% of the total protein of castor bean and can be extracted from the mash produced as a by-product of castor oil production by several simple enrichment steps (Franz and Jaax, 1997). Because of the copious amounts of processed castor beans and the high content of ricin, a rough calculation indicates that, in any single year, it may be possible to purify over 50,000 tons of pure ricin.

In addition to its relative ease of preparation, ricin in semi-purified or purified form is extremely toxic. Only botulinum toxin is more potent than ricin (Arnon et al., 2001; Schechter and Arnon, 2000). Whereas botulinum toxin is an endoprotease that selectively targets peripheral neurons, resulting in descending paralysis of peripheral nerve function, ricin's potency is due to its promiscuity (it can intoxicate all known cell types) and extremely efficient enzymatic activity. Ricin was developed, but never used, as a weapon by the United States during World War II, under the code name of "Compound W." Since World War II, there has been little need to produce castor oil in the United States. Before the First Gulf War in 1990, the Iraqi military had attempted to devise ways to disseminate ricin as an explosive bomb (Shea and Groton, 2004; Stone, 2002), attempts that were forestalled by the war and ensuing events. Ricin has also been detected in a powder form sent in a letter addressed to Senator Frist in 2004 and several other similar but less publicized incidents.

For the reasons mentioned above, ricin has been classified by the Centers for Disease Control and Prevention (CDC) as a category B select agent. The CDC classification system categorizes biological agents based upon their risks for causing mass casualties in the event of a bioterrorist attack (Khan et al., 2000; Rotz et al., 2002). The highest priority agents (category A) are organisms or toxins that can be easily disseminated or transmitted person to person, cause high mortality with potential for major public health impact, might cause public panic and social disruption, and require special action for public health preparedness. Category A agents include variola major (smallpox), *Bacillus anthracis*, *Yersinia pestis*, *Clostridium botulinum* toxin, *Francisella tularensis*, Ebola virus, Lassa fever virus, and several other related viruses. Category B includes biothreats that are relatively easy to disseminate and cause moderate morbidity and low mortality. In addition to ricin, the category B list includes *Coxiella burnetti* (Q fever), *Brucella* species (brucellosis), *Burkholderia mallei* (glanders), alphaviruses, Venezuelan equine encephalomyelitis (VEE), eastern and western equine encephalomyelitis, epsilon toxin of *Clostridium perfringens*, *Staphylococcus* enterotoxin B, and select foodborne or waterborne pathogens, including *Salmonella* species and *Vibrio cholerae*. Although Shiga toxin itself is not considered a biothreat agent, Shiga toxin-producing bacteria notably *Shigella dysenteriae* and *Escherichia coli* O157:H7, are classified as category B agents and represent a significant threat to public health. Finally, category C agents include emerging pathogens that could be engineered for mass dissemination in the future because of availability, ease of production and dissemination, and potential for high morbidity and mortality and major health impact. They include Nipah virus, hantaviruses, tick-borne hemorrhagic fever viruses, tick-borne encephalitis viruses, yellow fever, and multidrug-resistant tuberculosis.

Thus, the toxicity and availability of purified and semi-purified ricin has been the greatest impetus for development of vaccines and therapeutics. Although it would be technically difficult to achieve mass dissemination of ricin, it is clear that localized dissemination via aerosol or adulteration of food chains could disrupt public health and the perceived safety of the United States from bioterrorists. The development of vaccines and therapeutics will absolutely depend on the correct interpretation of the correlates of protection, which can be obtained only through evaluation of efficacy in relevant animal models. Additionally, a vaccine must be designed to protect against the circulating toxin as well as the local effects on mucosal tissues in the lung or the gastrointestinal (GI) tract. Further, a postexposure therapeutic may have to address the temporal nature of the rapidity of toxin action and the downstream effects of the toxins that cannot be addressed by neutralizing antibodies or molecules that inactivate the toxins per se. It is becoming increasingly apparent that the host's response to intoxication (i.e., inflammation) may actually amplify the damage elicited by the toxin and be more detrimental than the toxin itself.

SIMILARITIES BETWEEN RICIN AND SHIGA TOXINS

Ricin and Shiga toxins are similar in a number of respects, including enzymatic activity, intracellular trafficking, and activation of cellular stress pathways.

The family of Shiga toxins consists of several antigenically related toxins (e.g., Stx1 and Stx2) that are expressed by certain strains of *Shigella* and *E. coli*, most notably *E. coli* O157:H7, that are increasingly associated with foodborne outbreaks of hemorrhagic colitis and hemolytic uremia syndrome (HUS). HUS is the major cause of acute renal failure in infants and young children. Enzymatically, ricin and Shiga toxins are identical. These toxins are RNA *N*-glycosidases, whose sole substrate is a highly conserved adenine residue within ribosomal RNA (Endo and Tsurugi, 1987; Endo et al., 1987). Both ricin and Shiga toxins are members of the A–B family of toxins in which the A subunit confers enzymatic (i.e., cytotoxic) activity, whereas the B subunit mediates toxin attachment to cell surfaces. Shiga toxin is an A_1:B_5 toxin, meaning that five B subunits assemble as a donut-shaped pentamer in which a single A subunit sits within its center. In the case of ricin, the A–B subunits associate in a 1:1 stoichiometry and are linked by a single disulfide bond. By definition, ricin and Shiga toxins are categorized as type II ribosome-inactivating proteins (RIPs) (i.e., an A and B subunit). Type I RIPs, on the other hand, consist solely of a single catalytic subunit analogous to the A chain and are invariably derived from plant sources. Although ricin and Shiga toxins bind to different cellular receptors (see below), both toxins reach their ribosomal targets by retrograde transport through the Golgi apparatus and the endoplasmic reticulum (ER). Finally, both ricin and Shiga toxins activate the so-called ribotoxic stress response, which triggers the initiation of events that lead to apoptotic cell death, as opposed to necrosis, and the activation of multiple pathways that lead to secretion of proinflammatory cytokines and chemokines.

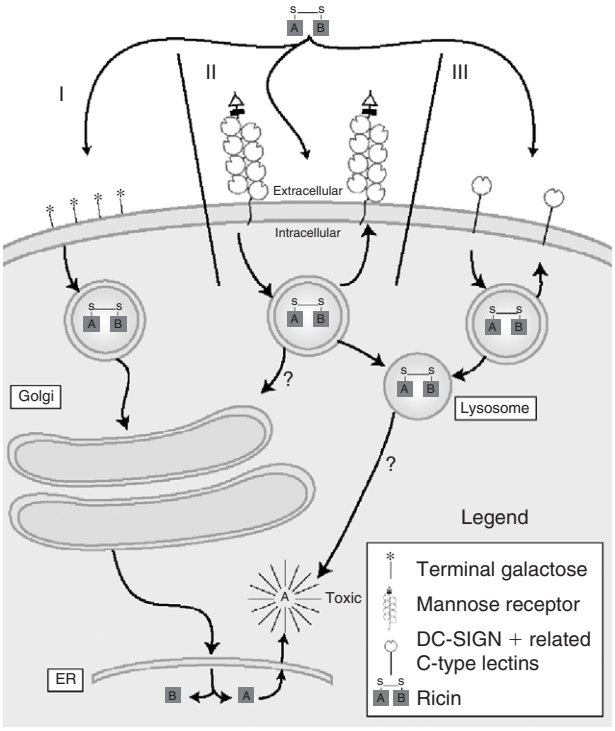

FIGURE 55.1 Pathways of ricin uptake into host cells. There are two known (and one postulated) pathways (I–III) by which ricin is internalized into host cells. In *Pathway I*, RTB binds to galactose-containing glycoproteins and glycolipids on host cell surfaces. The toxin is internalized by all known endocytic processes. A fraction of the internalized toxin is transported retrograde to the Golgi apparatus, and eventually to the ER. The toxin subunits dissociate, and RTA is translocated into the cytoplasm via a Sec61-dependent process. RTA exerts its cytotoxic properties once within the cytoplasm. In *Pathway II*, ricin is recognized by the mannose receptor (MR), which is expressed on macrophages and hepatic endothelial cells. Uptake by the MR is approximately 100 times more efficient than the Pathway I, although virtually nothing is known about the details of how this occurs. It is postulated that ricin initially resides within an acidic endosome, but it is unclear whether the RTA gains access to the cytoplasm by merging with Pathway I (i.e., via retrograde transport) or is translocated across the endocytic membrane (see question marks). *Pathway III* remains speculative but proposes that ricin may utilize other mannose-specific lectins (e.g., DC-SIGN) to gain access to the inside of host cells.

RICIN TOXIN STRUCTURE AND FUNCTION

Ricin Toxin A (RTA) and B (RTB) Chain Function

As mentioned above, ricin is a prototypic A–B toxin. It exists as a 64-kilodalton (kDa) globular glycoprotein heterodimer consisting of a 32-kDa RTA chain linked via a single disulfide bond to the 32-kDa RTB chain (Montfort et al., 1987). The RTA chain is enzymatically active and is responsible for the induction of the toxicity (Olsnes and Pihl, 1973). RTA enters the cytosol by at least two distinct pathways, as will be discussed below (Fig. 55.1). Once in the cytoplasm, RTA depurinates a single adenine residue (A4324) near the 3′-end of 28S RNA in ribosomes, the identical site for Shiga toxins (Yamasaki et al., 2004), blocking protein synthesis (Barbieri et al., 1993). The X-ray crystal structure of RTA has been determined, and the residues responsible for depurination of 28S RNA have been identified (Ready et al., 1991; Lamb et al., 1985; Montfort et al., 1987; Mlsna et al., 1993; Weston et al., 1994). Residues Y80, Y123, E177, R180, N209, and W211 constitute RTA's enzymatically active site (Lebeda and Olson, 1999; Olson, 1997). Mutations in some of these amino acid residues have yielded RTA mutants with negligible toxicity as determined by the inhibition of protein synthesis (Kim and Robertus, 1992). The latest vaccine

candidates have been developed with the purpose of reducing the enzymatic activity of the A chain to levels below detection of activity.

RTB is a bivalent lectin specific for β1,3-linked galactose and *N*-acetylgalactosamine and is capable of binding to both glycolipids and glycoproteins on host cell membranes (Baenziger and Fiete, 1979; Wu et al., 2006). The primary function of RTB is to mediate attachment of ricin to cell surfaces (Fig. 55.1). RTB consists of two globular domains with identical folding topologies (Montfort et al., 1987). Each of the two domains (1 and 2) themselves comprise three homologous sub-domains (α, β, γ) that probably arose by gene duplication from a "primordial" carbohydrate recognition domain (CRD) (Rutenber et al., 1987). Only domains 1α and 2β retain functional carbohydrate binding activity, as inferred by the crystal structure of ricin in the presence of lactose (Rutenber and Robertus, 1991), as well as binding studies with RTB mutants (Swimmer et al., 1992). The two galactoside pockets are separated by 70 Å, suggesting that each pocket binds a different galactoside-containing side chain when attached to the surface of a cell (Rutenber and Robertus, 1991).

It is important to note that both RTA and RTB carry *N*-linked mannose side chains (Foxwell et al., 1985c; Kimura et al., 1988). RTA has a single side chain composed of $GlcNAc_2Man_4$ at position N10, while RTB has two side chains: $GlcNAc_2Man_6$ at position N95 and $GlcNAc_2Man_7$ at position N135 (Kimura et al., 1988). The significance of the mannose side chains is revealed by the fact that deglycosylated ricin (dgRicin) is ~90% less toxic than unmodified holotoxin in standard in vitro cytotoxicity assays and in mouse models of systemic intoxication (Foxwell et al., 1987; Simeral et al., 1980; Simmons et al., 1986; Thorpe et al., 1985). Discerning the basis of this attenuation has relied on the use of hybrid toxins in which only one of the two subunits is deglycosylated. Removal of RTA mannose side chains has no effect on the RTA's ability to inactivate ribosomes or the capacity of the holotoxin to kill host cells (Simmons et al., 1986; Thorpe et al., 1985). In contrast, holotoxins consisting of deglycosylated RTB are highly attenuated (Simeral et al., 1980; Simmons et al., 1986). Because deglycosylation had no effect on RTB's lectin activity, it has been postulated that the mannose side chains function to either interact with mannose-binding proteins during intracellular transport or stabilize RTB intracellularly (Simeral et al., 1980; Simmons et al., 1986). It has recently been shown that ricin interacts with a α-mannosidase during retrotranslocation, although it is unclear if this enzyme interacts with the mannose side chains on RTB (Slominska-Wojewodzka et al., 2006).

Ricin Uptake into Host Cells via RTB and Retrograde Transport: Pathway I

Although there are specific differences between Shiga and ricin toxins, both toxins enter cells and traffick intracellularly through common pathways. The intracellular trafficking pathways followed by both toxins have been well reviewed recently (Sandvig and van Deurs, 2005; Sandvig et al., 2004). The salient features of toxin trafficking that relate to the pathogenesis of these toxins are the steps in which the toxins bind to surface receptors and are taken up through clathrin and clathrin-independent endocytosis, with possible release of some toxin directly from the endosomes into the cytosol, fusion of endosomes with the trans-Golgi network (TGN), translocation into the ER, and retrotranslocation into the cytosol. Currently, there is little controversy that ricin and Shiga toxins enter the cytosol through retrograde transport through the ER, although the precise molecular steps are not well defined. As the first part in the uptake process, receptor-bound toxins are slowly endocytosed (Sandvig et al., 1976) and a portion of the internalized ricin is transported back to the cell surface; another portion is delivered to lysosomes and degraded, and a part is transported to the TGN (van Deurs et al., 1986). Subsequently, RTA is translocated to the cytosol from the ER (Wales et al., 1992, 1993; Tagge et al., 1996). The first convincing evidence of the involvement of the ER in this was demonstrated in experiments that documented the *N*-glycosylation of nonglycosylated recombinant RTA that was reconstituted with RTB, since glycosylation occurred only within the ER (Llorente et al., 2003; Rapak et al., 1997). Intimate association of RTA with ER-located Sec61 by cross-linking (Wesche et al., 1999) demonstrated the presence of RTA in the ER. Although ricin itself has not been visualized in the ER by electron microscopy, Shiga toxin has been directly detected, suggesting that perhaps a greater portion of Shiga toxin actually enters the ER pathway than ricin toxin (Sandvig et al., 1993). It is possible that only a small portion of endocytosed ricin (~5%) productively reaches the TGN (van Deurs et al., 1988). Hence, the precise fate of all of endocytosed ricin is still unclear, and there is also evidence that ricin can completely avoid Golgi processing (Llorente et al., 2003). The TGN and Golgi steps involved are partly clarified. For example, ricin can intoxicate cells inhibited in both the classical constitutive photomorphogenesis 1 (COP1)-dependent and the less-well-defined COP1-independent pathways (Chen et al., 2003). Nonetheless, intracellular routing of ricin and Shiga toxins differs somewhat from that of several other bacterial toxins (e.g., cholera toxin) that

have C-terminal Lys-Asp-Glu-Leu (KDEL) sequences that are thought to act as retrieval signals (Chaudhary et al., 1990). Ricin does not contain such a sequence, but there is some experimental evidence that RTB interacts with the chaperone calreticulin, which possesses a KDEL retrieval signal (Day et al., 2001). The fact that calreticulin-deficient cells are sensitive to ricin suggests that ricin exploits additional pathways to enter the ER. Addition of the KDEL signal to RTA by genetic fusion enhanced the toxicity of both a reconstituted AB holotoxin and the A chain alone (Wesche et al., 1999; Wales et al., 1992, 1993).

Ricin travels from the Golgi complex to the ER, where it likely subverts the ER-associated degradation (ERAD) pathway and unfolds and refolds through the Sec61 protein, a translocating conserved heterotrimeric membrane protein (Sandvig et al., 2002, 2004; Rapak et al., 1997; Lord and Roberts, 1998; Wesche et al., 1999). The Sec61 pathway is normally used to redirect misfolded and incorrectly assembled proteins to the cytosol for ubiquitination and proteasomal degradation (Plemper and Wolf, 1999). This is thought to hold true for the A chains not only of ricin (Rapak et al., 1997) but also of *Pseudomonas* exotoxin (Kreitman and Pastan, 1995), cholera toxin (Jackson et al., 1999), and Shiga toxin (Sandvig et al., 2004). For RTA to act, the disulfide bonds between RTA and RTB must be reduced to expose the active site. Protein disulfide isomerase (PDI) is thought to be involved with the reduction of RTB (Bellisola et al., 2004) and other toxins (Di Cola et al., 2001). RTA appears to be unfolded for retrotranslocation (Beaumelle et al., 1997) and may be refolded in the cytoplasm in contact with substrate ribosomes (Argent et al., 2000). RTA is low in available lysine sites for ubiquitination (Deeks et al., 2002) and avoids substantial proteasome-mediated degradation.

Ricin Uptake into Host Cells via the Mannose Receptor: Pathway II

It has been recognized for more than two decades that ricin exploits the mannose receptor (MR) as a second pathway (independent of RTB's galactose-binding activity) by which to deliver RTA into the cytoplasm of host cells (Simeral et al., 1980; Simmons et al., 1986; Thorpe et al., 1985; Frankel et al., 1997). The MR (CD206) is a 175-kDa transmembrane endocytic receptor that recognizes complex oligosaccharides terminating in mannose, fucose, or *N*-acetylglucosamine (East and Isacke, 2002; Taylor et al., 2005). It was first identified on alveolar macrophages (Largent et al., 1984; Shepherd et al., 1981) and later discovered to be expressed on a variety of cell types, including hepatic sinusoidal endothelial cells (HSECs) and Kupffer cells. Skilleter et al. (1981) noted that ^{125}I-labelled ricin accumulated in rat liver non-parenchymal cells to a much greater extent than parenchymal cells and showed that this accumulation could be inhibited by D-mannose, fucose, or ovalbumin. Magnusson and colleagues in a series of papers demonstrated ex vivo that ricin uptake by Kupffer cells and HSECs was in fact MR mediated in the sense that the process was inhibited by mannan (Magnusson and Berg, 1993; Magnusson et al., 1991, 1993). Intravenous injection of plant-derived RTA could selectively deplete mouse Kupffer cells associated with uptake through the MR (Zenilman et al., 1988). Macrophage cell cultures that expressed the MR were shown to be sensitive to mannosylated plant-derived RTA but not to *E. coli*-derived RTA, and the toxicity of plant-derived RTA could be blocked by mannan. These lines of evidence strongly suggest that there are two pathways operable in vivo for the uptake of ricin, some of it occurring through the RTB galactosyl pathway and a portion not entirely dependent upon the RTB subunit and mediated by mannosyl residues on RTB and RTA.

Despite the fact that MR-mediated uptake is an important route by which ricin is internalized into cells in vivo, virtually nothing is known about the underlying mechanism by which this occurs. Simmons et al. (1986), using rat bone marrow-derived macrophages, demonstrated that RTB-mediated and MR-mediated uptake pathways are biochemically distinct from each other. For example, MR-mediated uptake results in ricin passing through an acidic vesicle prior to translocation of RTA into the cytoplasm, whereas RTB-mediated uptake does not (see above). This is consistent with the MR's role as an endocytic receptor that continuously cycles between the plasma membrane and the endosomal compartment (East and Isacke, 2002). However, it is completely unknown how RTA escapes acidic endosomes and translocates into the cytosol. The fact that RTA itself (without RTB) is toxic to cells following uptake by the MR indicates that the mechanism of RTA translocation is distinct from the well-studied retrograde transport/ER translocation that occurs following RTB-mediated uptake (Rapak et al., 1997; Simmons et al., 1986) (see below). However, the relative contributions of uptake through galactosyl-mediated RTB receptors and the MR may be dependent on the cell type. The realization over the past decade that the MR is only one member of a large family of mannose-specific lectins expressed on lymphoid and non-lymphoid cells suggests that much remains to be explored with respect to how RTA gains access to the cytosol of host cells (van Kooyk and Geijtenbeek, 2003).

Vascular Leak Syndrome

An additional site and residues involved in the binding of RTA to endothelial cells have also been identified, which occur extracellularly and do not require toxin entry into host cells (Baluna et al., 2000; Baluna and Vitetta, 1999; Smallshaw et al., 2003). The endothelial binding site on RTA is implicated in the damage to isolated human umbilical vein endothelial cells (HUVECs) and to the induction of vascular leak syndrome (VLS), which has been determined to be a dose-limiting toxicity in the use of RTA-containing immunotoxins (Smallshaw et al., 2003). VLS has been a side effect of the intravenous administration of monoclonal antibody conjugates constructed using enzymatically deglycosylated RTA (dgRTA) during Phase I and II trials in cancer (Sauseville and Vitetta, 1997). In VLA, fluids leak from blood vessels leading to hypoalbinemia, weight gain, and pulmonary edema. The portion of RTA involved in both pulmonary vascular leak, vascular leak in human skin xenografts in severe combined immunodeficient (SCID) mice, and HUVECs appears to involve amino acid residues L74, D75, and V76 (Baluna et al., 1999). The residues involved in vascular leak were predicted from comparison of motifs in other toxins and interleukin-2 (IL-2). In one of the vaccine candidates under development (RiVax™), residue V76 has been modified by mutagenesis (i.e., V76M) to abrogate the VLS activity and minimize any possible endothelial cell damage.

TOXICITY OF RICIN

Little human data are available for the toxicity of ricin, although it is predicted from animal models that pure ricin will be toxic to humans by inhalation, oral, and systemic exposure. Essentially all of the data on the toxicity comes from studies in animals, with the exception of the single well-known human case of Georgi Markov, who was assassinated from an injection of sub-milligram quantities of ricin (Crompton and Gall, 1980). Although ricin toxin acts quickly on cells in vitro, clinical signs after ingestion, injection, or inhalation appear within 24 h of exposure. In the Markov incident, symptoms over the 4 days preceding his death were well characterized. In essence, intramuscular (i.m.) or subcutaneous (s.c.) administration induced local lymphoid necrosis, hemorrhages in the GI tract, liver necrosis, nephritis, pulmonary failure, and cardiac arrest. Data concerning oral exposure to ricin come from 750 reported cases of castor bean or ricin ingestion and a single study of oral administration of a crude castor bean extract in animals (Balint, 1974).

The toxicity of ricin in animals depends on the route of exposure (Franz and Jaax, 1997). Inhalation induces death in 60 h with an LD_{50} of 3–5 μg/kg (Franz and Jaax, 1997; Bradberry et al., 2003). By intraveneous (i.v.) injection, the LD_{50} is 5 μg/kg and death occurs in 90 h. Following s.c. injection, the LD_{50} is 24 μg/kg and death occurs at 100 h. Because of the rapid internalization of ricin by endocytosis and the catalytic amounts of ricin needed to inhibit protein synthesis, the toxic action of ricin is irreversible (Lord et al., 1994). Ricin is toxic in many animal species, and there is no evidence that there is a species-specific toxicity (Table 55.1). Thus, for vaccine development, there is every reason that no specific animal model is preferred as a model of pathogenesis and immune response. That is, protection data generated in mice can be generally translated to what can be expected in humans to the extent that if antibodies generated in a mouse protect a mouse, then it is expected that antibodies generated in a human will protect a human.

TABLE 55.1 Published lethal doses for ricin

Species/route	Toxic dose	References
BALB/c mouse/ inhalation[a]	12 μg/kg LD_{50}	Roy et al. (2003)
CD-1 mice/ inhalation	<3 μg/kg 3 μg/kg, 80% death 10 μg/kg, 100% lethality	Doebler et al. (1995)
Rhesus monkey/ inhalation	21–42 μg/kg LD_{100} in 48 h	Wilhelmsen and Pitt (1996)
Rat/oral	30 mg/kg LD_{100} in 36 h	Ishiguro et al. (1992d)
Mouse/intragastric (oral gavage)	20 mg/kg	Franz and Jaax (1997)
Swiss Webster[d] mouse/oral	10 μg/kg	Smallshav et al. (2007)
Swiss albino mouse/ i.p.[b]	25 μg/kg	Kumar et al. (2003)
CD-1 mouse/i.p.	20–60 μg/kg[c]	Pincus et al. (2002)
B6D2 mice/i.v.	2 μg/kg	Fodstad et al. (1976)
Mice/i.v.	5 μg/kg	Franz and Jaax (1997)
Rats/i.v.	0.35–5 μg/kg	Fodstad et al. (1976)
Rabbits/i.v.	LD_{50} 0.54 μg/kg; minimum lethal dose of 0.44 μg/kg	Christiansen et al. (1994)

Note: Published LD_{50} data from parenteral, aerosol, and gastrointestinal exposure in several animal species.
[a] 1-μm MMAD particle. MMAD = mass median aerosol diameter.
[b] Mice sacrificed at 24 h, therefore an estimate of LD_{50}. Significant increases in serum enzymes indicative of liver and kidney injury were observed at this dose.
[c] Significant decreases in blood glucose occurred at 60 μg/kg, but not 20 μg/kg, suggesting an LD_{50} between the two doses.
[d] Mice fasted 24 hr prior to oral ricin garage.

Respiratory Toxicity

The effect of aerosolized ricin on the respiratory tract has been studied in rodents (Brown and White, 1997; DaSilva et al., 2003; Doebler et al., 1995; Griffiths et al., 1999) and rhesus monkeys (Wilhelmsen and Pitt, 1996). In laboratory animals, ricin inhalation results in respiratory distress and airway and pulmonary lesions. Inhalation of ricin in rats leads to rapid apoptotic changes in alveolar macrophages within 6 h after exposure, finally culminating in interalveolar edema at 12 and 15 h after exposure, mixed inflammatory cell infiltrates, and alveolar flooding followed by tissue necrosis (Brown and White, 1997). Similar pathological and histological changes have been seen in nonhuman primate studies, where death from ricin inhalation occurs 48 h after the challenge in a dose-dependent fashion. Aerosol administration to primates results in the sudden onset of congestion, itchiness of the eyes, tightness of the chest, wheezing, and asthma (Franz and Jaax, 1997). This rapidly progresses to diffuse necrotizing pneumonia, interstitial and alveolar inflammation, edema, and alveolar flooding (Franz and Jaax, 1997).

When administered as an aerosol to mice, ^{125}I-labled ricin accumulated in both the respiratory and GI tracts, with a small fraction detected in other organs (Doebler et al., 1995). Monkeys exposed to lethal doses of ricin (~20–40 μg/kg) died (or were sacrificed upon onset of respiratory distress) roughly 36–48 h postexposure (Wilhelmsen and Pitt, 1996). Death was preceded by widespread necrosis in the airways and alveoli, peribronchovascular edema, and mixed inflammatory cell infiltrates. Similar results were observed in rats (Brown and White, 1997). Similarly, rodents exposed to lethal doses of aerosolized ricin develop necrotizing airway lesions, interstitial edema, and pulmonary inflammation, including massive neutrophil influx, and die 2–4 days later (Griffiths et al., 1997, 1999; Hewetson et al., 1993; Poli et al., 1996). In both monkeys and rodents, death was attributed to massive pulmonary alveolar flooding. There are no case reports of inhalation ricin exposure in humans.

Gastrointestinal Toxicity

Compared to aerosol exposure, ricin administered orally is considerably less toxic. The literature indicates that the oral LD_{50} is 20 mg/kg (Table 55.1), approximately 1000-fold higher than the aerosol or systemic LD_{50} values. Ingestion of whole castor beans results in severe abdominal pain, vomiting, diarrhea, and (depending on the number of beans and degree of mastication) death (Audi et al., 2005; Bradberry et al., 2003; Mantis, 2005; Olsnes, 2004). As there are no known reported cases of intentional ricin intoxication by the oral route in humans, our understanding of both the pathogenesis and mechanisms of intestinal immunity to ricin relies exclusively on experimental animal models, namely, rodents (Sekine et al., 1986; Smallshaw et al., 2007; Yoder et al., 2007) and, in some instances, rabbits (Hazen, 1927). Ishiguro and colleagues reported, in a series of short and highly descriptive papers, the histologic and physiologic changes that occur in the rat jejunum following ricin intoxication (Ishiguro et al., 1983, 1984, 1992a, 1992b, 1992c, 1992d; Sekine et al., 1986). Rats challenged with ricin by gavage (1–30 mg/kg) developed dose-dependent lesions in the stomach and the proximal small intestine (Sekine et al., 1986). In the latter tissue, there was widespread villus atrophy, crypt elongation, sloughing of the epithelium, and infiltration of inflammatory cells, including eosinophils and neutrophils. Similar histopathologic changes have been observed in mice challenged intragastrically with ricin (Yoder et al., 2007). It is postulated that following intestinal exposure, ricin ultimately disseminates from the mucosa into circulation (Ishiguro et al., 1992d). Indeed, ricin has been shown to cross polarized epithelial cell monolayers in vitro, although how much toxin crosses the intestinal barrier in vivo remains unknown (Mantis et al., 2006; van Deurs et al., 1990).

The inherent resistance of the GI tract to ricin is likely due to a number of factors that impede toxin absorption, including intestinal proteases, digestive enzymes, mucus, and secretory IgA, whose galactose-rich oligosaccharide can competitively inhibit ricin attachment to the apical surfaces of intestinal epithelial cells (Mantis et al., 2004). It should be mentioned that Smallshaw et al. (2007) have recently challenged the accepted LD_{50} based on results from a mouse model in which animals are fasted 20 h prior to gavage to ensure that food particles in the stomach do not interfere with toxin absorption. Under these circumstances, doses of ricin equal to or exceeding 100 μg/kg were consistently lethal. Although intestinal histology appeared largely normal in animals exposed to this fasting/challenging regimen, it should be kept in mind that food deprivation of this duration is known to have dramatic effects on the intestinal physiology of mice (Lenaerts et al., 2006).

Cellular Basis for Downstream Effects of Ricin and Shiga Toxins

While tissue damage is a hallmark of intestinal and pulmonary ricin intoxication, it remains unclear how

much of the damage is a result of the direct effects of the toxin (i.e., protein synthesis arrest and apoptosis) and how much is a consequence inflammation. There are now many studies documenting that epithelial cells, for example, exposed to Shiga or ricin toxin elicit a number of proinflammatory chemokines and cytokines, including IL-8, growth-regulated oncogene-alpha (GRO-alpha), GRO-beta, GRO-gamma, epithelial cell-derived neutrophil-activating protein-78 (ENA-78), and monocyte chemotactic protein 1 (MCP-1), also known as CCL2 (O'Loughlin and Robins-Browne, 2001; Thorpe et al., 1999, 2001; Yamasaki et al., 2004). Some of these observations have been performed in animal models of disease. These studies have essentially been iterated in a number of cell lines of human and murine origin, including endothelial, epithelial, and macrophagic cell lines (Table 55.2). Generally, the effects of ricin and Shiga toxins constitute the activation of inflammatory pathways and pathways acting through nuclear factor kappa B (NF-κB) and mitogen-activated protein (MAP) kinase p38 (p38 MAPK), extracellular regulated kinase (ERK), and c-jun *N*-terminal kinase (JNK) (Fig. 55.2). This results in the secretion of numerous proinflammatory cytokines and chemokines. Chemokines of the CXC subfamily, such as IL-8, can recruit neutrophils into areas of infection (Baggiolini et al., 1995; Baggiolini and Loetscher, 2000; Baggiolini, 2001). IL-8 can also stimulate neutrophil granule content release and the respiratory burst. The release of granule contents, such as proteases, toxic oxygen products, and other proinflammatory substances, can subsequently damage the intestinal mucosa (Grisham and Granger, 1988).

To determine whether ricin intoxication is accompanied by a local increase in proinflammatory cytokines in vivo, Yoder et al. (2007) challenged mice intragastrically (i.g.) with ricin at a range of doses (1–10 mg/kg) for various time periods (0, 5, 12, and 24 h) and then measured cytokine/chemokine levels in intestinal homogenates. There was no detectable increase in local IFN-γ, IL-1, IL-6, IL-12p70, or TNF-α levels following ricin challenge. In contrast, there was a dose- and time-dependent increase in MCP-1. MCP-1 has been previously implicated in mediating intestinal inflammation (Reinecker et al., 1995) and could possibly be involved in ricin-mediated tissue damage. MCP-1 is a chemoattractant for lymphocytes, monocytes, and macrophages, and can stimulate macrophages to undergo respiratory burst resulting in release of oxidative intermediates (Carr et al., 1994;

TABLE 55.2 Mediators of inflammation and apoptosis induced by ricin or Shiga toxin in cell cultures

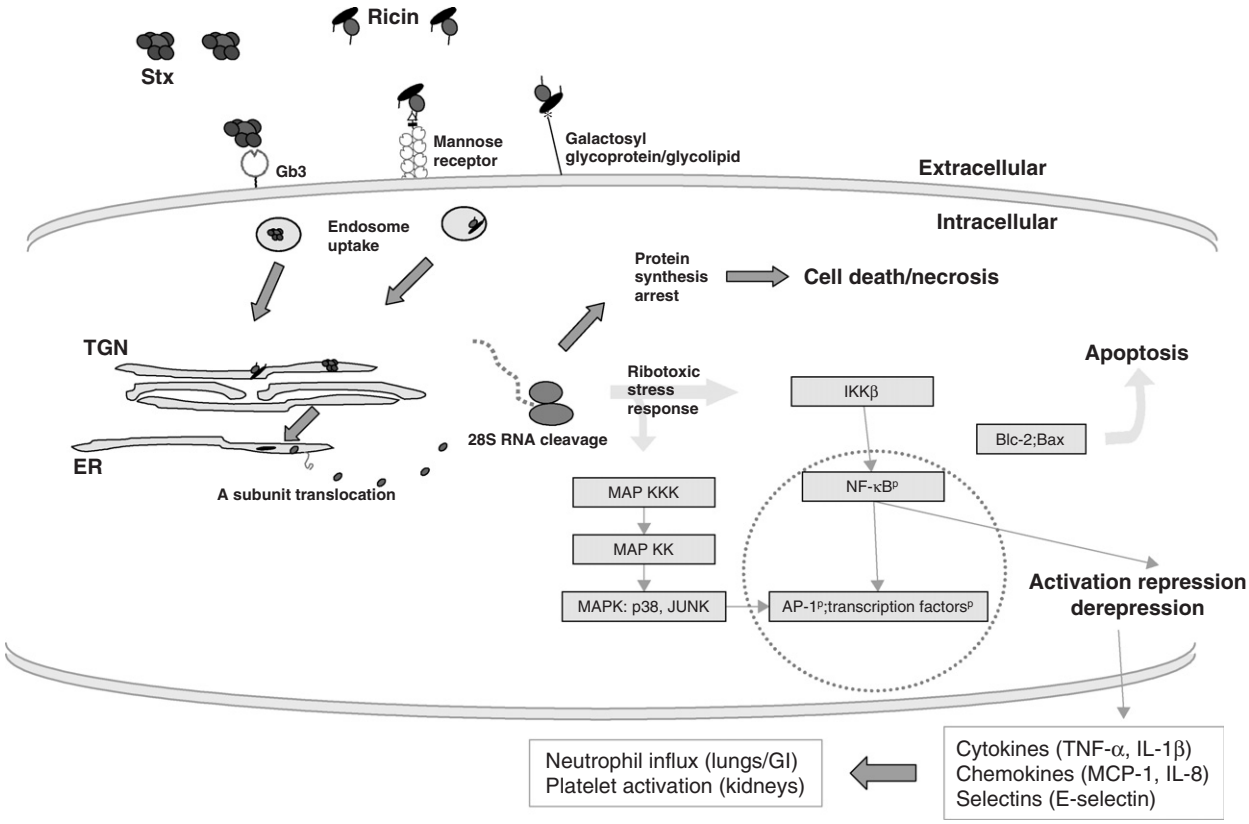

FIGURE 55.2 Pathways of intoxication implicated in the cellular actions of ricin and Shiga toxins. Ricin is a 64-kDa dimer of RTA and RTB. Ricin binds, via specific recognition sites, on RTB to galactosyl moieties on glycoproteins and glycolipids present virtually on all mammalian cell types and alternatively to the MR through *N*-linked mannosyl residues on either RTA or RTB. Shiga toxin is an A-B_5 toxin of 64 kDa that binds exclusively to globotriaosylceramide receptors that are primarily located in kidney and microglial cells. Through clatharin-dependent and -independent endocytosis, both Shiga and ricin toxins are taken up by endosomes and traffick through the TGN to the ER, where reductive cleavage of the subunit occurs, and the A subunits of each toxin translocate to the cytoplasm by subversion of the ERAD pathway. Once in the cytosol, the A subunits cleave specific sites in 28S rRNA, resulting in cessation of protein chain elongation. Through a series of unknown signaling steps, p38 MAPKs, ERK, and JNK are activated, resulting in the upregulation of cytokines, chemokines, and other gene families. The events culminate in recruitment of neutrophils to the sites, and separately to apoptosis.

Bischoff et al., 1992; Connor et al., 2004; Lu et al., 1998; Rollins et al., 1991). Moreover, MCP-1 is released by intestinal epithelial cell lines following bacterial infection (Hu and Hickey, 2005; Jung et al., 1995) and exposure to microbial toxins, including *Bacteroides fragilis* enterotoxin (Kim et al., 2005) and *Clostridium difficile* A toxin (Kim et al., 2002). MCP-1 expression is regulated in part by the p38 MAPK (Waterhouse et al., 2001). The availability of MCP-1 knockout mice permits one to examine the contribution of the chemokine-driven inflammation in toxin-induced tissue damage and the potential of p38 MAPK inhibitors to serve as postexposure therapeutics.

The inflammation associated with Shiga toxin-induced HUS is also indicated by the release of cytokines and chemokines, and experiments conducted in isolated cell cultures and animals also indicate the expression of proinflammatory mediators. The levels of IL-8 and MCP-1 are significantly increased in urine samples collected from HUS patients, suggesting the local action of cytokine on glomerular endothelium (van Setten et al., 1998). As with ricin, treatment of intestinal epithelial cell types with Stx1 or Stx2 leads to increased expression of CXC chemokines (Thorpe et al., 2001). The expression of inflammatory cytokines, such as IL-6 and IL-8, in macrophages in response to Shiga toxin and lipopolysaccharides (LPS) was reported more than 10 years ago (Tesh et al., 1994) and in other monocytic cells more recently (THP-1 monocytic cells) (Harrison et al., 2005; Table 55.2). These studies have also been extended to a variety of endothelial and epithelial cell lines. Stx2-treated HUVECs have

been shown to release IL-8 and MCP-1, which stimulated adhesion and transmigration of leukocytes (Zoja et al., 2002). Development of HUS may also depend on other proinflammatory stimuli, such as LPS, TNF-α, or IL-1β (van de Kar et al., 1992), that are associated with increased Gb3 levels in human brain and kidney endothelial cells (Stricklett et al., 2002), which increase sensitivity to the toxins by upregulating Gb3 receptor (van de Kar et al., 1992). Consistent with this, LPS and TNF-α increase the direct cytotoxic effect of Shiga toxin on HUVECs in vitro (Louise and Obrig, 1991, 1992).

Shiga toxins gain access to the systemic vasculature from the gut lumen, possibly by direct transcytosis or intracellular replication of *E. coli* cells, and circulate to target organs and cause damage to microvascular endothelial cells. There are no comparable data that ricin is also capable of gaining access to target organs escaping from the GI lumen, but recently acquired indirect data have indicated that lethal amounts of ricin given to mice by oral gavage act in the absence of obvious lesions, although inflammatory responses were not measured (Smallshaw et al., 2007). These results suggest that some ricin enters through undetected lesions or there is a minor mechanism for uptake of ricin directly through transcytosis. By the same token, some detailed studies exploring the intratracheal instillation of ricin at high doses, twofold above the LD_{50}, indicated induction of inflammatory responses not only in the lungs but also in kidney tissues (Wong et al., 2007a). This was accompanied by deposition of fibrin/fibrinogen in lung tissue of mice after 48 h, plus influx of neutrophils, focal areas of hemorrhage, necrosis and apoptosis of the airway epithelium and alveolae, increased expression of proinflammatory transcripts (TNFα, IL-1β, IL-6, CXCL1 and CXCL2, and transcription factors c-jun and c-fos), and activation of ERK and JNK. Interestingly, at lethal doses, elevated transcripts were seen in kidney tissue and other organ tissues, which was associated with lesions in 28S rRNA in the tissue samples examined, indicating presence of ricin in those tissues. At sublethal doses (0.2 LD_{50}), JNK and ERK activation was accompanied by increased expression of NK-κB and neutrophil infiltrates, and differed from the lethal dose as there was no evidence of hemorrhage or fibrin/fibrinogen deposition in lung or airway tissue. There was no evidence of distal organ damage. This suggests a situation in which local necrosis of tissue may allow the penetration of ricin, as suggested for Shiga toxin, and the effects may be dose related. These results are important for consideration of the types of endpoints that may be examined in vaccine studies since protection against high- and low-dose exposures may be indicative of significantly different processes.

IMMUNITY TO RICIN

For more than a century, ricin has served as a powerful model to understand the fundamental interactions between toxins and the adaptive arm of the immune system. In the late 1800s, for example, Paul Ehrlich demonstrated that feeding mice or rabbits castor bean "cakes" induced immunity in the animals to subsequent challenges with normally lethal doses of castor bean extract, demonstrating for the first time the possibility of adaptive immunization against a biological toxin. We now appreciate that immunity to ricin is in fact mediated by antibodies, although the underlying mechanisms by which this occurs remain largely unknown (Chanh and Hewetson, 1993; Foxwell et al., 1985a; Godal et al., 1983; Griffiths et al., 1995; Hewetson et al., 1995; Houston, 1982; Lemley et al., 1994; Smallshaw et al., 2002). All of the published vaccine protection data are obtained from challenge studies and passive transfer studies performed in rodents. There are, however, unpublished studies performed by the U.S. Army that indicate nonhuman primates are protected against ricin challenge in an antibody-mediated fashion (Chad Roy and Charles Millard, personal communication). Mice immunized with sublethal doses of ricin (Godal et al., 1983; Hewetson et al., 1993) or formalin-inactivated ricin toxoid (Yan et al., 1995, 1996; Kende et al., 2002; Foxwell et al., 1985b) produce high-titer anti-ricin IgG antibodies in serum and are protected from lethal doses of ricin given i.v., s.c., and intraperitoneally. Protection can also be imparted to mice by passive transfer of polyclonal or certain monoclonal anti-ricin antibodies (Chanh and Hewetson, 1993; Colombatti et al., 1987; Foxwell et al., 1985a; Houston, 1982; Lemley et al., 1994). Polyclonal antibodies against either RTA or RTB are protective (Foxwell et al., 1985b). However, protection does not necessarily correlate with total antitoxin serum antibody titers, suggesting that a specific subset of antitoxin antibodies is responsible for neutralizing ricin in vivo (Smallshaw et al., 2002). It should be noted that the utility of postexposure passive antibody therapy to rescue an animal from the toxic effects of ricin is questionable, as the therapeutic window is likely to be very narrow. For example, rabbit antitoxin polyclonal antisera against ricin toxoid, RTA, or RTB could only rescue mice from ricin intoxication, if given intravenously within 20–40 min of toxin exposure (Foxwell et al., 1985a).

Similarly, results were obtained using a neutralizing murine monoclonal antibody (Chanh et al., 1993).

Monoclonal Antibodies

A number of investigators have produced anti-ricin monoclonal antibodies (MAbs) with the goal of identifying the subpopulation of antibodies involved in neutralization of ricin in vivo (Colombatti et al., 1986; Dertzbaugh et al., 2005; Lebeda and Olson, 1999; Maddaloni et al., 2004; Mantis et al., 2006; McGuinness and Mantis, 2006) (Table 55.3). The most potent MAb identified to date is UNIVAX 70/138, also referred to as R70, which is a mouse IgG_1 directed against RTA. R70 was produced from mice immunized with ricin toxoid and identified as being capable of protecting mouse leukemia cells from the cytotoxic effects of ricin in vitro. The in vitro neutralization activity of R70 proved to be consistent with its in vivo activity. When administered intravenously to mice before or concurrently with a lethal dose of ricin (18μg/kg), R70 fully protected animals from death. It was estimated that protection was achieved when antibody-to-antigen ratios were greater than 80 (w/w) (Lemley et al., 1994). In a subsequent study, Lebeda and Olson (1999) suggest that R70 recognizes an epitope within residues Y91-F108, a solvent alpha helix that borders the toxin's active site. Using peptide array, the epitope specificity has been further confined to residues N97-F108 (C. McGuinness and Mantis, unpublished data) was determined. R70's equilibrium dissociation constant (K_D) to be 3.2×10^{-9}M (McGuinness and Mantis, 2006).

Two other anti-RTA-neutralizing IgG MAbs, referred to as RAC17 and RAC18, have been described by Maddaloni et al. (2004). RAC17 is postulated to recognize amino acids H65–L68 within "domain 1" of the protein (Katzin et al., 1991), whereas RAC18 is proposed to bind a discontinuous epitope consisting of residues A178, Q177, and W211 (Maddaloni et al., 2004). Residue A178 is immediately adjacent to two residues that are part of the toxin's active site, suggesting RAC18 interferes with RTA's enzymatic activity. Indeed, this is supported by in vitro protein synthesis inhibition assays in which RAC18 prevented ricin from ribosome inactivation (Maddaloni et al., 2004). Additional anti-RTA IgG MAbs with complete or partial neutralization activity have been described (Chanh and Hewetson, 1993; Colombatti et al., 1986; Gao et al., 2002; Lemley et al., 1994), but the epitopes recognized by these antibodies have not been identified, nor have they been characterized in vivo. It should also be noted that two reports have identified anti-RTA MAbs that enhance ricin cytotoxicity in vitro and in vivo (Colombatti et al., 1986; Maddaloni et al., 2004).

It remains largely unknown how antibodies against RTA neutralize ricin. R70, for example, reduces ricin attachment to cell surfaces but not to an extent that can account for its potent neutralizing activity (McGuinness and Mantis, 2006). RAC18 interferes with RTA's capacity to arrest protein synthesis in vitro, yet it has not been investigated if toxin–MAb immunocomplexes can be internalized, trafficked, and translocated across the ER membrane into the host cell cytoplasm without disassociating. It is more likely that anti-RTA MAbs interfere with steps involved in intracellular trafficking or retrotranslocation, possibly

by blocking ricin's association with host molecules involved in these processes (Slominska-Wojewodzka et al., 2006; Utskarpen et al., 2006). In support of this model, there are some preliminary results using Vero cells that toxin–MAb immunocomplexes formed extracellularly are internalized and accumulate within the Golgi apparatus (C. McGuinness and Mantis, unpublished data).

Numerous MAbs against RTB have been described, although only two have been characterized in detail (Colombatti et al., 1986; Maddaloni et al., 2004; Mantis et al., 2006; McGuinness and Mantis, 2006). The MAb 75/3B12 is a murine IgG_1 that blocks ricin attachment to cell surfaces in vitro (Colombatti et al., 1987). Antibody recognition of RTB was competitively inhibited by the addition of lactose, but not sucrose or glucose, suggesting 75/3B12 recognizes one or both of RTB's galactose-binding domains. 75/3B12 protected mice against a lethal injection with ricin (270 ng of toxin/per animal given i.v.), although it was not as protective as R70 (Colombatti and Dosio, 2001; Lemley et al., 1994). The second well-characterized anti-RTB MAb is 24B11 (McGuinness and Mantis, 2006). In vitro, 24B11 is approximately twice as effective at neutralizing ricin as R70. The equilibrium dissociation constants of 24B11 ($K_D = 4.2 \times 10^{-9}$ M) is virtually identical to that of R70, indicating the relative differences in neutralizing activity are not due to differences in affinity for ricin. Like 75/3B12, 24B11 blocks ricin attachment to galactoside receptors on primary mouse splenocytes and on the apical surfaces of human mucosal epithelial cell monolayers. Unlike 75/3B12, however, the binding of 24B11 to RTB is not affected by galactose or galactose-containing glycoproteins. Using a phage-displayed peptide library, it was determined that 24B11 binds an epitope on RTB adjacent to, but not within, one of the two galactose-binding domains, which has led us to propose that 24B11 neutralizes ricin by steric hindrance (i.e., physically obstructing RTB from attaching to galactose residues on cell surfaces). It should be noted that the association of any MAb with RTB is not sufficient to interfere with toxin attachment. This is exemplified by TFTB-1, a murine IgG_1 MAb directed against RTB, which binds ricin as well as 24B11 but shows no detectable neutralizing activity (McGuinness and Mantis, 2006).

Mucosal Immunity to Ricin

The mucosal epithelia of the respiratory and GI tracts are vulnerable to ricin intoxication, and protecting these tissues is an important consideration when developing a ricin vaccine (Mantis et al., 2006). There is a general consensus that protection against lung injury requires antibodies in respiratory secretions to effectively intercept ricin before it can adversely affect the respiratory epithelium (Griffiths et al., 1997, 1998, 1999; Poli et al., 1996; Yan et al., 1996). For example, animals immunized parenterally (i.e., subcutaneously) with ricin toxoid were protected against a lethal aerosol challenge but suffered significant lung damage (Hewetson et al., 1995; Poli et al., 1996). Similar experiments conducted in rats immunized with ricin toxoid revealed little lung damage in immunized animals 28 days after challenge, although rats developed some symptoms during the first week after challenge (Griffiths et al., 1995). Protection against lethal challenge was associated with high titers of serum anti-ricin antibodies. Protection against lung lesions was accomplished by passively pretreating animals with an aerosolized goat IgG cocktail enriched with anti-ricin antibodies (Poli et al., 1996). Active vaccination of rats intratracheally with liposomal formulations of ricin toxoid or plant-derived RTA was associated with increased antitoxin secretory immunoglobulin A (SIgA) in lungs and protection against intratracheal challenge with ricin that was correlated with decrees in neutrophil influx into the lungs (Griffiths et al., 1997, 1998, 1999). Similar studies with ricin toxoid encapsulated in poly-lactide co-glycolide microspheres in mice vaccinated orally or intranasally have also suggested an association of more effective protection against aerosol challenge by stimulation of local SIgA (Yan et al., 1996; Kende et al., 2002).

The concept that antitoxin serum antibodies protect against death but not damage to the respiratory mucosa is reinforced by a recent paper by Smallshaw et al. (2007) in which mice were immunized intramuscularly with an attenuated RTA vaccine (RiVax) and then challenged with $10LD_{50}$s of ricin by aerosol. All animals in groups receiving the two highest doses of vaccine (10 or 3 μg three times at 4-week intervals) survived challenge, whereas other groups suffered 20–80% death rate. However, even animals immunized with the highest dose of vaccine suffered some lung damage, as assessed by plethysmography (a measure of lung function) and histological examination. Survival and lung function were correlated to total serum anti-RTA antibodies. Lung function in mice vaccinated with high-dose vaccines and having the highest anti-RTA titers returned to baseline values 3 days following aerosol exposure, although there was evidence, 21 days following exposure of mild epithelial hyperplasia, suggestive of ongoing lung repair. The actual contribution of SIgA in protecting the respiratory epithelium will not be known until similar vaccination studies are performed in

available IgA- and polymeric immunoglobulin receptor (pIgR)-deficient mice (Mbawuike et al., 1999).

In the intestinal tract, mucosal immunity to ricin in mice correlates with antitoxin IgG and IgA levels in serum as well as elevated antitoxin IgA antibodies in intestinal secretions (Yoder et al., 2007). Intragastric immunization with ricin toxoid elicits IgA antibodies against RTA and RTB that are capable of protecting polarized epithelial cell monolayers from ricin in vitro. In tissue section overlay assays, IgA MAbs against RTB blocked ricin attachment to the luminal surfaces of human duodenum, suggesting that if these antibodies were present in mucosal secretions, they would be capable of interfering with the earliest steps in the intoxication process (Mantis et al., 2006). IgA MAbs directed against RTA are equally effective at neutralizing ricin in vitro, although they have little effect on toxin attachment to epithelial cell surfaces. The availability of anti-ricin IgG and IgA MAbs (Mantis et al., 2006), in combination with a well-characterized mouse model (Yoder et al., 2007), now permits us to identify the isotypes and epitope specificities of antibodies involved in intestinal immunity to ricin in vivo.

VACCINE IMMUNOGEN CANDIDATES

The molecular immunogens proposed and studied in animal models as vaccine candidates over the last decade have progressed from plant-derived toxoid, ricin holotoxin, to isolated plant-derived subunits, such as chemically deglycosylated RTA, to recombinant derivatives of RTA and RTB. A variety of formulation approaches have been advocated with the intent of delivering as either a conventional injected vaccine with a conventional approach to immunological adjuvants, or more exploratory delivery approaches that are intended to alter the route of administration, principally for the stimulation of mucosal immunity in the lungs and the GI tract or to generate more long-lasting and robust immunity in fewer doses. In addition, the formulation approach to subunit vaccine development is aimed at providing chemical and conformational stability to the candidate immunogens. To date, the immunogens that are candidates for more advanced development have centered on the biophysical, biochemical, and immunological properties of RTA derivatives that lack either enzymatic or VLS activity (Vitetta et al., 2006; Carra et al., 2007). The focus on RTA derivatives is supported by a number of studies that indicate that protection, associated with the induction of serum neutralizing antibodies and perhaps neutralizing antibodies in mucosal secretions, can be generated by active vaccination with the A chain and supported by some of the studies described above with the high neutralizing activity of several MAbs to RTA. There are few published studies that directly compare the protection induced by RTA and RTB, but one recent study (Maddaloni et al., 2004) demonstrates a more robust protective immune response to RTA in comparison to RTB. It is intuitive that antibodies to RTB may be more efficient at the inhibition of ricin binding to galactosyl cellular receptors. However, it is surprising that RTA antibodies protect animals and neutralize in vitro unless one considers that uptake through the MR is mediated through RTA and takes into account that antibodies to the A chain may modulate the intracellular trafficking of RTA.

Ricin Toxoid and dgRTA

Treatment of ricin toxin with formalin results in a toxoid that induces protective immunity in rodents and primates (Hewetson, 1996; Franz and Jaax, 1997). Although active immunization with the toxoid vaccine protects against lethal inhalation of ricin toxin in mice, the vaccine may only partially protect against lung damage (Hewetson et al., 1995; Poli et al., 1996). Data regarding the toxoid vaccine made by the U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID) were submitted to the Food and Drug Administration (FDA) in 1995. However, clinical trials were not done with this vaccine due to concern over residual toxicity. The vaccine may not be completely inactivated, and it was difficult to obtain reproducibly inactivated batches of ricin. Published data have suggested that long-term treatment with formaldehyde may be necessary to substantially inactivate ricin (Griffiths et al., 1997). Plant-derived ricin holotoxin is extensively glycosylated, and it is well established that chemically deglycosylated native RTA (dgRTA) is effective at protecting mice against systemically administered and aerosolized ricin, although surviving mice expressed some lung damage as evidenced by elevations of albumin in bronchial fluids. Immunized mice had high levels of anti-RTA antibody in their sera (Hewetson, 1996). Bronchial fluids were not evaluated for antibody levels. dgRTA is stable as a lyophilized formulation for 22 months and after reconstitution is stable for 24 h at 4°C. Safety testing in rodents showed that female mice lost more weight than male mice, but that weight loss was not dose related and resulted from decreased food and water intakes. A single i.m. injection was associated with a local inflammatory response and degenerative

changes in the muscle that continued beyond 15 days. These changes could be related to direct muscle damage since similar symptoms have been observed in patients treated with dgRTA-containing immunotoxins (Sauseville and Vitetta, 1997). There was mild but reversible neutropenia and limited single cell necrosis in the intestinal crypt epithelium that resolved in 15 days. Hence, although this vaccine had efficacy, it also had some toxicity. In addition, it is expensive and dangerous to make, and commercial sources of dgRTA are no longer available.

Recombinant Vaccines

There are several recombinant vaccines that are in various stages of development by different groups. Three of these candidates have been recently described in the literature, and all of them are derived from RTA (McHugh et al., 2004; Smallshaw et al., 2002; Marsden et al., 2004) The isolated A and B subunits of ricin can be produced in *E. coli* and other recombinant hosts. RTB is also a candidate for inclusion in a vaccine, especially when protection is focused on mucosal compartments (Maddaloni et al., 2004). Although RTA in the absence of RTB is at least 1000-fold less toxic than the native ricin, it still retains residual enzymatic activity that may result in toxicity when used as a vaccine (Thorpe et al., 1985).

One approach to making an RTA vaccine has involved creating a double mutant of RTA containing both a single mutation in its enzymatic site (Y80A) and mutations in the vascular leak site (V76M). Several variants have been initially characterized, of which one has been studied in great detail and produced for clinical trials (Smallshaw et al., 2002). This vaccine has been given the trade name RiVax, has progressed through preliminary mouse protection studies and rabbit good laboratory practice (GLP) toxicology, and has been evaluated in a Phase I safety and immunogenicity trial in a "trial" formulation.

Another RTA-based vaccine candidate has been produced by inserting a peptide into a surface-exposed loop of RTA distal from the active site. This mutant has substantially reduced catalytic activity, resistance to proteolysis, and virtually no cytotoxicity. It induced immunity to systemic ricin challenge in mice (Marsden et al., 2004).

A third approach to an RTA vaccine has involved a structural approach to eliminate parts of the A chain that are implicated in low thermostability of RTA (McHugh et al., 2004). This particular candidate contains an internal deletion that improves solubility and an extensive deletion in the carboxy-terminal region, resulting in stability in aqueous solutions under a variety of conditions. This vaccine candidate is more stable to thermal denaturation than the parental native RTA and protects mice against ricin lethality (Olson et al., 2004).

Each of these candidates protects mice from ricin exposure and appears to contain the epitopes that have been characterized from the study of the human response of cancer patients given multiple doses of RTA-antibody conjugate immunotoxin to which antibodies to the A chain had developed. These studies have determined that there is a single, major linear B cell determinant in the A chain that is associated with ricin neutralization in cell-based assays (L161-E185) (Tommasi et al., 2001; Castelletti et al., 2004). This epitope is contained in a single helical loop that impinges upon the active site. A second epitope described by the peptides that bound to a neutralizing MAb, located in an exposed loop (residues 95–110) (Lebeda and Olson, 1999), is also present in each of the vaccine candidates. These two epitopes have been characterized as being involved in ricin neutralization. The neutralizing antibody that has been described by Pincus (MAb 18) (Maddaloni et al., 2004) and discussed above is thought to overlap the active site but has not been mapped to a linear peptide. It may be a conformationally dependent neutralizing epitope. There may be additional conformationally dependent epitopes or other linear B and T cell epitopes that have not yet been characterized in animal or human studies. The introduction of mutations in or near the active site has the possibility of disrupting nearby B cell epitopes, which raises the concern that vaccine immunogenicity can be affected in some of the candidates (Marsden et al., 2005).

PRECLINICAL AND CLINICAL STUDIES

There are several key factors in manufacture and formulation that impinge upon the development of any of the ricin vaccine candidates mentioned above. The success of vaccine studies in the research stage can reveal that a vaccine has the appropriate characteristics to induce protective immunity in a relevant animal model and later in development considerations of manufacture and formulation with adjuvants, and delivery systems become extremely important as the vaccine progresses toward Phase I and II human testing (and pivotal animal trials). RTA is known to be extremely thermally unstable in aqueous buffers, but conditions that allow for retention of maximal conformational stability can be identified (Peek et al., 2007)

for molecules closely related in structure to RTA, such as RiVax immunogen (Smallshaw et al., 2005). This vaccine candidate induces rabbit and human antibodies that are neutralizing in an in vitro cell-based assay, which indicates the total functionality of the antibodies (Vitetta et al., 2006; Smallshaw et al., 2005) and is likely to predict the capacity of a serum to protect an animal. Furthermore, those antibodies, purified and passively transferred to naive mice, protect against parenteral challenge.

A high-yield current good manufacturing practice (cGMP) fermentation and purification process for RiVax has been developed and implemented at a scale anticipated to be in the range for commercial production (Brey et al., unpublished data). It is now known, based on crystal structure data, that this protein is identical in structure to native RTA (Charles Millard, unpublished data), indicating that the point mutations contained in the molecule do not disrupt any potential tertiary structure (or potential conformationally dependent epitopes). At the same time, this molecule is known to induce antibodies that compete with known neutralizing MAbs, suggesting that the important complement of structural epitopes is still contained within the molecule. The aqueous stability of RiVax can be improved by the addition of excipients and the optimization of pH and salt conditions, which among other things can modify water structure, and the drug substance (the protein per se) can be maintained in solution in the presence of glycerol for up to 2 years or longer without loss of conformation and physical properties. The physical properties of the protein are associated with the ability of the protein to induce protective immunity in animal models and protective antibodies in humans. The presence of glycerol results in a 10°C increase in the melting temperature of RTA, the point at which the protein begins to unfold and aggregate irreversibly. The relevance of stability in solution is thought to relate to long-term stability that would be required if the vaccine were produced for a stockpile that would be used only under emergency conditions or in very limited target populations. The real stability issue concerns the final formulation of the vaccine rather than the solution stability per se, and the stability concerns the endpoints that are not necessarily totally related to conformation, that is, the ability to induce protective immunity or correlates of protective immunity. The ideal vaccine would have high thermal stability that would be predictive of long-term storage under ambient conditions or under refrigeration, but those conditions must be evaluated with the final clinical or marketable formulations.

The RTA1-33/44-198 vaccine candidate has elements of built-in solution stability resulting from the deletion of regions and residues that otherwise are obscured by RTB in the holotoxin (McHugh et al., 2004; Carra et al., 2007). This vaccine has also been formulated with aluminum salt adjuvants, and recent evidence suggests that it contains long-term stability while bound to aluminum adjuvants in terms of potency in a mouse model of protection against ricin challenge.

A recent study of RiVax was conducted with an investigational formulation that did not contain an immunological adjuvant and was stabilized against gross aggregation by the inclusion of sucrose and Tween detergent (Vitetta et al., 2006). A safety and immunogenicity trial was performed with this formulation with the motive of addressing the potential toxicity of the subunit in the absence of any potential interference from an adjuvant. The vaccine was safely tolerated at doses up to 100 μg given three times at monthly intervals, with little evidence of local side effects attributable to the immunogen. More importantly, the vaccine stimulated seroconversion in a dose-dependent manner, and antibodies purified from seroconverters mixed with ricin toxin were protective upon transfer to mice. The fact that human serum also contained antibodies that neutralized ricin in a cell-based assay (Daudi cells, a human B cell line) indicates that humans, rabbits, and mice are capable of generating protective and functional antibodies elicited by a totally inactive RTA. More recent unpublished studies have indicated that RiVax, similarly to RTA1-33/44-198, maintains potency in a dose-dependent manner for long periods of time when adsorbed to aluminum hydroxide (Alhydrogel®), suggesting that adsorption of a relatively unstable protein immunogen to the crystalline surface may aid in the long-term stability of the vaccine. This aluminum adjuvant version of this vaccine is currently being evaluated in nonhuman primate trials to examine the potential of this vaccine to protect against lethality and lung damage after parenteral vaccination. Concurrently, human trials are underway to establish an optimized dosage regimen and dose level that can be correlated to protection in the most relevant animal model.

The most relevant animal model is a nonhuman primate model, and Rhesus macaque and African green monkey models have been developed (Chad Roy, Tulane University, personal communication), but other mammalian species, such as the rabbit, develop neutralizing antibodies in response to RTA vaccines (Smallshaw et al., 2005) and are susceptible to ricin. In developing the correlates of immunity and pathology during vaccine development, there is no way to know the actual dose of ricin to which a human might become exposed, but there is a way of examining extreme situations of high-dose exposure in animal

models and beginning to correlate the outcomes of those extremes with immune responses in humans. For example, if a certain vaccine dosage regimen is shown to protect against a high-dose aerosol challenge that induces significant pathology in unvaccinated animals, the levels and duration of antibodies in serum and secretions can be determined and used in functional assays of antibody activity, including avidity, neutralization, and passive transfer to naive animals. However, the actual measure of pathology, such as inflammatory markers, local cytokines, chemokines, influx of neutrophils, and microarray analysis of upregulated genes, can be performed only in a challenged animal.

Further development of these vaccine candidates in human clinical trials is dependent on establishing the relevant correlates of immunity in animal models that will include endpoints of lung pathology, inflammation markers, as well as the determination of functional antibodies in serum and mucosal secretions.

PROSPECTS FOR THE FUTURE

Recombinant subunit vaccines for ricin based on RTA have been shown to induce antibodies that are protective in rodent models and correlated with protection against ricin exposure by aerosol and oral exposure in rabbits and humans. That is, the antibodies present in the serum are neutralizing in vitro and can passively convey protection to naive animals. The role of secretory antibodies and possibly other effector mechanisms may implicate compartmentalization of responses and suggest that these antibodies can function to prevent binding of toxin to luminal cell surfaces. Thus, the role of secretory antibodies in preventive vaccination may be important in protecting epithelial surfaces against toxin exposure. Equally, the possible transudation of antitoxin IgG across luminal surfaces may aid to inactivate toxin prior to binding. Therefore, it may be possible to induce protective immunity to mucosal tissue damage, primarily through stimulation of humoral antibodies. This remains to be thoroughly tested in animal models. The current data indicate that RTA subunit vaccines, in common with prior vaccine candidates, can induce protection against lethal toxin exposure but may not completely prevent all morbidity; this, of course, is related to toxin dose exposure.

A vaccine for ricin toxin will have utility solely as a biodefense countermeasure, as there is no burden of human or animal disease. The existence of vaccines in an advanced state of development and readiness for production is key to several key objectives: first, to provide a deterrent to further development of the toxin weapon and, second, to provide a vaccine that can actually be used in emergency situations prior to marketing authorization by the FDA and other regulatory authorities while the vaccine is proceeding through pivotal animal and human safety/immunogenicity trials. A vaccine for ricin may provide the best approach since postexposure therapy must be instituted within a very narrow window after exposure, and once the toxin has stimulated an inflammatory cascade, it cannot be counteracted by antitoxin antibodies. The similarities of the action of ricin and Shiga toxins and the connections to the induction of inflammatory cascades provide additional leads into areas of therapeutics development for ricin poisoning per se and for HUS.

KEY ISSUES

- Long-term stability of vaccine formulations. A stockpile of vaccine that is not intended to be used in routine immunization must have long-term stability, possibly at storage temperatures that avoid the cold chain.
- Determination of the correlates of immunity in appropriate animal models. The U.S. FDA has mandated development of well-understood animal models that are to be used as correlates of protection in human vaccine studies. The correlates of immunity involve most likely antibodies that can be evaluated for functionality in vitro and in vivo by passive transfer. A vaccine for ricin would probably have an indication that involves the description of a respiratory exposure endpoint.
- The major question in human studies is the magnitude as duration of protective antibodies and how to induce them most effectively
- A parenterally administered vaccine, for instance, by i.m. injection, is expected to induce primarily serum antibodies to the subunit and little secretory IgA. The role of antibodies present at the mucosal surface arising from parenteral vaccination is not clear and may be critical to the degree of protection to aerosolized toxin.

Rickettsia

Xuejie Yu, Nahed Ismail and David H. Walker
Department of Pathology, Sealy Center for Vaccine Development, Center for Biodefense and Emerging infectious Diseases, University of Texas Medical Branch, Galveston, TX, USA

OUTLINE

ABSTRACT

Among the 17 named species of the Rickettsiaceae that have been documented to cause human illness, 5 are significant threats of a fatal outcome, namely *Rickettsia rickettsii*, *Rickettsia prowazekii*, *Orientia tsutsugamushi*, *Rickettsia typhi*, and *Rickettsia conorii*. These *Rickettsia* can be obtained in nature, propagated by available methods, and prepared in a stable state of infectivity by a low dose. Thus, they could be used by terrorists. After a series of attacks, the public would seek to receive a protective vaccine. Rocky Mountain spotted fever, louse-borne typhus, and scrub typhus are currently reemerging infectious diseases with increasing incidence. Epidemic louse-borne typhus requires a vaccine to control large epidemics that occur in association with natural and manmade disasters including wars. The vast majority of emerging rickettsial diseases have existed for eons, are seldom life threatening, and were only discovered recently: African tick bite fever (*Rickettsia africae*), Flinders Island spotted fever (*Rickettsia honei*), Japanese spotted

fever (*Rickettsia japonica*), tick-borne lymphadenopathy (*Rickettsia slovaca*), maculatum spotted fever (*Rickettsia parkeri*), flea-borne spotted fever (*Rickettsia felis*), the unnamed eschar-associated infections (*Rickettsia aeschlimannii* and *Rickettsia massiliae*), and the unnamed infection caused by *Rickettsia monacensis*. Other rickettsioses (North Asian tick typhus, *Rickettsia sibirica*; Queensland tick typhus, *Rickettsia australis*; rickettsialpox, *Rickettsia akari*) are rarely severe illnesses. A vaccine should be developed against *R. prowazekii* and would likely provide good crossprotection against *R. typhi*. Because *R. rickettsii* is the most virulent *Rickettsia* and genetic engineering to complete antibiotic resistance is highly feasible, development of a vaccine against Rocky Mountain spotted fever would be a very wise biodefense strategy. Such a vaccine would very likely provide crossprotection against other spotted fever group rickettsiae. The preparation of a vaccine that protects against all *Rickettsia* species is a genuine possibility. Such a vaccine would have a commercial value for use in travelers, especially those going on safari in southern Africa, where more hunters and tourists suffer from African tick bite fever than malaria.

Development of a vaccine that is protective against scrub typhus poses tremendous challenges owing to transient active immunity and vast antigenic diversity of the agent.

HISTORY OF RICKETTSIAL DISEASES

Records of the recognition of diseases that are now known to be caused by rickettsiae were clearly described by Ge Hong (scrub typhus) in 313, Hieronymus Fracastorius (epidemic typhus) in 1546, E.E. Maxey (Rocky Mountain spotted fever) in 1899, and Conor (boutonneuse fever) in 1910. Two pathologists, Louis Wilson of the Minnesota State Board of Health and William Chowning of the University of Minnesota, described the geographic and seasonal distribution, the clinical features of the severe form of Rocky Mountain spotted fever, age- and gender-specific incidence and case fatality rate, and pathologic lesions. They determined the absence of a conventional bacterial agent and predicted an infectious etiology and tick vector. Their erroneous identification of intraerythrocytic protozoa as the cause led to the investigations of Howard Ricketts, who between 1906 and 1910 proved that Rocky Mountain spotted fever was an infectious disease transmitted by tick bite that resulted in solid protective immunity. Experimental retention of infectivity by Berkefeld filters led to his prediction that the agent would be visible microscopically, which was supported by his visualization of small diplobacilli in blood and ticks. That the agent was in fact a novel type of obligately intracellular bacterium was established by its histochemical detection in endothelial cells of infected humans and in ticks by S. Burt Wolbach between 1916 and 1919, propagation in embryonated chicken eggs by Herald Cox in 1938, recognition of the therapeutic efficacy of tetracycline and chloramphenicol in the late 1940s and early 1950s, visualization in living cell culture by Mosielo Schaechter in 1957, and electron microscopic characterization as gram-negative cytosolic organisms by Anderson in 1965.

The clinical similarities of typhus and Rocky Mountain spotted fever were recognized by physicians prior to the discovery of the causative agents. A patient diagnosed as having typhus by the world's foremost physician William Osler died and was examined postmortem by the father of American academic pathology, William Welch, at Johns Hopkins University in 1903. Later reexamination of the tissues by immunohistochemistry revealed that the patient had actually died of Rocky Mountain spotted fever, which was not recognized to occur in the eastern US until more than 25 years later.

The early discoveries relied upon experimental transmission of infectivity from human blood or vector arthropods to guinea pigs and nonhuman primates. The vector-association of these diseases was also discovered in early studies such as that of Charles Nicolle, who demonstrated experimentally in 1909 that typhus was transmitted by human body lice. The recognition that *Rickettsia prowazekii* is the etiology of typhus relied upon observations of Ricketts and von Prowazek, who both died of typhus, da Rocha-Lima, and Wolbach, who visualized the bacteria in humans, experimental lesions and lice, which were used as a means of cultivation by xenodiagnosis.

Recrudescent typhus fever was described clinically by Nathan Brill in 1896 and 1910, and was shown by Hans Zinsser in 1934 to be caused by reactivation of latent *R. prowazekii* infection. A similar illness, now known as murine typhus, was differentiated clinically and epidemiologically from other typhus fevers by Maxey in 1926, and Dyer isolated the agent, *Rickettsia typhi*, from rats and fleas, the natural zoonotic cycle, in 1931.

Other spotted fevers and their agents continue to be discovered around the globe. An illustrative example is African tick bite fever, which was described clinically by MacNaughton in southern Africa in 1911, and was distinguished from boutonneuse fever by Pijper in 1936. Not until 1996 was the agent rediscovered and designated taxonomically as *Rickettsia africae*. Other spotted fever group (SFG) rickettsioses and rickettsiae were identified by Mill (North Asian tick typhus) in 1936 and Krontovskaya (*Rickettsia sibirica*) in 1938;

rickettsialpox by Shankman and *Rickettsia akari* by Huebner in 1945; Queensland tick typhus and *Rickettsia australis* by Andrew reported in 1946; Japanese spotted fever by Mahara in 1984 and its causative agent, *Rickettsia japonica*, by Uchida in 1992; Flinders Island spotted fever by Stewart in 1991 and its etiologic agent, *Rickettsia honei*, by Stenos in 1998; *Rickettsia slovaca* in 1976 and the disease that it causes, tick-borne lymphadenopathy, by Lakos in 1997; *Rickettsia parkeri* by Lackman in 1949 and the first human infection by Paddock in 2004; *Rickettsia felis* and its human infection first reported by Azad in 1994.

Pioneering studies of these organisms included investigations of metabolic activities of the bacteria separated from their host cells by Bovarnick in 1949, of rickettsial antigens by Shepard in 1945, of rickettsial proteins by Anacker in 1983, and the genome of *R. prowazekii* by Andersson in 1998.

Orientia tsutsugamushi were visualized as intracellular organisms in smears from animals by Nagayo in 1924. In 1929 Ogata passaged the organism 80 times in rabbit testis and also observed them in stained macrophages. Three years later he developed the method for isolation of *O. tsutsugamushi* by intraperitoneal inoculation of mice. In 1995 Tamura separated *Orientia* into its own genus on the basis of significant genetic divergence and phenotypic differences from *Rickettsia*.

ETIOLOGIC AGENTS

Classification

The family Rickettsiaceae includes the genera *Rickettsia* and *Orientia*, which are small gram-negative, obligately intracellular bacteria that reside in the cytosol of host cells. *Rickettsia* (0.3–0.5 × 0.8–1.0μm) are smaller than *Orientia* (0.5–0.8 × 1.2–3.0μm). *Rickettsia* organisms have undergone genome reduction resulting in a smaller genome (approximately 1Mb) than *Orienta* (2.4–2.7Mb), and has lost genes encoding enzymes for sugar metabolism, lipid biosynthesis, nucleotide synthesis, and amino acid synthesis. Although *Rickettsia* can synthesize adenosine triphosphate (ATP), *Rickettsia* are also energy parasites. They transport ATP into the rickettsiae from the host cell cytoplasm using the ATP/ADP translocase, which is unique to *Rickettsia* and another intracellular bacterium *Chlamydia* (Andersson et al., 1998; Plano and Winkler 1991).

Rickettsia

Organisms in the genus *Rickettsia* are divided into two antigenically distinct groups based on their lipopolysaccharide (LPS): the typhus group (TG) and the SFG as well as an ancestral group and transitional group.

TG rickettsiae include two species: *R. prowazekii*, the agent of epidemic typhus, and *R. typhi*, the agent of murine typhus. SFG rickettsiae include 16 validated species and numerous unvalidated rickettsial species. However, most of these named SFG rickettsiae are so closely related that they could be considered strains of a single species. There is less than 0.5% divergence of the 16S rRNA gene among the core species of SFG rickettsiae including *Rickettsia rickettsii*, *Rickettsia conorii*, *R. sibirica*, *R. africae*, *R. parkeri*, *R. slovaca*, and many others. The tick-borne SFG rickettsiae range from avirulent to highly virulent. Studies of rickettsial phylogeny have led to a proposal to consider *R. akari*, *R. australis*, and *R. felis* as the transitional group branching between the TG and SFG and an ancestral group that includes *Rickettsia bellii* and *Rickettsia canadensis* (Vitorino et al., 2007).

Multiplication of *R. rickettsii* occurs primarily in the cytoplasm, but intranuclear growth is sufficiently prominent to have stimulated early investigators to use it as a criterion for the classification of SFG. Because of cell-to-cell spread via actin-based mobility and greater cytopathogenicity, plaques on monolayers occur earlier and are larger than in the case of TG rickettsiae.

Orientia

Genus *Orientia* contains a single species, *O. tsutsugamushi*, which was formerly called *Rickettsia tsutsugamushi. Orientia* possess an unusual gram-negative cell wall that lacks LPS and peptidoglycan (Amano, et al., 1987). The outer leaflet of the cell wall is considerably thicker than the inner leaflet, while the opposite is true of *Rickettsia* (Silverman and Wisseman, 1978). The diversity among strains of *O. tsutsugamushi* is greater than the diversity among the species of *Rickettsia* as determined by the 16S rRNA gene. Phylogenetic analyses based on homologies of 56-kDa type-specific antigen genes classify *Orientia* isolates from China, Korea, Japan, and Southeast Asia into seven genotypes. All isolates originating in southeast Asia, including the prototype Gilliam and Karp strains isolated in Burma and New Guinea, respectively, are distantly located in the phylogenetic tree from those isolates in Japan, Korea, and China, indicating that strains of *O. tsutsugamushi* distributed in northeastern and southeastern Asia have diverged evolutionarily (Enatsu et al., 1999).

Rickettsial Antigens

The major antigens of *Rickettsia* that are recognized by the humoral immune response are LPS, lipoprotein,

outer membrane proteins (OMPs), and heat shock proteins. The Weil–Felix reaction was used as a presumptive diagnostic test for rickettsial diseases. It is based on the crossreaction of antibodies to rickettsial antigens from primary rickettsial infections, apparently owing to IgM, with the antigens of two bacteria: *Proteus vulgaris* (OX19 or OX2) and *Proteus mirabilis* (OXK). They do not elicit an anamnestic antibody response in recrudescent typhus. The antibodies of Japanese spotted fever patients are reactive with the LPS of OX2 as well as OX19. The antibodies of scrub typhus patients recognize OXK LPS only (Amano et al., 1996). Thus, the crossreactive antigens between rickettsiae and *Proteus* are most likely present in the LPS. The *O*-polysaccharides of typhus rickettsial LPS are composed of glucose, glucosamine, quinovosamine, and phosphorylated hexosamine, which are also found in the *O*-polysaccharide of the LPS from *P. vulgaris* OX19 used in the Weil–Felix test, suggesting that they may represent the antigens common to LPS from TG rickettsiae and *P. vulgaris* OX19 (Amano et al., 1998). *O. tsutsugamushi* lacks LPS.

A 17-kDa-protein is a genus-common protein of rickettsiae and has been identified in all *Rickettsia* species examined (Anderson, 1990). The sequences of the 17-kDa-protein gene are conserved among rickettsial species, indicating the importance of it to the survival of the rickettsiae. The protein is predicted to be a lipoprotein, and part of the protein is surface exposed. Thus, it has been speculated that the 17-kDa protein may play a scaffolding and protective role in the rickettsiae (Anderson, 1990).

All rickettsiae have a 135-kDa outer membrane protein B (OmpB) that has been identified as an S-layer protein of rickettsiae (Ching et al., 1990). OmpB is the most abundant rickettsial surface protein, and it contains species-, group-, and genus-specific epitopes (Anacker et al., 1987a, 1987b). OmpB consists of 10–15% of the total cellular protein and is released as a soluble fraction, when the cells are suspended in hypotonic solution lacking Mg^{2+} and are incubated at 45 °C for 20 min (Dasch, 1981). The amino acid sequence of OmpB is very conserved among *Rickettsia* species.

Spotted fever and transitional group rickettsiae have an additional outer membrane protein, OmpA, which contains a hydrophilic region of tandem repeat units, that comprises over 40% of the amino acid sequences (Anderson, 1990). The repeat units are not identical and thus are divided into three types with type I of 75 amino acids, type II of 72 amino acids, and type III of 85 amino acids. The type II repeats are less conserved and are further divided into two subtypes (IIa and IIb) (Anderson, 1990). The *ompA* sequences upstream and downstream of the repeat region are conserved among SFG rickettsial species. Although the sequences of the repeat units are conserved among *R. rickettsii*, *R. conorii*, and *R. akari*, the number and the order of arrangement of the repeat units are varied among SFG rickettsiae (Gilmore, 1993); however, the type III of repeat unit that is found in *R. australis* differs greatly from other SFG rickettsial repeat units. *R. australis* contains only type III repeat units, which have only 21% identity to the type I repeat of *R. rickettsii* (Stenos and Walker, 2000). The antigenic diversity of SFG rickettsiae is determined in large part by the number, order, and type of repeat units.

OmpA of *R. felis* is truncated by a premature stop codon at one-third of the sequence from the N-terminus of the protein. *Rickettsia peacockii*, a tick symbiont, does not express OmpA, and the *ompA* of *R. peacockii* contains a deletion of G at 403 bp and insertions of GT and A following 4872 and 5828 bp, respectively, resulting in premature stop codons (Baldridge et al., 2004). The *ompA* of avirulent *R. rickettsii* Iowa strain was also interrupted by a nucleotide deletion that introduces a stop codon truncating *ompA* at 660 bp from the start codon (Ellison et al., 2008).

O. tsutsugamushi Antigens

SDS-polyacrimide gel analysis reveals as many as 30 proteins of *O. tsutsugamushi*, and it is difficult to correlate the molecular sizes of the proteins in different studies (Tamura et al., 1985; Hanson, 1985; Stover, et al., 1990). The most abundant antigen of *O. tsutsugamushi* is the 56 kDa surface protein (Tamura et al., 1985). It comprises 10–15% of the total bacterial cellular protein content, and it is the most immunodominant protein (Hanson, 1985; Ohashi, et al., 1989, 1988). The 56-kDa protein varies among geographic isolates of *O. tsutsugamushi* and thus is designated the type-specific protein (Ohashi et al., 1992). The 56-kDa protein has the feature of transmembrane proteins with alternating hydrophobic and hydrophilic regions. Analysis of the 56-kDa protein of *Orientia* variants revealed four variable domains with spans of 16–40 amino acids. The variable domains are located in the hydrophilic regions of the molecule that are likely surface exposed and have different amino acid sequences among the strains (Ohashi et al., 1992).

Another major immunodominant protein is the 60-kDa protein, which is the homolog of the GroEL (heat shock) protein family (Ohashi et al., 1988) (Stover et al., 1990). Genetic analysis of the DNA sequences of *groESL* of several geographic foci revealed a limited number of variants within each focus and diversity of strains from focus to focus.

CLINICAL DISEASE

Rickettsial diseases are characterized by systemic symptoms at onset: fever, severe headache, and muscle

aches. The characteristic maculopapular rash typically appears 3–5 days later. In severe disease, petechiae subsequently appear in the center of the maculopapules. The rickettsioses that are usually less severe such as African tick bite fever and murine typhus have a lower incidence of rash. However, a small portion of patients with fatal Rocky Mountain spotted fever have no rash but suffer lethal damage to vital organs such as the brain and lungs. Erythematous maculopapules are difficult to see in darkly pigmented skin. The rash in Rocky Mountain spotted fever is described as centripetal, beginning on the wrists and ankles and later appearing on the trunk and vice versa for epidemic typhus, a centrifugal rash. However, this generalization is not a constant observation. Great emphasis is placed on the involvement of the palms and soles in SFG rickettsioses, but a significant fraction do not have this manifestation, and in others it appears late in the course. Early in the course of Rocky Mountain spotted fever, nausea, vomiting, and abdominal pain occur more often than rash. Focal skin necrosis with a dark scab (an eschar) at the site of tick or mite feeding is a common feature of boutonneuse fever, African tick bite fever, rickettsialpox, North Asian tick typhus, Queensland tick typhus, Japanese spotted fever, Flinders Island spotted fever, and tick-borne lymphadenopathy, but is rare in Rocky Mountain spotted fever, and nonexistent in epidemic and murine typhus.

Systemic vascular infection in Rocky Mountain spotted fever results in encephalitis, leading to stupor (25%), coma (10%), and seizures (8%), as well as interstitial pneumonia and noncardiogenic pulmonary edema causing cough (33%), pneumonitis (15%), and even adult respiratory distress syndrome. Hypovolemia and hypotensive shock lead to acute renal failure. In the preantibiotic era the case fatality rates were 23% for Rocky Mountain spotted fever and 15% for epidemic louseborne typhus. Currently case fatality rates are still significant: approximately 4% for Rocky Mountain spotted fever, boutonneuse fever, and epidemic typhus and 1% for murine typhus, largely owing to misdiagnosis or late diagnosis leading to treatment with ineffective antibiotics or delayed effective antirickettsial treatment.

Scrub typhus frequently manifests an eschar at the site of chigger (larval mite) feeding during the incubation period. Regional lymphadenopathy, fever, headache, and myalgias begin abruptly. Hearing loss is present in a third of cases. Conjunctival redness and generalized lymphadenopathy are frequently present. The occurrence of rash is variable. Cough, tachypnea, and radiologic pulmonary infiltrates are frequent presenting findings as are confusion and mild personality changes. Severe cases may manifest adult respiratory distress syndrome, acute renal failure, and hypotensive shock. In the preantibiotic era, case fatality rates varied drastically from less than 1 to 30%.

Animal Models

Guinea Pig

Guinea pigs are the standard animal model for Rocky Mountain spotted fever and epidemic typhus. After infection with rickettsiae, guinea pigs develop fever and scrotal swelling. A fatal outcome may occur in *R. rickettsii* infection. Guinea pigs also develop humoral and cellular immune responses. Rickettsiae can be isolated from blood, liver, spleen, and testes. Development of illness depends on the strain of guinea pigs, route of inoculation, and dose. Rocky Mountain spotted fever can be induced experimentally in Hartley strain guinea pigs by the subcutaneous, intraperitoneal, intranasal, aerosol, or conjunctival route. Aerosol, intranasal, and subcutaneous routes are the most sensitive, and guinea pigs can be infected by as low a dose as one organism via these routes. The conjunctival route is less sensitive; 10^6 organisms are required to infect guinea pigs (Kenyon, et al., 1979).

Nonhuman Primates

A rhesus monkey (*Macaca mulatta*) model has been used for both Rocky Mountain spotted fever and epidemic typhus (Saslaw et al., 1966). Due to the limited availability of the rhesus monkey, a cynomolgus (*Macaca fascicularis*) monkey model was developed for further vaccine testing for both Rocky Mountain spotted fever and epidemic typhus. Both monkey species develop clinical signs similar to epidemic typhus and Rocky Mountain spotted fever in humans.

For Rocky Mountain spotted fever, the severity of the disease in the monkey depends on the route and dose of the rickettsial inoculation. When 100 organisms are inoculated into monkeys via the intravenous route, 100% of monkeys develop fever, and 85% of them die. Subcutaneous inoculation requires a higher dose than intravenous inoculation and yields inconsistent results. Aerosol inoculation is the most sensitive means of transmission, causing 100% of monkeys to develop fever and 75% die with as small a dose as one organism. The incubation period is 3–9 days, and is not dependent on the inoculation route or the dose. The most frequently observed microscopic lesions are vasculitis and thrombosis of the capillaries, arterioles, and venules of in numerous tissues. The lesions are characterized primarily by perivascular infiltration of lymphocytes and plasma cells. Coagulopathy occurs in some monkeys. Blood chemistry changes include mildly increased leukocyte counts due to an absolute neutrophilia during the febrile period. Skin rashes are

less frequently observed in cynomolgus than in rhesus monkeys due to the darker cutaneous pigmentation of the cynomolgus monkey (Gonder, et al., 1979).

Monkeys are susceptible to *R. prowazekii* infection and develop clinical signs of illness and pathological changes characteristic of epidemic typhus infection in humans. Monkeys can be infected with 10^3 organisms when rickettsiae are injected intravenously. However, intravenous inoculation of 10^7 plaque-forming units of *R. prowazekii* are required for the monkeys to develop clinical signs of illness and pathological changes characteristic of epidemic typhus infection in humans. The incubation period is 1–9 days, and is longer for the low dose inoculum. Typical typhus nodules are observed in the brain (Gonder et al., 1980).

Monkeys are not a good disease model for scrub typhus although they have been used for scrub typhus studies since 1918. The early studies used wild silver leaf monkeys, and difficulty in maintaining the silver leaf monkeys in captivity prompted investigators to use cynomolgus monkeys. The only detectable signs of infection in monkeys are an eschar at the site of intradermal inoculation of *O. tsutsugamushi* and rickettsemia. Rickettsemia lasts 1–2 weeks (Chattopadhyay et al., 2005).

Mice

The C3H/HeN mouse inoculated intravenously with *R. conorii* provides an excellent model for boutonneuse fever, and intravenous inoculation of *R. typhi* is an excellent model of epidemic typhus or murine typhus. These intravenous infection mouse models faithfully represent the human infections in the aspects of disseminated endothelial infection and injury, cellular immune response, histopathology of the vascular lesions, critical target organs with characteristic life-threatening lesions such as meningoencephalitis and interstitial pneumonia (Feng et al., 1994; Walker et al., 1994, 2000). Some mouse strains intravenously inoculated with other SFG rickettsiae also develop rickettsial disease associated with disseminated endothelial infection by rickettsiae, e.g., *R. australis* in Balb/c mice and *R. sibirica* in C3H/HeN, Balb/c, or Swiss-Webster mice.

PROTECTIVE IMMUNE RESPONSE

Although most natural infections with *Rickettsia* enter via the skin, most animal models characterizing immune responses to this pathogen employ intravenous inoculation to initiate infection. Thus, most studies of infection with SFG or TG rickettsiae focus on immune responses to systemic *Rickettsia* infection. In contrast, dermal immune responses to infection with *Rickettsia* are less well characterized but are increasingly the focus of investigation. Most of our understanding of the immune response against *Rickettsia* is derived from in vitro studies as well as the murine models of rickettsioses.

Innate Response

Following infection with *Rickettsia*, innate immune responses are rapidly triggered and contribute to host survival, as indicated by the impact of infection on mice that lack various molecules with important innate immune functions such as IFN-γ, tumor necrosis factor-alpha (TNF-α), and NK cells. IFN-γ and TNF-α are essential for primary defense against infection with *Rickettsia*, and mice that lack these cytokines rapidly succumb to infection (Walker et al., 2000; Billings et al., 2001; Feng et al., 1994; Feng and Walker, 1993). IFN-γ and TNF-α mediated resistance is partly attributed to the production of microbicidal effector molecules such as nitric oxide (NO) (Feng et al., 1994; Feng and Walker, 1993; Walker et al., 1993; Feng and Walker, 2000). Mice that lack these cytokines have decreased NO production and an overwhelming rickettsial infection (Feng et al., 1994). Similarly immunocompetent mice treated with NO synthesis inhibitor N^G-monomethyl-l-arginine (N^GMMLA) fail to control rickettsial growth (Feng et al., 1994). Mouse endothelial cells activated in vitro with IFN-γ and TNF-α trigger the expression of inducible NO synthase (iNOS), an enzyme involved in NO production, and control rickettsial infection (Feng and Walker, 1993, 2000; Walker et al., 1993).

IFN-γ is essential for resistance to *Rickettsia* infection, and multiple cell types have the ability to rapidly secrete IFN-γ (Yeaman et al., 1998; Ohteki et al., 1999; Munder et al., 1998; Fultz et al., 1993). NK cells are a major source of IFN-γ early in rickettsial infection (Billings et al., 2001). The activity of NK cells is increased early during the course of murine infection with *R. typhi* and *R. conorii*. Depletion of NK cells results in increased rickettsial infectivity titers in the spleen of infected mice (2). NK cells secrete IFN-γ in response to IL-12 (Pillarisetty et al., 2005; Gerosa et al., 2005). IL-12 is a cytokine produced mainly by activated monocytes, macrophages, and B cells and has immunoregulatory effects on NK cells and T cells (Gately et al., 1998). IL-12 and IFN-γ are both important components of the Th1 immune response that effectively controls intracellular pathogens including *Rickettsia* (Walker et al., 2000; Biron and Gazzinelli, 1995).

Several lines of evidence point to the protective role of proinflammatory cytokines such as IL-1 and TNF-α

in host defense against *Rickettsia* (Sporn and Marder, 1996; Vitale et al., 1999). In vitro activated macrophages and endothelial cells infected by *R. conorii* or *R. rickettsii* synthesize proinflammatory cytokines such as TNF-α and IL-6 (Manor and Sarov, 1990; Kaplanski et al., 1995). Production of bactericidal NO by LPS-activated endothelial cells is dependent on endogeneous production of IL-1α and TNF-α. In an animal model of SFG rickettsiosis employing a sublethal dose of *R. conorii*, depletion of TNF-α results in fatal infection, with high rickettsial burden in endothelial cells, macrophages, and hepatocytes (Feng et al., 1994; Feng and Walker, 1993), suggesting a protective role of TNF-α in host response against *Rickettsia*. The biologic activities of TNF are mediated by two structurally related, but functionally distinct, tumor necrosis factor receptors (TNFR), p55 and p75 (Locksley et al., 2001; Mauri et al., 1998; Monastra et al., 1996). TNFRp55 is the primary signaling receptor on most cell types through which the majority of inflammatory responses and antimicrobial host defenses classically attributed to TNF occur. High plasma levels of soluble TNF-receptors, mainly TNFRp55, are present in patients with severe Mediterranean spotted fever (MSF) (Vitale et al., 2001). These data suggest that soluble TNFR released into the circulation of patients with severe rickettsiosis binds to the secreted or membrane form of TNF-α, thus preventing its binding to membrane TNFRp55, and results in impaired TNF-α mediated activation of intracellular bactericidal effector killing mechanisms.

Consistent with the above studies, we found that eschar lesions from patients with mild-to-moderate MSF express high mRNA levels of TNF, IFN-γ, and IL-10. Interestingly, very high levels of intralesional IL-10 were inversely correlated with lower levels of IFN-γ and TNF. This mixed proinflammatory and anti-inflammatory response in skin lesions from patients with MSF was also associated with significantly increased mRNA of RANTES, indoleamine-2,3-dioxygenase (IDO; an enzyme involved in limiting rickettsial growth by tryptophan degradation), and (iNOS: a source of microbicidal nitric oxide). Thus, humans with rickettsial infections express many of the effector mechanisms that have been identified in experimental animals and in vitro. Skin lesions from patients with severe MSF have significantly higher RANTES expression than those with mild or moderate disease. RANTES is a chemokine that mediates recruitment of T cells to the site of infection. In addition, RANTES activates *Rickettsia*-infected target cells, which results in intracellular killing of rickettsiae by an NO-mediated mechanism. However, very high concentration of RANTES in vivo can lead to T cell apoptosis, and subsequent disease progression. Further studies are needed to determine whether these cytokines and chemokines responses in patients with MSF are simply a correlate of mild and severe disease or contribute to antirickettsial immunity and pathogenesis.

At the cellular level, human hepatocytes and human umbilical vein endothelial cells (HUVECs) stimulated in vitro by IFN-γ, TNF-α, IL-1β, and RANTES (regulated by activation, normal T cell-expressed and secreted chemokine; CCL5) kill intracellular rickettsiae by a NO-dependent mechanism (Feng and Walker, 2000). Neither primary human monocytes nor the monocytic cell line THP-1 produces NO with the same stimuli; however, an antirickettsial effect is elicited in these cells by the combination of cytokines (without CCL5) (Feng and Walker, 2000). This activity is mediated by production of hydrogen peroxide and tryptophan starvation of intracellular bacteria due to degradation of tryptophan by the enzyme IDO. Hydrogen peroxide-dependent intracellular killing of *Rickettsia* also occurs in HUVECs, but not in the human hepatocytes. Thus, *Rickettsia*-infected nonprofessional phagocytic host cells, such as endothelial cells and hepatocytes, possess intracellular microbicidal effector mechanisms similar to those mounted by professional phagocytic cells such as macrophages.

Since the primary target cell for *Rickettsia* is the endothelium, examination of factors that control the interaction between endothelial cells and T lymphocytes is important. Among these factors are chemokines, particularly inflammatory chemokines that specifically target activated T cells through the CXCR3 receptor such as CXCL9 (Mig) and CXCL10 (IP-10). CXCL9 and CXCL10 are inflammatory chemokines that are expressed in vascular lesions in the brain of patients with fatal Rocky Mountain spotted fever (Valbuena and Walker, 2004; Valbuena et al., 2003). In animal models of SFG rickettsiosis, CXCL9 and CXCL10 (CXCR3 ligands) are expressed early in the liver and lungs of mice infected with a sublethal dose of *R. conorii* (Valbuena et al., 2003; Valbuena and Walker, 2005). The mouse endothelial cell line SVEC4-10 expresses CXCL9 and CXCL10 when stimulated with IL-1, IFN-γ, and TNF-α (Kaplanski et al., 1995; Sporn and Marder, 1996; Dignat-George et al., 1997). In infections with other intracellular pathogens, CXCL10 is expressed in inflamed tissues in which the Th1-type cytokine IFN-γ is upregulated (Qin et al., 1998; Kim et al., 2001; Sallusto et al., 1998; Bonecchi et al., 1998). Similarly, CXCR3 is expressed predominantly on Th1 clones and on a significant fraction of circulating memory T cells and is required for migration of in vivo activated T cells, particularly effector CD8+ T cells to dermal sites of inflammation (Nishimura et al., 2002; Ng et al., 1985). Therefore, it is possible

that the early rise in the expression of CXCL9 and CXCL10 may participate in the Th1 polarization and effector cell generation that are so important in the clearance of rickettsiae from infected hosts. However, antibody-mediated neutralization of CXCL9 and CXCL10 and absence of CXCR3 expression in knockout mice did not affect survival or bacterial loads of these mice infected with rickettsiae (Valbuena and Walker, 2004), suggesting a possible compensatory or alternative mechanism that circumvents the need for these chemokines in triggering antirickettsial effector mechanisms.

Many studies have examined the interaction between *Rickettsia* and their main target, endothelial cells. However, endothelial cells are not professional antigen presenting cells and lack the required costimulatory molecules necessary for the induction of T cell responses. In addition, the fact that rickettsiae are transmitted via the dermis suggests that resident dendritic cells could play a more important role than endothelial cells in innate immunity as well as in induction of specific T cell responses in vivo. Analysis of the in vitro interaction of rickettsiae with bone marrow-derived DCs (BMDCs) from mice that are resistant (C57BL/6) and susceptible (C3H/HeN) to lethal *R. conorii* infection suggests that dendritic cells not only contribute to the initial clearance of rickettsiae during the innate response but also determine the type of acquired immune response against *Rickettsia*. Compared to the immediate and exclusive cytoplasmic localization within endothelial cells, rickettsiae efficiently enter and localize in both phagosomes and cytosol of BMDCs from both mouse strains (Fang et al., 2007). This dual intracellular localization of rickettsiae within dendritic cells would enable efficient priming of antigen-specific $CD4^+$ and $CD8^+$ T cells via major histocompatibility complex (MHC) class II and I pathways, respectively. *R. conorii* infection induces maturation of BMDCs from both mouse strains as evidenced by increased expression of MHC and costimulatory molecules. However, compared to susceptible mice, BMDCs from resistant mice exhibit higher expression levels of MHC class II and Th-1 promoting cytokines such as interleukin-12p40 (IL-12p40) upon rickettsial infection. Importantly, BMDC from resistant C57BL/6 background are very efficient in activation of naive $CD4^+$ T cells, and promotion of their differentiation into Th1 cells producing IFN-γ production is indispensable for activation of intracellular microbicidal functions of infected target cells and, thus, killing of intracellular rickettsiae. In contrast, in vitro coculture of naive $CD4^+$ T cells from susceptible C3H mice with *Rickettsia*-infected syngeneic BMDC reveals delayed $CD4^+$ T cell activation and suppressed expansion of $CD4^+$ Th1 and Th2 cells compared to unstimulated naive T cells (Fang et al., 2007). The suppressive $CD4^+$ T cell phenotypes or responses detected in vitro upon coculture of T cells and BMDC from susceptible C3H mice are associated with expansion of $Foxp3^+$ natural T regulatory cells. Analysis of T cell priming functions of DC compared to macrophages indicates that DC are more efficient inducers of T cell activation, as characterized by the production of significant quantities of the prototypical Th1 cytokines, IFN-γ and IL-2 (Jordan et al., 2007). In addition, *R. conorii*-infected DCs are able to activate naive $CD8^+$ T lymphocytes in vitro in the absence of T cell help (Jordan et al., 2007). However, further investigation of the $CD8^+$ T cell priming function of DC is necessary to determine whether a similar phenomenon occurs in vivo. Interestingly, transfer of *R. conorii*-infected DCs protect C3H/HeN mice against lethal rickettsial infection. This protection is associated with significant expansion of splenic lymphocytes and NK cells in vivo. Together, these data suggest that differential interactions of rickettsiae with BMDCs might contribute greatly to different host susceptibilities to rickettsial diseases. IL-12p40-producing mature DC could drive the differentiation of $CD4^+$ T cells toward a protective Th1 phenotype in the resistant host, while decreased MHC class II expression and lack of IL-12p40 production by DC in the susceptible host stimulate T regulatory cells and suppress effector Th1 or Th2 cells. Whether suppression of effector CD4+ T cell responses by DC from the susceptible host is mediated indirectly by T regulatory cells or directly by *Rickettsia*-stimulated DC remains to be investigated.

The immune response to *O. tsutsugamushi* has been studied in laboratory mice. This bacterium infects a variety of host cells in vitro and in vivo, including macrophages and endothelial cells, where it replicates in the cytoplasm without being surrounded by a phagosomal membrane (Ng et al., 1985; Chi et al., 1997). Analysis of early immune responses to *O. tsutsugamushi* infection in mice showed that macrophage-mediated cellular immunity is essential for resolution of this infection (Nacy and Groves, 1981). The pathogenesis of scrub typhus and protection of *O. tsutsugamushi*-infected animals are influenced by at least three factors: (1) route of inoculation, (2) *Orientia* strain, and (3) natural resistance of the host. Natural resistance of mice to lethal infections of *O. tsutsugamushi* is controlled by a single, autosomal, dominant gene, which is designated *Ric*, with "*r*" and "*s*" representing the resistant and susceptible alleles, respectively (Nacy and Groves, 1981; Groves et al., 1980; Jerrells and Osterman, 1981). The expression of the early T lymphocyte activation (*Eta-1*)/Osteopontin (*op*) gene, which maps to the natural resistance gene

(*Ric*), correlates with resistance to *O. tsutsugamushi* infections in mice (Patarca et al., 1989). The expression of Eta-1a allele represents an essential early step in the pathway that leads to Th1 immunity, an effective arm of immune response against *Orientia*, by balancing IL-12/IL-10 production. In addition to its immunomodulatory effect, Eta-1a/op enhances resistance to rickettsial infection by affecting the ability of macrophages to migrate to the site of infection and/or to exert bactericidal activity (Singh et al., 1990). Replication of *O. tsutsugamushi* is controlled by a cellular immune response dominated by type 1 cytokines, in particular IFN-γ. In a mouse model of scrub typhus, IFN-γ production was closely associated with the development of immunity against *O. tsutsugamushi* (Koh et al., 2004; Yun et al., 2005), and elevated levels of circulating IFN-γ have been observed in a limited number of patients with scrub typhus (Chierakul et al., 2004; de Fost et al., 2005; Watt and Parola, 2003). In addition, the plasma concentrations of the IFN-γ-inducing cytokines IL-12p40, IL-18, IL-15, and TNF-α are also elevated in patients with scrub typhus (Yun et al., 2005). Although data obtained from patients with scrub typhus must be evaluated carefully since cytokine levels vary on a daily basis and the levels of these cytokines/chemokines can be influenced by several confounding factors in humans, these data suggest that a cell-mediated immune response is critical in host defense against *O. tsutsugamushi*.

Adaptive Immunity

The generation of protective T cell responses to infectious agents is a complex process in which cytokines and costimulatory molecules provide signals that direct the development of adaptive immunity. Understanding the events that influence the initial generation and expansion of effector cells and the maintenance of memory is critical for the rational design of vaccines. Similar to other intracellular pathogens, cell-mediated immunity characterized by substantial generation of IFN-γ producing Th1 and CD8 type-1 cells plays a critical role in host defenses against rickettsial infections (Feng et al., 1997; Walker et al., 2000, 2001). $CD8^+$ T cells provide a greater contribution to long-term protective immunity against rickettsiae than $CD4^+$ T cells. MHC-class I knockout mice that lack CD8+ T cells are highly susceptible to *R. australis* rickettsial infection (Walker et al., 2001). All MHC-I gene knockout mice succumb to infection with *R. australis* and develop severe subcutaneous edema and pleural and peritoneal effusions. Furthermore an ordinarily sublethal dose of *R. conorii* is lethal or causes persistent infection in mice depleted of CD8+ T lymphocytes (Feng et al., 1997; Walker et al., 2000, 2001). In contrast, mice depleted of CD4+ T cells clear the infection in a similar time frame as normal mice (Feng et al., 1997). Adoptive transfer of immune CD4+ or CD8+ T lymphocytes before infection with *R. conorii* protects immunocompetent naive mice (Feng et al., 1997). However, the immunity provided by the transferred cells is dose-dependent, as neither CD4 nor CD8+ T cells protect mice against a higher dose of rickettsiae. $CD4^+$ T cell-mediated protective immunity requires T cell production of IFN-γ, whereas $CD8^+$ T cells mediate protection via IFN-γ production and cytotoxic killing (Feng et al., 1997; Walker et al., 2001). The importance of IFN-γ in immunity to rickettsiae is emphasized by the observation that the IFN-γ gene knockout mice with the C57BL/6 background are 100 times more susceptible to a lethal outcome of *R. australis* infection than wild-type C57BL/6 mice (Walker et al., 2001). Despite the increased susceptibility of IFN-γ knockout mice, these mice survived lower doses of rickettsiae infection. This observation together with the finding that mice do not survive the lowest dose of rickettsial infection without CD8+ T cells suggests that an IFN-γ-independent CD8 T cell-mediated cytotoxic effector function plays a major role in host defense against *Rickettsia*. MHC-class-I-restricted $CD8^+$ T cell responses to *Rickettsia* determined by CTL activity against *Rickettsia*-infected, MHC-matched target cells reach peak frequencies approximately 10 days after intravenous infection. Several cytotoxic cell death-mediating effector molecules including Fas/Fas ligand, TNF/TNFR, perforin, and granulysin may contribute to function of CD8+ T cells (Shresta et al., 1998; Doherty et al., 1997). Perforin gene knockout mice are much more susceptible than wild-type mice indicating that perforin-mediated activity accounts for a large component, but not all, of the CTL-mediated antirickettsial effect (Walker et al., 2001). A recent study in Thai patients with scrub typhus caused by *O. tsutsugamushi* displayed elevated plasma concentrations of granzymes A and B together with IFNγ and IFN-γ-inducible protein 10 (IP-10) (de Fost et al., 2005). These data suggest that activation of cytotoxic lymphocytes is part of the early host response to scrub typhus.

Taken together, these data strongly suggest that there are two important effector components of acquired immune response against *Rickettsia*, namely IFN-γ production by $CD4^+$ and CD8+ type-1 cells, which activates intracellular bactericidal mechanisms of endothelial cells and macrophages, and the generation of *Rickettsia*-specific cytotoxic CD8+ T cells that lyse infected target cells via pathways involving perforin and/or granzymes.

Humoral Response

The concept that only cell-mediated immunity plays a role in resistance to intracellular pathogens in large part stems from work initially begun in the 1960s by George Mackaness examining *Listeria* infection in mice (Mackaness, 1962, 1969). These experiments demonstrated that immune splenocytes could transfer protection via the activation of macrophages. Earlier studies of correlates of protection of patients with SFG rickettsiosis (Ricketts, 1908; Topping, 1940, 1943) or in guinea pigs (Murphy et al., 1980; Sumner et al., 1995) passively immunized with immune sera against *Rickettsia* also provided little evidence of a role for antibodies in primary host defense against *Rickettsia*. On the other hand, pretreatment of rickettsiae with immune serum before infection prevents lethal disease. Because the latter situation mimics a secondary rather than primary immune response against *Rickettsia*, investigations have focused on cellular immunity as the main mechanism of protection against primary infection with these intracellular pathogens. However, it should be noted that some monoclonal antibodies (MAbs) of a defined specificity and isotype can provide protection. Natural infection does not result in the production of protective antibodies prior to clearance of rickettsiae. These observations indicate that humoral immunity may be more important in preventing reinfection than in clearance of primary infection. In the past few recent years, provocative studies have shown the role of antibody in protection against certain intracellular pathogens (Edelson et al., 1999; Edelson and Unanue, 2000a, 2000b).

In the animal model of SFG rickettsiosis, C3H/SCID mice that receive MAbs against *Rickettsia* OmpA or OmpB or polyclonal antisera specific to *Rickettsia* 48h prior to intravenous infection with 10 LD_{50} of *R. conorii* are completely protected, while anti-LPS antibodies or Fab fragment of the polyclonal antibodies are not protective (Feng et al., 2004a). Polyclonal antibodies or MAbs against OmpA or OmpB given after the establishment of infection are effective in killing rickettsiae, presumably interacting with rickettsiae that exist extracellularly as they spread from one cell to another. Kinetic analysis of antibody development against *R. conorii* reveals that antibodies to LPS appear on day 6 during the illness, while antibodies to OmpA and OmpB appear on day 12 after recovery from the infection. The T cell response against *Rickettsia* reaches a peak at 9–12 days postinfection (Feng et al., 1997; Walker et al., 2001), which suggests that antibodies to OmpA and OmpB are T cell dependent, while antibodies against LPS are T cell independent. Since antibodies to OmpA and OmpB were detected on day 12, after recovery from the illness had occurred, it seems more likely that an antibody response would play an important role in protective immunity against reinfection than in clearance of the primary infection in an immunocompetent host. Recently, the potential mechanism(s) of antibody-mediated protection against *Rickettsia* has been examined (Feng et al., 2004b). The observation that Fab fragments of polyclonal antiserum do not provide protection in vivo indicates that antibodies mediate protection most likely via enhancement of opsonization and phagocytosis of organisms. In vitro cultured mouse endothelial and macrophage-like cell lines incubated with *R. conorii*-coated with different types of antibodies reveal that the Fc portion of the antibodies enhances adherence of opsonized rickettsiae and subsequent internalization. Binding of polyclonal antibodies or MAbs against OmpA or OmpB to *Rickettsia* enhances eventual intracellular killing. In addition, polyclonal antibodies and anti-OmpB MAb inhibit the escape of *R. conorii* from the phagosome, resulting in intraphagolysosomal rickettsial death mediated by NO, reactive oxygen intermediates, and L-tryptophan starvation (Feng et al., 2004b).

Persistence of Rickettsial Infection, Latent Infection, and Reactivation

Although rickettsiosis has been identified as an acute infectious disease, several lines of evidence suggest that *Rickettsia* can cause chronic infection. *R. rickettsii* organisms were isolated from lymph nodes of patients 1 year after recovery from RMSF (Parker et al., 1954). Persistence of *Rickettsia*-specific antibodies in patients recovered from RMSF suggests a latent infection. Similarly, in naturally infected dogs, antibody titers can be detected at least 12 months after *R. rickettsii* infection, suggesting a persistent infection (Tesouro et al., 1998). *O. tsutsugamushi* also persist in tissues of patients recovered from scrub typhus (Smadel et al., 1952). *R. prowazekii*, the etiologic agent of epidemic typhus and recrudescent typhus (Brill–Zinsser disease), causes latent infection (Zinsser and Castaneda, 1933; Walker et al., 2003).

The long-term persistence of pathogens in a host that is also able to maintain strong resistance to reinfection is a characteristic of certain infectious diseases. The ability of certain intracellular pathogens to establish latency in immune individuals is often associated with a suppressed immune response or antigenic variation (Salgame, 2005; McCulloch, 2004). To the best of our knowledge, antigenic variation does not occur in *Rickettsia.* Sterile immunity in resistant *R. conorii*-infected mice maintained by $CD4^+$ T cells, IL-12, IFN-γ, and inducible iNOS suggests that impairment of these responses may result in rickettsial persistence and possible reactivation. The explanation as to why

these control mechanisms fail to completely eliminate the *Rickettsia* is not known. Transient immunosuppression occurs in vivo during chronic infection of mice with *O. tsutsugamushi* administered subcutaneously (Jerrells, 1985). Spleen cells from subcutaneously infected mice do not proliferate in vitro in response to a polyclonal T cell stimulator such as ConA. Additionally, mice infected subcutaneously with *O. tsutsugamushi* develop chronic infection and are unable to mount an antibody response to either T cell dependent antigens such as SRBC or T cell independent antigens such as TNP-ficoll (Jerrells, 1985). However the suppressed antibody response to the T-independent antigen TNP-ficoll was not as severely affected as antigens requiring T cell help to produce antibodies, suggesting that the transient immune suppression following *O. tsutsugamushi* infection is due to suppression of T cells. Nevertheless, the mechanism(s) of the observed immunosuppression is not completely understood, and it is controversial as to whether or not T suppressor cells play a role in this mechanism. More importantly, if such transient immunosuppression occurs following natural rickettisal infection and whether this could be a mechanism of persistence of rickettsiae remain to be determined. In support of the concept of immunosuppression is the observation that *O. tsutsugamushi* infection suppresses the production of proinflammatory cytokines (e.g., TNF-α) in murine macrophages cocultured in vitro with the rickettsiae or conditioned medium from *O. tsutsugamushi*-infected macrophages (Kim and Kang, 2001). Further study revealed that *Orientia*-mediated suppression of macrophage activation is due to production of immunosuppressive cytokine IL-10 (Kim et al., 2005). In humans, elevated serum levels of IL-10 are also present in patients with boutonneuse fever (Cillari et al., 1996). Nevertheless, the source of IL-10 in murine or human rickettsiosis has not been determined. Consistent with the hypothesis of immunosuppression in severe rickettsial disease, infection of C3H/HeN mice with *R. conorii* that closely mimics severe human rickettsioses with similar disseminated vascular injury is associated with inability to control bacterial replication resulting in an overwhelming infection (Walker et al., 1994). Splenocytes from these lethally infected mice exhibit suppressed proliferation to in vitro polyclonal stimulation (Feng et al., 1994). *Rickettsia*-infected DC stimulate significant expansion of Foxp3T regulatory cells, which correlates with suppressive adaptive immune responses (Fang et al., 2007). A similar immunosuppressive mechanism appears to occur in vivo following lethal *R. conorii* infection in susceptible C3H/HeN mice. Higher bacterial burden and fatal disease in mice infected with lethal dose of *R. conorii* are associated with unresponsiveness of CD4+ T cells as evidenced by suppressed nonantigen-specific proliferation and IL-2 production, which are strongly associated with significant expansion of inducible antigen-specific T regulatory cells producing IL-10 and IFN-γ.

Another mechanism of persistence is derived from studies with virulent and attenuated strains of *R. prowazekii*. Resistance to IFN-γ-mediated intracellular killing has been observed in vitro following culture of avirulent Madrid E strain of *R. prowazeki* in IFN-γ-treated fibroblast L929 cells (Turco and Winkler, 1989). Since the passage of rickettsiae in culture selects IFN-γ resistant strains, it is possible that this avirulent phenotype could emerge in vivo after recovery from primary infection, and acquire the ability to persist due to their IFN-γ resistance (Turco and Winkler, 1989, 1990; Turco et al., 1989). The ability of avirulent Madrid E strain to revert to the virulent phenotype may explain, to some extent, reactivation of *R. prowazekii* infection and development of recrudescent typhus.

EPIDEMIOLOGY

Natural rickettsial infections are all transmitted by arthropods. The four *Rickettsia* species that are threats for use by bioterrorists are all highly infectious by inhalation of a low dose of rickettsiae by aerosol. TG rickettsiae have an insect vector, the human body louse (*Pediculus humanus corporis*) for *R. prowazekii* and fleas (particularly *Xenopsylla cheopis*, the Oriental rat flea, worldwide and currently *Ctenocephalides felis* cat flea in the US).

TG rickettsiae are transmitted mainly in their vectors' feces, which contains a stable infectious form of the bacterium that is scratched into the skin, rubbed into mucous membranes such as the conjunctiva, or inhaled. *R. prowazekii* is highly lethal for its louse host; 100% die. Thus, the louse is not a reservoir host of *R. prowazekii*. Humans who survive acute louse-borne typhus maintain a latent infection and serve as reservoir host of the rickettsiae. Years later some latently infected persons fail to maintain effective immune control of the rickettsiae, allowing for reactivation of rickettsial growth, recrudescent typhus fever, and bacteremia that infects 5% of lice that are feeding on them. Human body lice live in the clothing of the person, where the temperature is suitable for them, and they leave a febrile person because of their aversion to the higher temperature. This departure seeking another host accomplishes transfer of the rickettsiae to a susceptible person. After 5–7 days the growth of *R. prowazekii* in louse gut epithelium results in rickettsial shedding in the feces onto the skin of the new

host. Successive cycles of these events in nonimmune, louse-infested persons under crowded conditions result in an outbreak. Travel of persons during the incubation period (e.g., displaced by warfare) spreads the infection leading to a widespread epidemic such as occurred among 100,000 persons during the civil war that occurred in the mid-1990s in Burundi.

R. prowazekii is also maintained in a zoonotic cycle involving flying squirrels (*Glaucomys volans*) and their specific flea and louse. Humans become infected from this cycle, presumably when contacting the infected fleas or infected feces from the lice and fleas. *R. prowazekii* also resides in some ticks.

The first biologic weapon developed by the Soviets was *R. prowazekii*. The history of Japanese biologic weapon development during World War II also includes typhus.

Murine typhus occurs in persons who contact the feces of the infected fleas and less often by flea bite. Globally murine typhus has a very high incidence although typically neither diagnosed nor treated effectively. Analyses such as disability adjusted days of life lost are blind to the importance of murine typhus and other unreported rickettsioses. The most common natural reservoir of *R. typhi* is a zoonotic cycle involving the Oriental rat flea and *Rattus* species. Infected fleas maintain *R. typhi* throughout a normal lifespan, and via transovarian transmission to a small portion of their eggs. Rats are easily infected, develop a sufficient concentration of *R. typhi* in their blood to infect fleas that feed on their blood, and do not become ill.

SFG and transitional group rickettsiae are maintained in nature largely via transovarian transmission in ticks, mites (*R. akari* only), or fleas (*R. felis* only). Some *Rickettsia* species are pathogenic for the vector tick (e.g., *R. rickettsii* causes reduced survival of *Dermacentor* ticks). Thus, infection of new ticks is required to establish new lines of transovarian rickettsial maintenance (e.g., *Dermacentor variabilis* ticks acquire *R. rickettsii* while feeding on rickettsemic cotton rats). The pathologic effects of *R. rickettsii* on ticks apparently account for their extremely low (less than 0.1%) prevalence in their tick hosts. The vectors of Rocky Mountain spotted fever are *D. variabilis* (American dog tick) in the eastern two-thirds of the US and regions of the Pacific coast states, *Dermacentor andersoni* (wood tick) in the Rocky Mountain states, *Rhipicephalus sanguineus* (brown dog tick) in the southwestern US and northern Mexico, and *Amblyomma cajennense* and *Amblyomma aureolatum* in South America.

Each *Rickettsia* has its particular vector(s), e.g., *R. conorii* (*R. sanguineus* tick), *R. africae* (*Amblyomma variegatum* and *Amblyomma hebraeum* ticks), *R. felis* (*C. felis* flea), *and R. akari* (*Liponyssoides sanguineus* mite). In some cases, there is a known amplifying vertebrate host, e.g., the domestic mouse (*Mus musculus*) for *R. akari* during outbreaks of rickettsialpox.

Some rickettsiae are apparently not significantly pathogenic for their vectors in which their prevalence is high (e.g., *R. africae* in *A. variegatum* ticks). The most prevalent rickettsiae are of no known pathogenicity and are apparently maintained purely by vertical transovarian transmission (e.g., *R. peacockii*).

The low dose infectivity of rickettsiae is well illustrated by *R. rickettsii*, which is 1000-fold more infectious by aerosol than the spores of *Bacillus anthracis*, an indication of their danger as a potential biologic weapon.

SFG rickettsioses such as Rocky Mountain spotted fever, boutonneuse fever (MSF), and African tick bite fever are transmitted by ticks during their feeding. Ticks attach to the skin and inject saliva that contains pharmacologically active substances that prevent pain, modulate host defenses, and inhibit coagulation. Sharp tick mouth parts cut dermal blood vessels creating a blood-filled cavity from which blood is ingested and into which *Rickettsia*-infected saliva is injected as soon as 6 h after attachment and later during feeding that typically lasts for a week or longer.

The seasonal and geographic distribution of each rickettsiosis reflects the months of activity of the vector and its contact with humans. Rocky Mountain spotted fever occurs between May and September in the southeastern, mid-Atlantic, and south-central US.

O. tsutsugamushi is maintained entirely by transovarial transmission in trombiculid mites. Humans are thus accidental hosts who become infected by feeding of the larval stage of mite for 2–10 days on the skin. The other life stages of the mites are free living, feed in the soil, and therefore do not transmit orientiae. The seasonal occurrence is determined by the feeding activity of the vector, e.g., *Leptotrombidium pallidum* in autumn-to-winter and late spring-to-early summer; *Leptotrombidium scutellare* in autumn and winter; and *Leptotrombidium deliense* year-round in tropical areas.

PATHOGENESIS

Rickettsia interact with their eukaryote hosts by way of parasitism or mutualism. Rickettsiae are arthropod-borne intracellular bacteria that in vertebrates primarily infect endothelial cells and cause acute diseases. Natural infection with *Rickettsia* involves intradermal inoculation of the organisms together with saliva during tick feeding or with the feces of a louse or flea. Therefore, analysis of the interactions among *Rickettsia*, their initial target cells including potentially

dermal microvessel endothelial cells, dendritic cells, and macrophages and infiltrating T cells in the skin is of paramount importance in understanding the pathogenesis of the disease and design of a rational vaccination strategy.

Because of experimental limitations imposed by the obligate intracellular nature of rickettsiae, little is known about specific virulence determinants utilized by these organisms that mediate initial rickettsiae–host interaction. SFG *Rickettsia* attach via its OmpA and OmpB, the latter of which binds to a transmembrane protein Ku70 in the endothelial cell membrane (Li and Walker, 1998; Uchiyama, 1999; Martinez et al., 2005). Binding of *Rickettsia* to Ku70 induces focal host cell cytoskeletal actin rearrangements at the site of attachment, resulting in induced phagocytosis (Uchiyama, 1999; Li and Walker, 1992; Martinez, 2004). Interestingly, *Rickettsia* bind to Ku70 via OmpB, and this binding results in activation of Ku70. Activation of Ku70 is postulated to lead to the activation of a cascade of signaling events, including the small GTPase, Cdc42, phosphoinositidyl-3-kinase, src-family tyrosine kinases, and the tyrosine phosphorylation of focal adhesion kinase (Martinez and Cossart, 2004). These signaling events are known to be strongly associated with activation of β1-integrin (Parsons, 2003) and bacterial entry (Martinez and Cossart, 2004). *R. conorii* infection also stimulates the ubiquitination of Ku70 that is mediated by recruitment of the ubiquitin ligase c-Cbl to *R. conorii* entry foci. The role of Ku70 ubiquitination in rickettsial entry is evident by data showing that down regulation of endogenous c-Cbl blocks Ku70 ubiquitination and bacterial entry. However, further studies are essential to dissect whether Ku70 is utilized directly by *R. conorii* or that indirectly through other host cell receptors or adhesion molecules that facilitate bacterial entry into host cells.

Internalized rickettsiae are initially bound within a phagosome (Teysseire et al., 1995). An increase in rickettsial membranolytic activity (phospholipase D and tlyC) occurs concomitantly with rickettsial entry, and facilitates rickettsial escape from the phagosome into the cytoplasm prior to phagolysosomal fusion, thus avoiding exposure to the lysosomal enzymes (Whitworth, et al., 2005; Walker et al., 2001; Renesto et al., 2003; Martinez et al., 2004). Once in the cytosol, rickettsiae are free to exploit the nutrient-rich environment and interact with host structural components (Austin and Winkler, 1988; Winkler and Turco, 1988). In the cytosol, they replicate by binary fission. The spread of TG rickettsiae occurs via bursting of the massively infected host cell. In contrast, spotted fever rickettsiae are released from the infected cells via long thin cell projections either extracellularly or into the adjacent cell. These projections from which they are released are caused by propulsion by the host cell's actin filaments (Heinzen et al., 1993; Nath, 2004; Teysseire et al., 1992). The nucleation of actin polymerization is activated by Arp2/3, which induces the continuous formation of a network of short and highly branched filaments of actin that appears as tails that propel the rickettsiae (Gouin et al., 2004). In *Rickettsia*-infected cells, Arp2/3 is detected on the rickettsial surface but not in actin tails (Nath, 2004; Gouin et al., 2004). Arp2/3 is normally inactive and has to be activated by proteins of the WASP/N-WASP/Scar/Wave-family proteins in eukaryotic cells (Pollard and Borisy, 2003; Frischknecht and Way, 2001; Gouin et al., 1999). Comparison of genome sequences of *R. prowazekii* and *R. conorii* has identified a 2-kb region that is present in the *R. conorii* genome and is absent from that of *R. prowazekii* (Gouin et al., 2004). This locus encodes a 517-amino acid protein, RickA, which recruits Arp2/3, activates it, and induces actin polymerization. Thus, RickA is a rickettsial actin nucleator that is most closely related to the WASP/N-WASP-family proteins, which are involved in actin-based motility (Gouin et al., 1999; Welch et al., 1998; Machesky et al., 1999; Boujemaa-Paterski et al., 2001). RickA is expressed on the surface of most SFG rickettsiae in infected cells (Gouin et al., 1999, 2004). However, it is unknown how RickA is expressed on the bacterial surface and whether the type IV secretion system predicted by the genome sequence is involved in targeting RickA to the surface. It is possible that posttranslational modification of RickA such as phosphorylation might control its activity. Whether another *Rickettsia* protein also participates in the actin-based motility has to be addressed.

Nevertheless, the mechanism of SFG rickettsial cell-to-cell spread in the microcirculation results in disseminated infection of contiguous networks of endothelial cells, which coincides with lesion development (e.g., maculopapular rash). *R. rickettsii* is more invasive than other rickettsiae, routinely spreading to infect adjacent vascular smooth muscle cells. Because SFG rickettsiae are adapted for both intracellular survival and direct cell-to-cell spread, they are protected, to a large degree, against antibody-mediated complement activation that plays a major role in elimination of extracellular bacteria.

Pathophysiology of Rickettsial Diseases

The fundamental pathology of both spotted fever and TG rickettsioses is vasculitis caused by proliferation of organisms in the endothelial lining of small arteries, veins, and capillaries. This *Rickettsia*-induced vascular injury accounts for most or all of the clinicopathologic

abnormalities including the presence of an eschar at the site of the tick bite followed by a hemorrhagic rash, which extends over the entire body, including the palms and soles of the feet. The vascular lesions that underlie the rash lead to increased vascular permeability, with resulting edema due to leakage of fluid from the bloodstream, and its accumulation in the surrounding tissues (Davidson et al., 1990). The interstitial edema in certain organs such as lung and brain can pose a life-threatening situation. Generalized leakage of fluid from the circulation results in hypovolemia and ischemia. In severe cases, rickettsiae cause noncardiogenic pulmonary edema, interstitial pneumonia, and adult respiratory distress syndrome associated with hypoxemia, interstitial myocarditis, perivascular glial nodules of the central nervous system, and similar vascular lesions in the skin, gastrointestinal tract, pancreas, liver, skeletal muscles, and kidneys (Walker et al., 1980; Walker and Mattern, 1980; Randall and Walker, 1984; Adams and Walker, 1981). However, focal lesions or injury in some organs such as the kidneys are not sufficiently extensive to result in organ failure. Rocky Mountain spotted fever and boutonneuse fever induce a procoagulant state including release of procoagulant components, activation of the coagulation cascade with thrombin generation, platelet activation, increased antifibrinolytic factors, consumption of natural anticoagulants, and secretion of coagulation-promoting cytokines (George et al., 1993; Sporn et al., 1991; Shi et al., 1996, 2000; Elghetany and Walker, 1999). It has been speculated that thrombus-mediated vascular occlusion, including disseminated intravascular coagulation (DIC), might be an important pathogenic mechanism in severe rickettsioses. However, DIC rarely occurs, and postmortem studies of fatal cases reveal that thrombi are few and do not constitute an important general pathogenic mechanism. Increased adherence of platelets to infected endothelial cells has been demonstrated in vitro. Consumption of platelets results in thrombocytopenia in 32–52% of patients with Rocky Mountain spotted fever. Analysis of the sequential changes in many hematologic and biochemical parameters in 108 patients with travel-associated African tick bite fever during the first 2 weeks of illness and prior to the institution of antirickettsial therapy revealed several changes that, although less pronounced, mimic those of potentially more severe SFG rickettsioses (Jensenius et al., 2003). For example, there are significant decreases in mean total leukocyte count (leucopenia), mean absolute lymphocyte count (lymphopenia), and mean platelet count (thrombocytopenia), and significant increases in mean serum levels of C-reactive protein (CRP) and serum level of liver enzymes (ALT and AST) (Jensenius et al., 2003). Interestingly, an increased serum level of CRP and lymphopenia are the two most consistent findings. These observations are consistent with sharp decreases in serum IFN-γ in Sicilian patients with acute boutonneuse fever in whom IFN-γ levels dropped sharply during the second week after infection (Cillari et al., 1996). The fall in IFN-γ in boutonneuse fever patients coincides with reduction in the levels of CD4+ T cells in peripheral blood and decreased serum levels of IL-6, IL-10, and TNF (Cillari et al., 1996), indications of a return toward homeostasis.

In scrub typhus, infections with *O. tsutsugamushi* cause local inflammation accompanying eschars at the site of infection, and then spread systemically. Inflammation is initiated by infected macrophages and endothelial cells in the dermis. In the murine model of mild and severe rickettsiosis caused by infection with low and high virulence strains of *O. tsutsugamushi*, an early strong PMN response, followed by mononuclear cell influx is associated with enhanced susceptibility of C3H/HeN mice to *O. tsutsugamushi* infection and coincides with a high mortality rate (Cho et al., 2000; Rikihisa and Ito, 1979). The prominent cellular influx in susceptible mice correlates with delayed but sustained increase in the production of chemokines including MIP-1α, MIP-2, and MCP-1, which are important chemokines for activating neutrophils and monocytes, respectively, recruiting these circulating immune cells to the sites of inflammation. These data suggest that increased PMNs and macrophages infiltration in susceptible hosts may be an indicator of more severe local tissue injury or even mediate tissue damage via secretion of oxidative molecules, rather than providing antirickettsial immunity.

Mechanisms of Cell Injury by *Rickettsia*

Several pathophysiologic mechanisms have been proposed to explain the tissue and organ injury in severe rickettsiosis. These include: (i) reduced delivery of nutrients and oxygen to tissues owing to hypoperfusion and hypoxemia due to decreased blood volume, pulmonary edema, and in severe focal lesions, thrombus-mediated vascular occlusion and (ii) increased vascular permeability associated with intra-endothelial infection (Valbuena et al., 2002). *Rickettsia*-induced increase in vascular permeability is considered to be the result of interplay between host and microbial factors, particularly in the heavily parasitized vasculature. A critical host factor that plays a dominant role in influencing vascular permeability in rickettsial infections is TNF-α. TNF-α increases endothelial permeability with subsequent vascular leakage contributing to severe organ dysfunction. Significant increases in

plasma levels of TNF-α in patients with severe MSF suggest that TNF-α could be a causal contributor to pathogenesis (Kern et al., 1996; Oristrell et al., 1994). Another pathogenic mechanism is production of high levels of reactive oxygen species (ROS) by *Rickettsia*-infected endothelial and phagocytic host cells, causing tissue damage via lipid perioxidation of host cell membranes (Silverman and Santucci, 1988, 1990; Santucci et al., 1992; Eremeeva and Silverman, 1998a; Eremeeva et al., 2001). The oxidative stress-mediated injury of cultured endothelial cells is associated with depletion of defenses against oxidative stress. These components include enzymes such as glucose-6-phosphate dehydrogenase, glutathione reductase, heme oxygenase, and catalase (Silverman and Santucci, 1990; Santucci et al., 1992; Eremeeva and Silverman, 1998a; Eremeeva et al., 2001; Hong et al., 1998; Rydkina et al., 2002). The ameliorating effect of antioxidant molecules such as α-lipoic acid in an in vitro infected endothelial cell model supports a significant role of *Rickettsia*-induced oxidative stress as a pathogenic mechanism of cell injury (Eremeeva and Silverman, 1998a, 1998b; Eremeeva et al., 2001). However, the role and importance of ROS-mediated endothelial cell injury has not been established in vivo although there is evidence of oxidative stress in *R. conorii*-infected mice. It is important to bear in mind that ROS together with NO exert microbicidal functions that contribute to the control of intracellular pathogens (Hong et al., 1998; Rydkina et al., 2002, 2004; Eremeeva and Silverman, 1998b). The paradox of ROS acting as a host defense and a pathologic mechanism is unresolved, but presumably is due to localization in different cellular compartments and an imbalance between the formation of ROS and their removal by endogenous antioxidant scavenging compounds (Eremeeva et al., 2001; Hong et al., 1998; Rydkina et al., 2002, 2004; Eremeeva and Silverman, 1998b). Oxidative stress and endothelial cell damage occur when there is an excessive generation of ROS. The latter could be due to failure of the innate immune response to control intracellular bacterial replication. Rickettsiae may induce persistent and substantial endothelial cell activation, resulting in excess generation of proinflammatory cytokines and oxidative molecules, both of which could play a role in tissue injury by inducing the activation of transcription factors of the NF-κB family. NF-κB regulates the expression of cytokines, chemokines, adhesion molecules, and other early response genes. These transcription factors remain in the cytoplasm bound to the inhibitor IκB, which upon phosphorylation is targeted to the proteasome for degradation, resulting in exposure of the nuclear translocation signals of NF-κB. *R. rickettsii* directly activates NF-κB, causing upregulation of antiapoptotic factors that protect against host cell death and support cell cycle progression (Joshi et al., 2003, 2004; Clifton et al., 2005a). When *R. rickettsii*-induced activation of NF-κB is inhibited, apoptosis of infected but not uninfected endothelial cells rapidly ensues. Therefore, the antiapoptotic effect of *Rickettsia* via NF-κB activation is considered as an immune evasion mechanism that potentially allows the host cell to remain as a site of infection, thus supporting rickettsial survival and replication. Thus, continuous activation of host cells by persistently replicating rickettsiae could contribute to pathology and tissue damage in rickettsial infection. Finally, rickettsial phospholipase(s) or protease(s) may also play a role in cell injury (Walker et al., 1983, 1984; Silverman et al., 1992). It is most likely that tissue injury by *Rickettsia* is a multifactorial process, in which proinflammatory cytokines, oxidative molecules, procoagulant factors, rickettsial phospholipase(s) and proteases act in damaging host cells and tissues.

Role of Chemokines in Pathogenesis of Rickettsiosis

Studies of two major pathogenic species of SFG rickettsiae, namely *R. rickettsii* and *R. conorii*, have established the occurrence of significant changes in the expression of important adhesion molecules and regulatory chemokines during in vitro and in vivo infection of host endothelial cells (Eremeeva et al., 2000; Valbuena et al., 2003; Clifton et al., 2005b; Valbuena and Walker, 2005). In vitro *R. conorii*-infected endothelial cells express higher levels of E-selectin, intercellular adhesion molecule-1 (ICAM-1), and vascular cell adhesion molecule-1 (VCAM-1) than uninfected cells (Dignat-George et al., 1997). The activation mechanism involves autocrine/paracrine stimulation with IL-1α. Patients with severe boutonneuse fever have significantly higher plasma levels of soluble E-selectin and soluble VCAM-1 than patients with mild disease, who also have increased levels of soluble ICAM-1 (Dignat-George et al., 1999). Thus the soluble forms of adhesion molecules may play a pathogenic role in rickettsiosis as they enhance endothelial adhesiveness and leukocyte accumulation. Another study in Sicilian patients with boutonneuse fever suggested that soluble forms of adhesion molecules may produce an immunomodulatory, anti-inflammatory effect by blocking adhesion between leukocytes and endothelial cells (Vitale et al., 1999).

TREATMENT

Early treatment of the spotted fever rickettsiosis is the most important factor in speeding convalescence

and reducing mortality. Antibiotic therapy that is begun early in the course results in rapid resolution of clinical abnormalities. Empiric treatment of rickettsioses should be started before laboratory confirmation of the diagnosis.

The preferred treatment for RMSF, boutonneuse fever, Japanese spotted fever, African tick bite fever, and other spotted fever rickettsioses is doxycycline (Vibramycin), 100 mg intravenously or orally every 12 h for adults and children who weigh more than 45 kg (Holman et al., 2001; Masters et al., 2003; Purvis and Edwards, 2000). The dose for children who weigh less than 45 kg and for children less than 8 years of age is 3 mg/kg body weight in two divided doses (maximum dose 200 mg/day). Adjunctive measures such as oxygen therapy, blood transfusion, anticonvulsants, mechanical ventilation, and hemodialysis are sometimes needed in severe cases. Although there are no published studies on the optimal duration of therapy for Rocky Mountain spotted fever, doxycycline therapy is usually continued for 5–10 days or until the patient has been afebrile for at least 48 h. Doxycycline is also the treatment of choice for children with Rocky Mountain spotted fever as the risk of dental staining is minimal when short doses of therapy are given. In patients with severe hypersensitivity to tetracyclines, 50–75 mg/kg of body weight/day of chloramphenicol can be considered as an alternative therapy, but it is less effective and its use is limited by side effects. Doxycycline should not be used in pregnant women (who should be treated with chloramphenicol [Chloromycetin] 500 mg intravenously every 6 h). Although both doxycycline and chloramphenicol are effective, neither drug is rickettsicidal. The antibiotics inhibit rickettsial growth until an adequate immune response by the patient eradicates the infection. Several quinolones have also been documented to be effective for treatment of patients with boutonneuse fever. Newer macrolides, such as clarithromycin and azithromycin have been proposed as alternatives to doxycycline and chloramphenicol in treatment of children and pregnant women with boutonneuse fever (Segura and Anton, 2002; Cascio et al., 2002, 2001). Azithromycin seems to be a better treatment option as it is administered once a day and has proven effective after a shorter duration of therapy (3 days) compared to clarithromycin (7 days). Because boutonneuse fever is a less severe disease and the macrolides were used to treat only children with mild illness, neither fluoroquinolones nor macrolides are recommended for treating severe rickettsioses such as Rocky Mountain spotted fever. Many classes of broad-spectrum antibiotics, including penicillins, cephalosporins, and aminoglycosides, are ineffective as therapy for rickettsial diseases (Rolain et al., 1998). Sulfa-containing antimicrobials are not only ineffective but also exacerbate rickettsioses (Ruiz Beltran and Herrero Herrero, 1992).

The treatment of choice for murine and epidemic typhus is oral doxycycline; even a single 200 mg dose usually leads to defervescence within 48–72 h.

The treatment of choice for scrub typhus is doxycycline. Scrub typhus cases from northern Thailand with a diminished response to doxycycline and chloramphenicol have been described (Watt et al., 2000), but neither the geographic distribution of resistance nor its mechanism have been defined. Limited data suggest that rifampicin is effective in areas where scrub typhus responds poorly to standard antirickettsial drugs (Watt et al., 2000). Roxithromycin, a macrolid antibiotic, was as effective as doxycycline and chloramphenicol in a trial of 39 Korean children (Lee et al., 2003), and azithromycin and clarithromycin have been used in pregnancy and where doxycycline and chloramphenicol resistance is a problem.

VACCINES

History

The history of development of vaccines against rickettsial diseases contains numerous failures and limited success in preventing or ameliorating disease. Technologic approaches to the preparation of vaccine materials have reflected advances in knowledge and methods. The three vaccines that have been developed to prevent Rocky Mountain spotted fever illustrate these advances. When it had been established that *R. rickettsii* not only survived but also replicated in ticks, a killed rickettsial preparation from infected ticks was developed by Spencer and Parker in 1924. Because preparation of this vaccine was cumbersome and dangerous to workers dealing with live infected ticks, the method of propagating *R. rickettsii* in yolk sac of embryonated chicken eggs was adapted soon after its development by Cox in 1938. A third killed rickettsial vaccine that was free of yolk sac antigens was prepared from cell culture-propagated organisms by the US Army in the 1970s.

The original tick rickettsial vaccine produced severe local inoculation site reactions. Evaluation of its protective effect in field use was impressive by the standards of the day. The fatality rate from Rocky Mountain spotted fever among vaccine recipients was reduced dramatically. Annual booster vaccinations were recommended. Vaccinated persons continued to get infected, but generally appeared to suffer less severe disease.

The killed yolk sac rickettsial vaccine was never field tested. Like recipients of the tick vaccine, some

vaccine recipients became ill with Rocky Mountain spotted fever. A challenge trial in human volunteers was conducted in 1973. Neither the yolk sac vaccine nor the tick vaccine prevented the illness, which, of course, was treated to prevent severe illness or death. The yolk sac vaccine was withdrawn from the market in 1978. Subsequent challenge trial of the cell culture killed-*R. rickettsii* vaccine yielded protection of 25% of the volunteers who received it. Evaluation of the recipients' immune responses revealed failure to stimulate sustained cellular immunity.

Attempts to develop a vaccine against epidemic typhus fever used living organisms as well as killed rickettsiae. A low dose of *R. prowazekii* from human blood or guinea pig brain or crossreactive less pathogenic *R. typhi* suspended in ox bile or in egg yolk and olive oil was reported to have protected some persons and to have caused severe illness, even death, in other vaccinees.

Propagation of *R. prowazekii* for preparation of killed rickettsial vaccines employed intrarectal inoculation of lice, infected louse nymphs, tunica vaginalis of intraperitoneally inoculated animals, and lungs of intranasally inoculated animals. Weigl's louse-derived vaccine required intrarectal infection of 30 lice, dissection of the lice's intestines, and phenol-inactivation for a single person's vaccination. Cox's chicken embryo yolk sac-propagated, killed-*R. prowazekii* vaccine was massively produced during World War II to protect US military personnel. Epidemic typhus caused many deaths in civilians, Axis military personnel, and concentration camp prisoners in North Africa, western Asia, and Europe, particularly on the Eastern Front during this period. Not a single death was caused by louse-borne typhus in US soldiers in North Africa and the Middle East between 1942 and 1945. Use of this vaccine was continued until 1968 when great variability in the potency of different vaccine batches was discovered. The FDA vaccine potency testing method was the level of stimulation of antibodies that neutralized the mouse toxicity phenomenon. This surrogate test depends on the presence of antibodies to conformational epitopes on OmpA and OmpB for spotted fever rickettsiae and to OmpB for TG rickettsiae. Antibodies to these rickettsial antigens may indeed play a role in prevention of infection or clearance of rickettsiae early in the infection before onset of illness.

Development of a vaccine against scrub typhus has proven extremely difficult. The approaches that have been attempted include vaccine containing killed organisms, live putatively attenuated *O. tsutsugamushi*, viable gamma irradiated orientiae unable to replicate, and a regimen of induced infection and prophylactic anti, rickettsial treatment. Immunity to neither homologous nor heterologous strains of *O. tsutsugamushi* has been achieved. Attenuation was not successful.

Rickettsial Antigens and Protective T Cell Epitopes

Crossprotection between SFG and TG rickettsiae, which are genetically related but antigenically different, in intravenously infected animal models is mediated by T cells, which recognize crossreacting antigens between the two rickettsial groups. Human T lymphocytes also are stimulated by shared antigens. The SFG rickettsiae differ from the TG rickettsiae not only in their capacity to stimulate host cell actin polymerization for cell-to-cell movement, but also in their larger genome size, the presence of species-specific LPS antigen, and rickettsial OmpA. The nature of the rickettsial antigens triggering acquired immune responses has been the subject of much research directed toward the development of a vaccine that may offer solid protection comparable to that acquired by natural infection. However, the immunodominant rickettsial antigens responsible for CD4+ and CD8+ T cell stimulation are only partially known. OmpA and OmpB are two major OMPs that were the first candidates identified based on their reactivity to immune sera, protection of guinea pigs by immunization with recombinant *R. rickettsii* or *R. conorii* OmpA, and protection of mice against lethal *R. typhi* challenge by immunization with native *R. typhi* OmpB. These proteins possess not only B cell epitopes but also T cell epitopes.

Attempts to identify the immunodominant epitopes of these OMPs was addressed by subcloning small fragments and assaying their stimulatory and protective effect by DNA immunization with different fragments from OmpA and OmpB ($ompA_{2176–3933}$, $ompA_{4999–6710}$, $ompB_{1550–2738}$, and $ompB_{2459–4123}$) and subsequent booster immunization with the homologous recombinant protein. These immunizations stimulate T lymphocyte proliferation and IFN-γ secretion in mice. All immunized mice are protected from lethal challenge by immunization with a combination of the four fragments. Immunization of mice with recombinant *Mycobacterium vaccae* expressing $ompA_{3006–3960}$ and subsequent boosting with the homologous protein produces partial protection against lethal challenge with *R. conorii*, as does DNA priming with $ompA_{2331–3976}$ with booster immunizations with the homologous protein. Despite the protection mediated by immunization with the OmpA and OmpB fragments, all mice exhibit signs of disease compared to no illness in rechallenged mice that have recovered from sublethal infection with *R. conorii.*

Similar observations have been made with the Karp strain of *O. tsutsugamushi*, where 56-kDa Omp and other proteins of this strain employed as vaccine candidates for prevention of scrub typhus are not as

efficient as infection with live organisms in preventing reinfection, despite the ability to induce strong humoral and cellular immune responses. These observations suggest that memory T cell responses to other unidentified rickettsial antigens or subdominant epitopes that are expressed upon infection with the whole organism are critical for controlling rickettsial replication and long-term protection.

The number of epitopes involved in the effector CD8+ CTL response to microbial infection is small relative to the total number of epitopes potentially available because effector CTL responses to dominant epitopes tend to suppress responses to subdominant epitopes on the same protein from which immunodominant epitopes are derived. This phenomenon is referred to as immunodominance. However, CTL responses to subdominant epitopes readily compensate for the loss of an effector CTL response to the dominant epitope. Thus, the failure of rickettsial fragment derived from OMPs to establish solid immunity and complete protection compared to natural infection could be due to absence of memory CD8 CTL precursors that are specific to subdominant epitopes on OmpA or OmpB, which could compensate for defective or inadequate generation of effector CTL to immunodominant epitopes. A genome-wide approach is thus essential to identify both immunodominant and subdominant epitopes.

VACCINES IN DEVELOPMENT

Rationale for New Generation Vaccine

Vaccines are required for two rickettsial diseases: epidemic typhus and Rocky Mountain spotted fever. The requirement of vaccines for these diseases is determined by the fact that both diseases can be fatal even with the availability of antibiotic treatment that is effective when given sufficiently early in the course, and antibiotic resistant strains have been obtained by natural selection in the laboratory for *R. prowazekii* and can be genetically engineered for both *R. prowazekii* and *R. rickettsii*. These agents are genuine threats for bioterrorism. The previously developed vaccines are either ineffective (e.g., killed *R. rickettsii*) or easily revert to the virulent state (e.g., attenuated *R. prowazekii* E strain).

Vaccine Candidates

Vaccine candidates for rickettsiae include an attenuated strain of *R. prowazekii* and subunit vaccines for both spotted fever and typhus rickettsiae.

Attenuated E Strain Vaccine

E strain was evaluated as a vaccine on a large scale in South America in the 1950s and in Burundi in the 1960s; 94% (170/181) of immunized persons were protected from natural infection by epidemic typhus compared to the unvaccinated controls in a 14-month period after vaccination (Kenyon et al., 1979). In another study, Fox and colleagues evaluated the duration of immunity stimulated by E strain vaccine in volunteers (Fox et al., 1957). Ninety-six percent (Gonder et al., 1979, 1980) of volunteers who were vaccinated with E strain and challenged with Breinl strain at intervals from 2 months to 36 months remained healthy following challenge, and 83% (5/6) of the volunteers who were challenged at 48–66 months were protected. However, the E strain vaccine caused a late reaction in up to 14% of vaccinated persons 9–14 days after inoculation. The late reaction varied from simple malaise and mild headache to modified typhus characterized by fever, headache, malaise, and occasionally a rash in a small proportion of subjects (Kenyon et al., 1979). One possible explanation for this reaction in some persons immunized with E strain is that E strain might have reverted to virulence in these vaccinated persons after initiating stimulation of immunity. In the early 1970s, Russian scientists reported that one or a few passages of E strain in guinea pigs resulted in the stable enhancement of virulence, and they isolated the virulent revertant Evir strain from animals (Balayeva and Nikolskaya, 1971).

Since the avirulent E strain reverts to virulence when passaged in animals, the mutation that affects the virulence of E strain must be reversible. Comparison of the genomes of *R. prowazekii* E strain with the genomes of *R. conorii*, *R. typhi*, *R. rickettsii*, and *R. sibirica*, identified one gene (Rp028/Rp027) that is inactivated by a frameshift mutation in E strain, but the mutation is not present in virulent revertant Evir strain and wild-type virulent Breinl strain (Zhang et al., 2007). This situation suggests that the mutation reverted to wild-type in the virulent revertant. Rp028/Rp027 shares homology with the regulatory domain of an S-adenosylmethionine (SAM)-dependent methyltransferase. The patterns of methylation of lysine in the surface antigens of E, Evir, and Breinl strains are different. The surface antigen of the virulent Breinl and Evir strains contains more N^{ε}-Me3-lysine and less N^{ε}-Me-lysine than to the avirulent E strain. OmpB, the major OMP of rickettsiae from the virulent strains, is heavily methylated while the OmpB from the attenuated strain is hypomethylated. Western blot analysis of partially digested OmpB revealed that one of the reactive fragments was located at the N-terminus (aa 33-272), in which the lysine residues were either mono-, di-, or tri-methylated (Ching et al., 1992, 1993). However, neither the significance of the difference in methylation

between the avirulent E strain and virulent strains of *R. prowazekii* nor the mechanism of the difference in methylation has been determined. The difference in OmpB methylation is most likely not caused by amino acid differences because there is only one amino acid difference in OmpB between the avirulent E strain and virulent Breinl strain. Thus, it seems that the deficiency in lysine methylation in E strain is caused by a mutation in the lysine methyltransferase rather than the mutation in OmpB. The correlation between the SAM-dependent methyltransferase mutation and the virulence of *R. prowazekii* needs to be investigated by genetic complementation of the avirulent E strain or gene knockout in virulent revertant Evir strain of *R. prowazekii*. With the progress in transforming rickettsiae that has been made in recent years, the *R. prowazekii* methyltransferase gene may be inactivated in the future to evaluate whether it is the determinant that attenuates E strain. A substantial knockout in the mutated gene of a virulence factor may prevent the reversion of E strain to the virulent state, thus creating an irreversibly attenuated vaccine against *R. prowazekii*.

Subunit Vaccine for Rickettsia

Two surface protein antigens of *R. rickettsii*, OmpA and OmpB, have been identified as major protective antigens and are candidates for use as subunit vaccines. The first evidence that OmpA and OmpB contain protective epitopes came from the studies of MAbs to heat sensitive epitopes of OmpA and OmpB, which neutralized *R. rickettsii* toxicity in mice and infection in guinea pigs (Anacker et al., 1987b; Li et al., 1988). The *E. coli*-expressed OmpA N-terminal fragment that includes the domain II repetitive peptide and a shorter nonrepetitive region after the repetitive region partially protects guinea pigs against a lethal challenge dose of *R. rickettsii* (McDonald et al., 1987, 1988). A fragment from the N-terminus of *R. conorii* OmpA protects guinea pigs against experimental infection with *R. conorii* and partially protects guinea pigs from challenge with the heterologous *R. rickettsii* (Vishwanath et al., 1990). The full length recombinant OmpA using the baculovirus-eukaryotic cell expression system confers complete protection in guinea pigs against homologous *R. rickettsii* challenge (Sumner et al., 1995). Fragments of the *ompA* and *ompB* genes have been tested as DNA vaccines. In a regime of DNA immunization followed by boosters of the corresponding peptide, mice immunized with one of the following *R. rickettsii ompA* or *ompB* fragments: $ompA_{2176-3933}$, $ompA_{4999-6710}$, $ompB_{1550-2739}$, or $ompB_{2459-4123}$ are partially protected against a lethal challenge with heterologous *R. conorii* (Crocquet-Valdes et al., 2002; Diaz-Montero et al., 2001). The recombinant protein alone from each DNA fragment above also provides partial protection to mice against heterologous *R. conorii* challenge, albeit less protection. However, DNA vaccination alone failed to stimulate protection to mice. It is not known whether the incomplete protection of OmpA and OmpB to the heterologous *Rickettsia* species challenge in these experiments is caused by the antigenic differences between the rickettsial species, the immunization regime, or the antigen composition. Immunization with a combination of all four fragments protected completely against death, but not against illness.

Broad Range Vaccine for Rickettsial Diseases

C3H/HeN mice infected with a sublethal dose of *R. conorii* are completely protected from lethal dose challenge of heterologous *R. australis* or vice versa. In contrast, heterologous immune sera did not protect mice against a lethal dose (2 LD_{50}) of rickettsiae in the mouse toxicity neutralization assay, the standard method for evaluation of rickettsial vaccine potency. These observations suggest that development of a broadly protective vaccine against SFG rickettsiae is feasible, and the results indicate that mouse toxicity neutralization is an inappropriate method for evaluation of candidate vaccines (Feng and Walker, 2002). T cell-mediated crossprotection of mice against challenge with a lethal dose of *R. conorii* or *R. typhi* suggests that a broadly crossprotective vaccine is feasible (Valbuena and Walker, 2004).

Subunit vaccine for O. tsutsugamushi

The antigenic variability of *Orientia* poses a challenge for vaccine design. Immunization with *Orientia* confers relatively strong protection that lasts only 1–3 years against challenge by the homologous strain, whereas protection is very weak and short-lived against heterologous strains (Seong et al., 2001; Choi et al., 2006). Despite the antigenic variation, most studies on subunit vaccine are focused on the 56-kDa protein of *O. tsutsugamushi*. Immunization with the recombinant 56-kDa protein results in potent lymphocyte proliferation and IFN-γ production, but the immunized mice are only partially protected from lethal dose challenge with *O. tsutsugamushi* (Seong et al., 1997). Immunization of monkeys with truncated 56-kDa protein of Karp strain of *O. tsutsugamushi* results in T cell proliferation and IFN-γ production, but does not provide sterile immunity to the monkeys (Chattopadhyay et al., 2005). Subsequent studies with conserved antigens of *O. tsutsugamushi* have demonstrated either partial or no protection. Elucidation of the immune mechanisms of protective immunity, mechanisms of immune avoidance, fate of anti-*O. tsutsugamushi* memory T lymphocytes, and discovery of the antigens that stimulate protective immunity may be required before an effective scrub typhus vaccine is developed.

CONCLUSIONS/FUTURE PROSPECTIVE

The protective immune response to infection with *Rickettsia* spp. is highly dynamic and involves both innate and adaptive immune responses. In SFG rickettsiosis, infection of mice with *R. conorii* has shown that $CD8^+$ T cells, and $CD4^+$ T cells, producing IFN-γ, as well as antibodies and B cells, are required to clear infection and to prevent reinfection.

The search for a vaccine against infection with *Rickettsia* continues to be a complex task. Nevertheless, progress has been achieved in the past few years and has led to the identification of various protective rickettsial antigens as potential vaccine candidates. Although immunization regimens involving priming with DNA vaccines and boosting with protein-based vaccines have been found to be protective, to some extent, in mice, their practical application in humans remains unclear. Given that multisubunit protein vaccines seem to be more effective than vaccines based on single antigens, in the future, rickettsial vaccine candidates are likely to include several antigens.

Rickettsial vaccine research will continue to focus on the identification of additional rickettsial antigens that induce protective T cell responses and on the mechanisms that promote protective immunity against these obligate intracellular pathogens that are transmitted mainly via skin. The gaps in our knowledge include the role of dendritic cells in vivo, and the role of proinflammatory cytokines in influencing the Th1/Th2 response bias. Further data are required to understand the mechanisms that allow evasion or down regulation of the immune responses in cases of latent infection with *R. prowazekii*, which would result in persistence of rickettsiae with possible reactivation. Potential immunomodulatory mechanisms in rickettsial infections could include the effects of tick saliva-containing immunosuppressive factors, anti-inflammatory cytokines as IL-10 and TGF-β, and the possible regulatory effect of particular T cell populations. Finally, a better definition of human immune response correlates with protective immunity against different rickettsial species and disease pathogenesis needs to remain an important research priority if we are to develop a protective vaccine against rickettsial infection.

KEY ISSUES

- *R. prowazekii*, a category US B bioterror threat, and *R. rickettsii*, a US category C organism, are Select Agents that because of potentially engineered antibiotic resistance and high fatality rate after aerosol infection need vaccines for strategic deterrence.
- Subunit vaccines that stimulate antibodies to OmpB of TG rickettsiae and outer membrane proteins A and B of SFG rickettsiae confer protection, presumably by opsonization, and enhancing intracellular killing.
- Recovery from rickettsial infection is mediated by cytokine-activated endothelial cell killing of rickettsiae and CD8 cytotoxic T lymphocyte elimination of infected cells.
- An effective live attenuated vaccine against typhus, *R. prowazekii* Madrid E strain, which reverts to virulence because it depends on a single point mutation, is an excellent candidate for further development by a permanently inactivating mutation of the methyltransferase gene.
- The existence of broadly crossprotective T lymphocyte immunity suggests that development of a pan-*Rickettsia* vaccine is feasible.
- Knowledge of the mechanisms of protective immunity in scrub typhus, reasons for its transience, and poor crossprotection among strains of *O. tsutsugamushi* are severely lacking and very likely hold the key to future progress in vaccine development.

Typhoid Fever

Robert A. Kingsley and Gordon Dougan
The Wellcome Trust Sanger Institute, The Wellcome Trust Genome Campus, Hinxton, Cambridge, UK

OUTLINE

ABSTRACT

Typhoid fever, caused by *Salmonella enterica* serotype Typhi, is an infection of global importance with an estimated 21.5 million infections and 200,000 deaths per year (estimated in the year 2000). *S.* Typhi is a potential bioterrorist agent that could be disseminated in untreated water supplies and food, resulting in moderate morbidity and low mortality. Resistance to chloramphenicol, ampicillin and trimethoprim/sulfamethoxazole is widespread and resistance to the fluoroquinolones is currently spreading throughout Asia. Typhoid has been a target for vaccine development for decades and whole cell, live oral and subunit vaccines have been developed and proved both safe and efficacious. Two currently licensed vaccines are available but are not commonly used in endemic areas and the need for extensive vaccination programmes are of critical importance.

INTRODUCTION

Typhoid fever is the clinical syndrome caused by the enteric bacterial pathogen *Salmonella enterica* serotype Typhi (*S.* Typhi). An English physician Thomas Willis (1621–1675) made perhaps the first clinical descriptions of the syndrome in 1659. A clinically similar syndrome called paratyphoid is caused by antigenically and phylogenetically distinct serotypes

of *S. enterica*, namely *S*. Paratyphi A, *S*. Paratyphi B, and *S*. Paratyphi C. Initially, discrimination between typhoid and typhus fever was not routinely made and this continued to be the case until 1837 when William Wood Gerhard defined these as distinct syndromes. Identification of the typhoid bacillus in 1880 by Carl Joseph Eberth and development of the Widal agglutination test by Georges Widal in 1896 resulted in considerable progress in the diagnosis of typhoid fever. Typhoid was endemic in most countries of Europe and North America in the late 19th and early 20th centuries at least in part due to urbanization of populations during the industrial revolution and poorly planned public water systems. At that time the disease burden was estimated to be 200–800 cases per 100,000 population and an associated 10–20% mortality (JAMA, 1920), rates that are similar to the current estimates for disease burden in some regions of Asia where typhoid remains endemic. Introduction of sanitation in the form of water chlorination and sand filtration drastically reduced the incidence of typhoid fever in the first half of the 20th century in the Western world.

Typhoid fever is still endemic in many areas of Asia, Africa, and South America, where sanitation of water supply and waste treatment is inadequate. In developed countries the risk of contracting typhoid fever is limited to travel in areas with endemic typhoid and for laboratory workers, where vaccination and regular boosting or revaccination is recommended. The severity of typhoid fever is underlined by the fact that up to 32% mortality is reported in some regions of the world (Hoffman et al., 1984).

The potential use of *S*. Typhi in bioterrorist attacks is generally considered to be minimal. Since *S*. Typhi is normally transmitted through water supplies and sewerage, large-scale attacks in the Western world would likely be limited due to water treatment and sanitation procedures that are in place in these countries. Smaller scale attacks on the other hand are possible and this has been underlined by events that took place in The Dalles, OR, USA in 1984. In this case a local commune, called the Rajneeshee, attacked diners at "Shakey's Pizza" by sprinkling a nontyphoidal *S. enterica* serotype into the salad bar. Although no deaths were recorded, the resulting outbreak was the largest in Oregon history with 751 confirmed cases of *Salmonella* gastroenteritis. The attack could have been considerably worse if *S*. Typhi had been used as the bioterrorist agent in which case several deaths would have been expected. Disturbingly, Federal investigators found an invoice at the commune's ranch headquarters indicating that the Rajneeshee had ordered and received several pathogenic bacterial strains from the American-type culture collection (ATCC) including *S*. Typhi. Similar attacks in the future cannot be discounted.

ETIOLOGIC AGENT

The genus *Salmonella* contains a diverse group of Gram-negative rod-shaped bacilli in the same proteobacterial group as *Escherichia coli*. Variants within the genus, called serovars, are traditionally distinguished on the basis of their major antigens; lipopolysaccharide (LPS), flagella, and in the case of *S*. Typhi, the polysaccharide capsule. *S*. Typhi most commonly have the antigenic formula 9,12, (Vi):d:-. That is, they express the immune-dominant somatic antigen O9, and also the O12 somatic antigen, associated with LPS and are monophasic with respect to flagella, expressing the d variant. *S*. Typhi also characteristically express the Vi polysaccharide capsule that is genetically unstable during passage in the laboratory. Serovar variants are further distinguished by phage typing, a powerful epidemiological tool based on the differential susceptibility of isolates to a panel of lytic bacteriophage.

EPIDEMIOLOGY

The true incidence of typhoid fever is difficult to ascertain since active surveillance and microbiological facilities are expensive and not widely available in areas where the disease is endemic. The best sources of data are large-scale field trials of vaccine candidates in which blood samples from placebo control groups are analyzed definitively. The most recent estimate indicates a global burden of 21.6 million cases of typhoid resulting in 216,500 deaths in the year 2000 (Crump et al., 2004). The incidence is greatest in south-central Asia, south-east Asia, and Southern Africa (>100 per 100,000), with fewer cases in the rest of Asia, Africa, Latin America, and Oceania (10–100 per 100,000). The highest incidence is in India in the age-group 0–40 years in which 980 cases per 100,000 population was estimated (Sinha et al., 1999), and similarly high incidence was reported in Southern Africa and Indonesia (Klugman et al., 1987). Typhoid is normally transmitted by consumption of contaminated food or water and specific risk factors include drinking contaminated water supply, ice cream, iced drinks, and fruit and vegetables grown in fields fertilized with sewage. Furthermore, a history of certain clinical conditions, including infection with *Helicobacter pylori*

is a risk factor probably due to the reduced gastric acidity associated with *H. pylori* infection (Bhan et al., 2002; Black et al., 1985; Levine et al., 1982; Luby et al., 1998; Mermin et al., 1999).

CLINICAL DISEASE

Following ingestion of *S*. Typhi an asymptomatic period is observed, usually lasting 7–14 days, but ranging from 3 to 60 days. Patients frequently present to the hospital with fever, flu-like symptoms, dull frontal headache, malaise, anorexia, abdominal discomfort, a dry cough, and myalgia (Bhan et al., 2005; Parry et al., 2002; WHO, 2003). The fever frequently rises in a stepwise fashion becoming persistent and high-grade by the second week and, without treatment, lasts for up to 4 weeks. Following this there is a return to normal temperature but malaise and lethargy may remain for several weeks. Other physical features that may be present include relative bradycardia, coated tongue, hepatomegaly, splenomegaly, and the patient may experience altered bowel movements that may manifest as diarrhea or constipation. Characteristic erythematous maculopapular lesions, also referred to as rose spots, are sometimes observed on the back of arms, legs, and the back during the first week of illness. Liver involvement is common and is accompanied by elevated levels of serum bilirubin and alanine transferase.

Up to 10–15% of untreated patients develop severe disease that is typified by a range of complications including gastrointestinal hemorrhage, gastrointestinal perforation, and a variety of neuropsychiatric manifestations. Gastrointestinal hemorrhage occurs during the latter stages of infection and is heralded by a rapid drop in body temperature and then subsequent increase at the onset of peritonitis. Hemorrhage is most common in the terminal ileum where erosion of Peyer's patch results in rupture of blood vessels. Colonoscopy reveals variable sized punched-out ulcers with slightly raised margins (Lee et al., 2004). Blood loss is most often limited to occult blood in stool or malaena, although breach of large blood vessels occurs occasionally and is rapidly fatal if untreated. Gastrointestinal perforation occurs in 1–3% of hospitalized cases and has an overall mortality rate of 40%. This complication most frequently affects the terminal ileum and requires rapid surgical intervention (van Basten and Stockenbrugger, 1994). Some typhoid fever patients exhibit neuropsychiatric manifestations, which have been described as muttering delirium or coma vigil but curiously these symptoms appear subject to geographical variation (Parry et al., 2002). Less frequent complications include disseminated intravascular coagulation or hemorrhages, severe pneumonia, granulomas (hepatic, splenic, or bone marrow) (Mert et al., 2004), abscesses (hepatic or splenic) (Chaudhry et al., 2003), multiple organ dysfunction syndrome (Snyder et al., 2004), hemolytic uremic syndrome (Albaqali et al., 2003), endocarditis (Wani et al., 2004), and pericarditis (Baysal et al., 1998).

Relapse occurs in 5–10% of cases, generally within a month of resolution of fever. The symptoms are generally milder than the original infection and in cases where molecular typing of *S*. Typhi has been applied the relapse is generally due to the same strain as the original isolate. Reinfection with a distinct strain may also occur (Wain et al., 1999).

One of the distinctive features of typhoid fever is the carrier state that has been popularized due in part to the "Typhoid Mary" episode. Mary Mallor, a resident of New York City and a domestic servant in a number of households during the early 20th century, was responsible for a number of typhoid fever outbreaks. Her unwillingness to accept that an apparently healthy person can spread disease contributed to a series of outbreaks that followed Mary from job to job. Following detective work by local health officials Mary was found to be an asymptomatic carrier of the bacillus and she was eventually removed form the city to a secluded location. Approximately 10% of convalescent patients excrete *S*. Typhi in their stool for at least 3 months and 1–5% go on to become chronic carriers (defined as isolation from stool for more than 1 year). Detection and treatment of chronic carriers is especially problematic since they are generally asymptomatic and one in four have no history of typhoid fever. It has been speculated that carrier status is a major factor for persistence of *S*. Typhi in human populations during interepidemic periods since unlike nontyphoidal Salmonellosis, *S*. Typhi has no known animal reservoir (Kingsley and Bäumler, 2000).

TREATMENT

The most important contributing factor to a poor outcome for typhoid fever patients is a delay in initiating effective antibiotic treatment. It is important to assure eradication of the *S*. Typhi from the patient in order to reduce the likelihood of relapse or carrier status. The more severe cases that present to hospital with abdominal distension, persistent vomiting, or severe diarrhea require admission to hospital and parenteral antibiotic treatment. However, the majority

of cases (up to 90%) are managed at home with oral antibiotic therapy and close medical follow-up (Bhan et al., 2005).

Introduction of chloramphenicol treatment of typhoid fever transformed what was frequently fatal to a readily treatable disease, often without need for admission to hospital. Currently the most effective group of antimicrobial drugs for the treatment of typhoid fever are the fluoroquinolones (Akalin, 1999). In randomized, controlled trials these drugs were more rapidly effective and associated with lower levels of carriage than the previous first-line drugs chloramphenicol and trimethriprim-sulfamoxazole. Cases involving quinolone-resistant *S*. Typhi that are generally also multidrug resistant can be treated with third generation cephalosporins (ceftriaxone, cefixime, cefotaxime, and cefoperazone) that achieve only marginally poorer results than the fluoroquinolones. The major drawback of these drugs is there relative expense and lack of availability. Chloramphenicol, amoxicillin, and trimethoprim remain excellent treatments if the infecting strain is fully susceptible. Although widely available and relatively inexpensive these drugs have significant drawbacks. In addition to the widespread resistance to chloramphenicol, amoxicillin, and trimethoprim, these drugs also require extended treatment for 2–3 weeks with four times a day oral regimen for full effectiveness. Consequently, noncompliance is a significant problem resulting in increased relapse and carrier rates.

ANTIBIOTIC RESISTANCE

S. Typhi isolates with resistance to chloramphenicol were first reported in a typhoid outbreak in Mexico in 1972 (Olarte and Galindo, 1973). A similar outbreak with a chloramphenicol resistant strain occurred in the late 1970s in Lima, Peru (Goldstein et al., 1986). In each case, following an initial large increase in incidence of resistant strains, within a few years resistance was markedly reduced. This may have been influenced by the shift to an alternative therapy, using amoxicillin and trimethoprim, thereby removing the selective pressure for maintenance of the plasmid encoded chloramphenicol resistance. Chloramphenicol resistance associated with an R factor also emerged in Vietnam in the early 1970s (Butler et al., 1973). On the whole, the incidence of chloramphenicol resistant strains was low during the 1980s and even when sporadic outbreaks occurred these strains were generally fully sensitive to amoxicillin and trimethoprim. However, in the early 1990s isolates which were resistant to amoxicillin and trimethoprim in addition to chloramphenicol were reported and termed multidrug resistance (MDR) (Anand et al., 1990; Gupta, 1994). MDR is associated with incH1 plasmids which are related to the R27 plasmid first reported in *S. enterica* in the 1960s (Parry et al., 2002; Taylor et al., 1985). MDR strains require therapy with quinolones or third generation cephalosporins, and perhaps due to the use of these alternative drugs, a trend toward a lower incidence of MDR strains has since been observed. For example, in one study the incidence of MDR in blood isolates in Bangladesh indicated a peak of 3.2% in 1994 that reduced to 1.0% by 1996 (Rahman et al., 2002) and similarly fluctuations in incidence of MDR *S*. Typhi strains were reported in Vietnam (Parry, 2004). The current emerging problem in treating typhoid fever is the emergence of partial or full resistance to fluoroquinolones in several areas of Asia (Mehta et al., 2001; Mermin et al., 1999; Wain et al., 1997). Low-level resistance to ciprofloxacin, which is invariably linked to complete resistance to nalidixic acid, is frequently not picked up in clinical microbiology labs but is of clinical significance.

PATHOGENESIS

Since *S*. Typhi is host restricted to man and higher primates, investigations of pathogenesis of *S*. Typhi infections are limited to a handful of studies with chimpanzees, biopsies of typhoid fever patients, volunteer trials, and autopsy reports. The first primate experiments were carried out as early as 1904 (Grenbaum, 1904) with further more comprehensive studies in the middle of the 20th century (Edsall et al., 1960; Gaines et al., 1968; Hornick et al., 1970a, 1970b). Monetary expense and ethical considerations has since limited the use of this model for studies of pathogenesis and vaccine development. Commonly, a surrogate murine model is used as an alternative. In 1892 Loeffler described the causative agent of murine typhoid, now called *S. enterica* serotype Typhimurium (*S*. Typhimurium) using current nomenclature. The pathology of internal organs and the distribution of the *S*. Typhimurium in the host superficially resembled that of *S*. Typhi in typhoid fever patients and experimentally infected primates. These early reports thereby established *S*. Typhimurium infections of mice as a surrogate model for typhoid fever (Santos et al., 2001). Consequently much of our understanding of typhoid fever pathogenesis results from extrapolating data from experimental infections of *S*. Typhimurium infections of mice.

Typhoid fever is initiated following ingestion of between 10^3 and 10^6 organisms depending on many factors, but likely dominated by the buffering effects of certain foods (Hornick et al., 1970a). A significant barrier to the progression of infection is the low pH of the stomach, hence the association of achlorhydria with increased susceptibility (Bhan et al., 2005). Following passage through the stomach, bacteria adhere to and invade mucosal cells most likely at the Peyer's patch—lymphoid aggregates associated with the intestinal wall. M-cells, which are specialized epithelial cells involved in internalizing lumen contents for antigen presentation to the immune system, likely represent a significant portal of entry. Binding to the cystic fibrosis transmembrane receptor (CFTR) mediated by the *S*. Typhi type IV pilus may be important in the process that culminates in colonization of the gut-associated lymphoid tissue (Pier et al., 1998). Significantly, the early interactions of *S*. Typhi with the intestinal mucosa does not normally result in a polymorphonuclear infiltrate, a characteristic of infections by nontyphoidal serotypes that cause gastroenteritis. Instead, *S*. Typhi induces a predominantly mononuclear response that is not associated with diarrheagenesis. Evidence is now beginning to emerge that Vi polysaccharide capsule expressed by *S*. Typhi may be involved in modulation of the immune response that would otherwise lead to PMN influx during early stages of infection (Raffatellu et al., 2005; Sharma and Qadri, 2004).

Following invasion of the intestinal mucosa *S*. Typhi next translocate to mesenteric lymph nodes and cells of the reticuloendothelial cells of the liver and spleen during a period of transient bacteremia. Part of this dissemination may involve trafficking of infected dendritic cells (Vazquez-Torres et al., 1999). *S*. Typhi are known to survive and multiply in mononuclear phagocytic cells in vitro and likely do so at this stage within similar cells of the lymphoid follicles, liver, and spleen. After a period of intracellular replication, viable *S*. Typhi become detectable in the blood stream initiating fever in the patient, a progression in disease for which the stimuli are not currently known. Following this second episode of bacteremia, the organism is widely disseminated to secondary sites of colonization including the liver, spleen, gallbladder, bone marrow, and Peyer's patches of the terminal ileum. It has been suggested that necrosis of the Peyer's patches observed in typhoid fever patients in the third week of infection may result from the interaction of host immunological mediators and bacterial factors by a mechanism similar to the Shwartzman and Koch reactions during secondary exposure of these lymphoid tissue to high concentrations of pathogen antigens (Everest et al., 2001).

ANTIGENS ENCODED BY S. TYPHI

The major antigenic determinants of intact *S*. Typhi are LPS, the Vi polysaccharide capsule, and the flagella. The two dominant antigenic components of *S*. Typhi LPS are the repeating sugar backbone composed of 2-α-mannose-1,4-α-Rhamnose-1, 3-α-galactose-1 (O12 somatic antigen) and the immune-dominant antigen tyvelose, a sugar side chain (O9 somatic antigen) (Reeves, 1993). Vi is a polymer of α-1,4-galacturonic acid with an *N*-acetyl at position C-2 and variable *O*-acetylation at C-3 (Mai et al., 2003). The presence of this polysaccharide capsule correlates with virulence since just 1 of 2222 clinical *S*. Typhi isolates tested, was negative for Vi as indicated by serology or multiplex PCR to assay for the presence of the biosynthetic genes in a survey in Pakistan (Wain et al., 2005). *S*. Typhi lacking Vi had a 10,000-fold greater lethal dose 50% in the mouse mucin model of infection following intraperitoneal inoculation (Hone et al., 1988). Furthermore, human volunteers inoculated with Vi expressing *S*. Typhi isolates had a higher incidence of typhoid fever than those inoculated with isolates not expressing Vi (Hornick et al., 1970a, 1970b). *S*. Typhi are monophasic with respect to flagella and generally express the H:d or H:j antigen. However, some isolates from Indonesia express an alternative flagellin termed the H:z66 antigen (Huang et al., 2004; Tamura et al., 1988). *S*. Typhi also expresses iron-regulated outer-membrane proteins (IROMPs) and porins that are targets for the immune system during infection (Blanco et al., 1993; Sood et al., 2005).

S. Typhi encodes a number of pili (fimbriae), proteinaceous hair-like appendages commonly encoded by enteric bacteria and involved in interactions with the host or self association. A type IV pilus, encoded by the *pil* locus on the *S*. Typhi *Salmonella* pathogenicityisland 7 (SPI-7), may be important during initial phases of infection in the intestine where it mediates interaction with the CFTR receptor on epithelial cells (Zhang et al., 2000). *S*. Typhi also encodes an ortholog of the *agf* fimbriae of the curli family, and 12 putative fimbriae of the usher-chaperone-family (Townsend et al., 2001). Six of the usher-chaperone-family fimbrial operons contain pseudogenes resulting from the presence of frame shift and/or a stop codon in the coding sequence and therefore may not be expressed. The genomic degradation of fimbrial operons may in part

be responsible for the reduced intestinal involvement in typhoid fever compared to nontyphoidal serotypes.

PROTECTIVE IMMUNE RESPONSE

Experimental infections of mice with attenuated *S*. Typhimurium or *S. enteritidis* results in antibody responses to a diverse set of antigens including LPS, Vi polysaccharide, porins, outer membrane proteins, lipoproteins, heat shock proteins, flagella, and fimbriae (Brown and Hormaeche, 1989; Harrison et al., 1997; Kuusi et al., 1979; Matsui and Arai, 1989; Ogunniyi et al., 1994). Antibody response to somatic LPS, flagella, and Vi antigen are generally monitored in human volunteer studies with live attenuated vaccine candidate *S*. Typhi strains. Vaccinees inoculated with live oral vaccine exhibit a humoral immune response to LPS or flagella with the immune response varying from low to relatively high titer, depending on the nature of attenuation of the vaccine strain and design of the trial (Dilts et al., 2000; Hindle et al., 2002; Hohmann et al., 1996; Levine et al., 1987a; Tacket et al., 2000). Killed vaccine preparations and subunit vaccines are considered by some experts to be potentially inferior to live oral vaccines because dead vaccines predominantly generate a humoral immune response. In contrast some live vaccines generate a potent cell-mediated immune (CMI) response in addition to a humoral immune response. Although killed vaccines of *S*. Typhimurium are able to generate a protective immunity against challenge with virulent live *S*. Typhimurium in genetically resistant mice, these vaccines provide poor protection in genetically susceptible mice (Eisenstein et al., 1984; Hormaeche et al., 1995). Live vaccines generate protective immunity in both genetically resistant and susceptible strains of mice. Furthermore, live vaccines are administered orally, and are therefore capable of generating a mucosal immune response that may be important in immunity during the early stages of infection (Hormaeche et al., 1995). However, the success of the Vi subunit vaccine shows that dead vaccines can offer considerable efficacy.

Robust CMI responses to attenuated *S*. Typhimurium and *S*. Typhi following immunization of mice or volunteers have been described. The responses are predominantly of the Th1 type, as indicated by delayed type hypersensitivity (DTH) and by production of IL-2 and IFN-γ cytokines on stimulation of sensitized T-cells in vitro (Harrison et al., 1997; Sztein et al., 1994). The antigens involved in cell-mediated responses in experimental infections of mice include unspecified proteinaceous antigens, porins, flagellin, and pilin (Cao et al., 1992; Cookson and Bevan, 1997). Cell-mediated response has been monitored by various assays including tracking proliferation of sensitized lymphocytes in vitro, detection of cytokine production by in vitro stimulated T-cells, cytolytic assays, ELISPOT assays, and monitoring the DTH response following stimulation.

The protective antigens of live vaccine strains are not well defined currently. Attempts to answer this question are frustrated by the complexity of live oral *S*. Typhi vaccines in which multiple antigens are expressed in the context of a sublethal infection. It seems likely that a combination of antibody and cell-mediated responses to immune-dominant LPS antigens as well as protein antigens are required for high levels of protection against virulent *S*. Typhi following a single dose of live oral vaccine (Hormaeche et al., 1991, 1996; Kuusi et al., 1979; Matsui and Arai, 1989).

VACCINES

History

There is a long history of typhoid vaccine development, production, and marketing. The first typhoid vaccine, a parentally administered heat-killed preparation of *S*. Typhi, was introduced in 1896 and has been variably attributed to the British pathologist Almroth Write and the German bacteriologist Richard Pfeiffer (Groschel and Hornick, 1981). It was first demonstrated that specific antibody against *S*. Typhi was able to protect guinea pigs against test challenge with virulent *S*. Typhi. Write tested his vaccine in two officers in the Indian Army Corps, demonstrating general safety. A larger scale test of efficacy in 2835 army volunteers then revealed significant side effects that were nevertheless deemed acceptable in the light of the encouraging level of protection against typhoid. This vaccine was subsequently employed on a large scale in soldiers during the Boer War in South Africa (1899) and for decades to follow. However, due to a high frequency of systemic and localized reactions associated with the heat-killed parental vaccine new vaccines have subsequently been developed and are now licensed for use in many countries in recent years. A summary of currently licensed vaccines is presented in Table 57.1.

Current Licensed Vaccines

Heat-Killed Whole Cell Vaccine

Although rarely used today a whole cell killed vaccine, essentially the same as that developed by

TABLE 57.1 *S.* Typhi currently licensed vaccines

Vaccine	Primary course	Booster/revaccination	Adverse reactions	Protective efficacy[a]
Killed whole cell	Adults: 0.5 ml sc or im	Adults and children every 3 years	Local reactions; persistent redness, swelling, pain and tenderness	51–67%
	Children (1–10 years): 0.25 ml sc or im Children <1 year: not recommended		Systemic; malaise, nausea, headache, pyrexia	
Vi poly-saccharide	Adults and children >18 months: 0.5 ml im or deep sc Children <18 months: not recommended	Adults and children every 3 years	Mild and transient local reactions and less frequent systemic reactions than the whole cell vaccine	55–75%
Live attenuated Ty21a	Adults and children >6 years: 1 capsule on alternate days × 3 doses Children <6 years: not recommended	Adults and children every 1–3 years	Infrequent transient mild nausea, vomiting, abdominal cramps, diarrhea and urticarian rash	62–79%

[a] Reported by WHO (http://www.who.int/en/).

Alroth Write in 1896, is available and is relatively inexpensive. Various methods of preparation have been described including treatment with heat, alcohol, and acetone, and protective efficacy rates ranging from 40 to 89% in field trials have been reported (Engels et al., 1998). The major drawbacks are that these formulations are associated with systemic reactions in 9–34% of recipients and variability in production quality can affect efficacy.

Vi Polysaccharide Capsular Vaccine

The current subunit vaccine is a preparation of Vi polysaccharide from *S.* Typhi currently produced under the commercial names Typhim® and Typherix®. Vaccine is administered deep subcutaneously or intramuscularly as a single dose of 25 μg in 0.5 ml of preparation. Protection against typhoid fever begins days after injection and revaccination by a single dose is recommended every 3 years to maintain protection. In a trial in Nepal with individuals aged 5–44, a level of 75% protection during a 20-month period of surveillance was reported (Acharya et al., 1987). In a second study in South Africa involving children aged 5–16 years, a 55% efficacy was reported 3 years after vaccination and the serological correlate of protection was estimated to be 1 μg/ml of Vi-specific antibody (Klugman et al., 1996). The vaccine is not effective in children less than 2 years of age and due to poor immunological responses may not be cost effective in children 2–5 years of age. The Vi polysaccharide vaccine can be given with other vaccines suggested for travelers and has no contraindications other than previous severe reaction. Adverse reactions are less frequent than with the killed whole cell vaccine but may include fever (<1% recipients), headache (1.5–3% of recipients), and erythema or induration at the site of injection (7% or recipients). In common with other polysaccharide vaccines there is no booster effect suggesting a lack of immune memory. New Vi–protein conjugate vaccines that are currently under development may overcome this drawback of the Vi vaccine (Canh do et al., 2004; Kossaczka et al., 1999; Szu et al., 1994).

Attenuated Live Oral Vaccine Strain Ty21a

S. Typhi strain Ty21a that is currently manufactured under the commercial name Vivotif®, was derived from the wild-type strain Ty2 by two rounds of nitrosoguanidine (NTG) chemical mutagenesis. Ty21a is normally administered orally as an enteric-coated capsule but liquid formulations have also been tested. When three doses are administered 2 days apart, protection may be established within days following the last dose and lasts for several years. However, a booster is recommended every 1–3 years depending on whether the recipient is visiting or living in an endemic area. A protective efficacy of 67% over 7 years has been demonstrated for the standard enteric-coated capsules. In a second trial involving 36,000 vaccinees aged 5–19 years, using a liquid formulation, a protective efficacy of 79% was reported after 5 years. Generally Ty21a is extremely well tolerated but may cause transient mild nausea, vomiting, abdominal cramps, diarrhea, and urticarian rash. Ty21a may be taken together with other vaccines, including live vaccines. As Ty21a is a live vaccine it should not therefore be used if the recipient is taking antimicrobial agents,

or if mefloquine is being taken as malaria prophylaxis. The vaccine is safe for use by HIV+ individuals with T-cell count (CD4) above 200/mm^3.

The mechanism of attenuation for Ty21a is not known, and this is a major drawback of this vaccine. However, it is known that Ty21a does not express the Vi polysaccharide capsule and carries a null mutation in the *galE* gene. The *galE* gene encodes galactose epimerase that catalyses the synthesis of diphosphate–galactose from uridine diphosphate–galactose. Galactose is an important component of LPS core, the major component of the outer membrane. In the absence of exogenous galactose this LPS deficiency gives rise to a rough colony-morphology that in *S*. Typhimurium, is associated with attenuation with respect to murine pathogenesis. Indeed, *S*. Typhimurium *galE* mutants are attenuated and effective as live oral vaccines in mice (Hone et al., 1987). However, a defined *galE* mutant of *S*. Typhi Ty2, that also lacked the Vi polysaccharide, retained virulence in human volunteers (Hone et al., 1988) indicating that these mutations alone do not account for the full attenuation of Ty21a.

Vaccines in Development

Currently available typhoid vaccines have a number of drawbacks. Neither the Vi polysaccharide capsular vaccine nor the Ty21a live oral vaccine confer complete protective efficacy, although this is a goal not readily attainable by any vaccine. Although the Vi vaccine is effective following a single parenteral inoculum, it is relatively expensive as it requires skilled personnel to administer the vaccine using a syringe and needle. The available live oral vaccine is only weakly immunogenic and requires three doses to provide maximal protective efficacy. Two approaches are being used to develop improved vaccines. First, Vi–protein conjugates are being developed that induce a memory component to the immune response to the subunit. Second, a series of live oral vaccines have been constructed (summarized in Table 57.2) with the aim to develop a vaccine that is safe, immunogenic, and efficacious following a single dose.

Subunit Vaccines in Development

To improve the immunogenicity of Vi polysaccharide various proteins have been conjugated including the B-subunit of the heat-labile toxin of *E. coli* or the recombinant exoprotein A of *Pseudomonas aeruginosa* (Vi-rEPA). In guinea pigs and mice the antibody response to Vi was four- to fivefold greater in conjugates compared to unconjugated Vi 26 weeks after vaccination. Furthermore, a second immunization with the conjugates resulted in a booster response not seen in the Vi vaccine (Szu et al., 1994). In human volunteer trials of Vi-rEPA the vaccine conjugate elicited no adverse reactions and was impressively immunogenic (Kossaczka et al., 1999; Lin et al., 2001). The vaccine was safe and had a protective efficacy of 89% in a double-blind, randomized, and placebo-controlled field trial with 2–5 year old children in Vietnam (Mai et al., 2003). This compares favorably with the 55% protective efficacy of the currently licensed vaccine (Klugman et al., 1996). A second Vi–porin conjugate vaccine has also been developed that in mice, induced a systemic and mucosal immune response against Vi and porins and was sixfold more protective than Vi alone (Singh et al., 1999).

Live Attenuated Vaccine Strains in Development

A number of approaches to generate attenuated *S*. Typhi strains suitable for development of live typhoid vaccines have been described. Early studies described the attenuating properties of auxotrophic mutant derivatives of *Salmonella* including those requiring purine, aspartic acid, and *p*-aminobenzoate (pABA) (Bacon et al., 1950a, 1950b, 1951). *Salmonella* require pABA as a precursor of folates, aromatic amino acids, and the siderophore enterochelin. Bacteria synthesize pABA from chorismate, the terminal product of the aromatic biosynthesis pathway and indeed the precursor of all aromatic metabolites including enterochelin, tyrosine, phenylalanine, and tryptophan. Loss of enzyme-function in the aromatic pathway due to mutations in the *aro* genes creates a requirement for endogenous sources of the three aromatic amino acids and pABA. Additionally *aro* strains are unable to biosynthesize enterochelin, a low molecular weight iron chelating molecule involved in iron scavenging. However, enterochelin-mediated iron supply to *Salmonella* is at least partially dispensable during infection by some strains (Benjamin et al., 1985) and therefore mutation of this gene does not appear to be the mechanism for attenuation of *aro* strains. While *Salmonella* can transport and use endogenous aromatic amino acids, endogenous folate cannot be scavenged, perhaps due to its bulky structure that precludes diffusion through the porins in the outer membrane. It is, therefore, most likely that a lack of available folate or pABA is the main reason for the observed attenuation (Stocker, 2000). The first report to suggest the potential utility of aromatic auxotrophs as vaccine strains was about a quarter of a century ago. An *aroA* strain of *S*.

TABLE 57.2 *S.* Typhi attenuated live oral vaccines in development

Strain	Mutation	Basis of attenuation	Immune response	Tolerance	References
CVD908	*aroC*, *aroD*	Aromatic metabolite auxotrophy	IgG seroconversion to *S.* Typhi O-antigen in 83% of vaccinees and stimulated specific IgA-secreting gut-derived lymphocytes in 100% of vaccinees	Well tolerated, no febrile or other adverse response; bacteremia in a small proportion of vaccinees	Hone et al. (1992)
541Ty and 543Ty	*aroA*, *purA*	Aromatic metabolite auxotrophy, purine biosynthesis	Meager humoral antibody response to O, H, and Vi; 69% of vaccines responded to *S.* Typhi particulate or O-antigen	Well tolerated, no febrile or other adverse response	Levine et al. (1987b)
CVD908-*htrA*	*aroC*, *aroD htrA*	Aromatic metabolite auxotrophy, oxidative stress response	Serum immune response to *S.* Typhi O-antigen in 75–100% of vaccinees and lymphoproliferative responses to flagella and particulate antigens with high dose	Generally well tolerated, but 3 of 36 volunteers had mild diarrhea and 1 had mild fever; in phase II trial no febrile responses were reported	Tacket et al. (1997b, 2000)
χ3927	*crp*, *cya*	Regulation of transport and breakdown of catabolites and biogenesis of flagella	53% developed IgG response to *S.* typhi O-antigen	2 of 12 vaccinees had vaccine bacteremia without symptoms; 1 of 12 had fever	Tacket et al. (1992)
Ty800	*phoP*, *phoQ*	Regulation of antimicrobial peptide resistance genes and SPI-2 genes	10 of 11 volunteers developed a mucosal immune response (IgA secreting cells in blood); 9 of 11 had humoral immune response	Generally well tolerated; two volunteers had self-limiting side effects but no vaccine bacteremia was reported	Hohmann et al. (1996)
Ty445	*aroA*, *phoP*, *phoQ*	As Ty800 but additional aromatic metabolite auxotrophy	2 of 14 volunteers seroconverted to whole *S.* typhi or O-antigen	Well tolerated, no febrile or other adverse response	Hohmann et al. (1996)

Typhimurium was found to protect mice even when genetically susceptible mice were challenged by the intraperitoneal route at a 1000-fold higher dose than the lethal dose 50% (Hoiseth and Stocker, 1981). In order to reduce the likelihood of the emergence of *aro*+ revertants by back mutation or complementation during passage or preparation of the vaccine, a *S.* Typhi vaccine candidate (CVD908) was constructed that harbored paired attenuating mutations, in the *aroC* and *aroD* genes that widely separated on the genome. In early clinical studies CVD908 appeared safe and immunogenic following a single dose. However, the presence of the vaccine in the blood of some volunteers was considered an unfavorable characteristic and this strain was not further developed (Hone et al., 1992).

Several attempts to further attenuate the *S.* Typhi aromatic biosynthesis mutant strains have since been made. An approach involving the introduction of purine auxotrophy by mutation of the *purA* gene failed, as this strain was over attenuated and poorly immunogenic. Only a fraction of vaccinees responded to *S.* Typhi antigens in a lymphocyte proliferation assay and antibody responses were very low (Levine et al., 1987b). In contrast, addition of *htrA* or *ssaV* mutations to the aromatic biosynthesis (*aro*) background has been extremely productive and such *S.* Typhi vaccine candidates are well advanced in clinical trials. The *Salmonella htrA* gene is homologous to a heat stress protein of *E. coli.* However, *S.* Typhimurium *htrA* mutants are not temperature sensitive but rather exhibit increased sensitivity to oxidative stress in vitro (Pallen and Wren, 1997). It is likely that this mutation results in an increased susceptibility to oxidative killing by polymorphonucleocytes (PMN) and macrophages in vivo, and

that this may be the basis of the observed attenuation of *htrA* mutants (Johnson et al., 1991). An *aroC*, *aroD*, and *htrA S*. Typhi triple mutant (CVD908 *htrA*) has been demonstrated to be safe in humans and induce humoral immune response to O-antigen and flagella. Furthermore, cellular immune response to flagella and particulate antigens, as indicated by lymphoproliferation and production of interferon-γ, was also reported (Tacket et al., 1997b, 2000). Another candidate vaccine called *S*. Typhi strain M01ZH09, is based on an *aroC* mutation combined with a mutation in the *ssaV* gene encoded on the *Salmonella* pathogenicity island 2 (SPI-2). SPI-2 is a horizontally acquired genetic island present only in *S. enterica*. The bulk of the island encodes the apparatus for a type III secretion system (TTSS-2), a macromolecular "syringe" involved in the transfer of effector proteins into the host cell cytoplasm. The TTSS encoded on SPI-2 is upregulated upon internalization of *Salmonella* into macrophages and subsequently several injected effectors modify the phagosome compartment such that the bacteria can survive and replicate (Meresse et al., 2001; Vazquez-Torres et al., 2000). ssaV is an integral protein of the secretion apparatus and in its absence no effector proteins are secreted into target cells. In clinical trials, the *S*. Typhi strain M01ZH09 was well tolerated, although a small fraction of volunteers in the medium and high dose groups had slightly elevated temperatures. However, no viable M01ZH09 were recovered from the blood and no adverse reactions were reported. All subjects tested in the highest dose group had a significant antibody-secreting cell (ASC) response and 75% had an increase in antibody titer for O or H-antigen (Hindle et al., 2002; Kirkpatrick et al., 2005a, 2005b).

Additional *S*. Typhi candidate vaccines have been developed that are based on mutations in regulator genes. One candidate harbors mutations in adenylate cyclase (*cya*) and the cyclic AMP receptor (*crp*). These genes regulate the transcription of genes involved in the transport and utilization of carbohydrates and amino acids (Alper and Ames, 1978), and in the expression of outer-membrane proteins, flagella, and fimbriae (Komeda et al., 1976; Movva et al., 1981; Saier et al., 1978). A *S*. Typhi strain designated χ3927 with defined mutations in *cya* and *crp* was found to be highly immunogenic in a volunteer study, but produced fever in 1 of the 12 volunteers and vaccine bacteremia in 2 of the volunteers (Tacket et al., 1992). A second candidate vaccine strain was engineered with a mutation in the *phoP* and *phoQ* regulatory genes. These genes form a two-component regulator comprising the membrane bound sensor-kinase (PhoQ) and a cytoplasmic transcriptional regulator (PhoP) (Groisman et al., 1989; Miller et al., 1989). PhoP/PhoQ is involved in the activation or repression of a number of unlinked genes, many of which have been associated with virulence. For example, the PhoP/PhoQ regulon includes the TTSS-2 that is essential for macrophage survival (Bijlsma and Groisman, 2005), genes required for resistance to antimicrobial peptides (Gunn and Miller, 1996; Shi et al., 2004), and genes associated with resistance to bile (van Velkinburgh and Gunn, 1999). A *S*. Typhi vaccine candidate called Ty800 was constructed that contained defined deletion of the *phoP/phoQ* locus. In a clinical trial Ty800 was more immunogenic in volunteers following a single oral dose compared to control vaccinees that were given four doses of the conventional Ty21a (Hohmann et al., 1996). A potential drawback of the *phoP/phoQ* vaccine is that it is attenuated due to deletion of a single locus, therefore raising the possibility of complementation back to full virulence by a single event. A second *S*. Typhi vaccine candidate called Ty445 was constructed that contained defined deletion of the *aroA* gene in addition to the *phoP/phoQ* locus. In a clinical trial in which escalating doses of Ty445 *S*. Typhi strain was compared with Ty21a, the candidate vaccine was found to be safe and nonreactogenic but was considerably less immunogenic even after administration of two inoculations at the highest dose compared to the conventional vaccine strain (Hohmann et al., 1996).

S. Typhi Vaccines for Delivery of Heterologous Antigens

In the last two decades considerable effort has been directed to the development of bivalent *S*. Typhi vaccines engineered to express antigens from heterologous pathogens. The aim is to develop a live oral *S*. Typhi strain capable of protecting against multiple pathogens such as bacterial and viral pathogens and even eukaryotic parasites. This technology has been developed mainly using *S*. Typhimurium as an experimental vector since this can be genetically manipulated and the immunogenicity and protective efficacy easily evaluated in the murine model of infection. Many antigens have been expressed in *Salmonella* and the effect of expression levels, choice of promoter, and context of expression on immunogenicity assessed. For example, the effect of gene dosage on immmunogenicity of *E. coli* heat-labile toxin (LTK63) expressed in a *S*. Typhimurium *cya/crp* vaccine strain was evaluated (Covone et al., 1998). They found that high expression levels especially at the early time points of infection, were of particular importance. The choice of promoter was evaluated by driving expression of tetanus toxin fragment C (TetC) from a number of

promoters. It was reported that the *nirB* promoter, which is activated in response to low oxygen tension, was particularly good for stable expression of TetC from multicopy vectors during infection (Chatfield et al., 1992).

The context of expression has been found to be of considerable importance. That is, antigen expressed on the surface or secreted into the milieu, generally results in an improved immune response compared to expression in the cytosol of the vector strain. Various strategies have been used to express heterologous antigens on the surface of *S*. Typhimurium. For example, epitopes of colonization factor antigen I (CFA/I) and cholera toxin have been fused to flagellin and expressed in *S*. Typhimurium vaccine strains (Chauhan et al., 2005; das Gracas Luna et al., 2000). In each case an immune response to the epitope in the chimeric flagellin was detectable following immunization of mice. A second strategy involved the presentation of antigens as part of engineered autotransporter proteins. The autotransporter-family of proteins share a common mechanism of secretion in which the C-terminus forms a β-barrel structure in the outer membrane through which the N-terminal passenger domain is secreted (Henderson et al., 1998). For example, antigen 43 and AIDA of *E. coli* have been used to express foreign antigens on the surface of *S*. Typhimurium vaccine strains (Kjaergaard et al., 2002; Kramer et al., 2003). Furthermore, autotransporter-based delivery systems can be engineered to release the "passenger antigen" into the external milieu where it may be more immunogenic. For example, the major B-cell epitope of the *Plasmodium falciparum* circumsporozoitic protein (NANP) has been fused with the *S*. Typhimurium MisL C-terminal transporter domain including protease (OmpT) recognition sequence (Ruiz-Olvera et al., 2003). NANP was detectable both associated with the surface of a *S*. Typhimurium vaccine strain and free in the milieu.

Despite the relative success in expressing heterologous antigens in *S*. Typhimurium vaccine vectors that result in the generation of impressive immune responses in animal trials, development of *S*. Typhi vaccines expressing heterologous antigens has been generally problematic. One of the main issues associated with further development is that there are no animal models available to optimize expression and presentation of the antigen in *S*. Typhi. One model that has been explored is the intranasal inoculation of *S*. Typhi vaccine candidates using the murine model. In this system, a vaccine candidate *S*. Typhi CVD908 (*aroC*, *aroD*) expressing TetC was shown to induce high titers of anti-TetC antibody and confer protection against a tetanus toxin challenge. A handful of bivalent *S*. Typhi vaccines have been evaluated in clinical trials with generally disappointing results. Two volunteer studies of the *S*. Typhi χ4073 (*cyr*/*crp*) vaccine candidate expressing hepatitis B antigen resulted in poor immune response to the heterologous antigen (Nardelli-Haefliger et al., 1996; Tacket et al., 1997a). Similarly vaccine candidate *S*. Typhi Ty800 expressing *H. pylori* urease failed to induce an immune response in volunteers even following oral boost with purified urease A/B with *E. coli* heat-labile toxin as adjuvant (DiPetrillo et al., 1999). At least one study has provided some promising observations. In a volunteer study in which candidate vaccine *S*. Typhi strain CVD908-htrA expressed TetC from a plasmid, three of the nine volunteers receiving medium to high doses generated immune response to TetC (Tacket et al., 2000). Furthermore, this study established that it was possible to generate protective levels of serum antitoxin.

Clearly more development is required before the possibility of efficacious bivalent or even multivalent *S*. Typhi vaccines becomes commercial reality. An important consideration that remains to be fully investigated is the impact of prior immunity to *S*. Typhi. One study reported that exposure to *S*. Dublin 2, 6, or 9 weeks previously did not decrease the immune response to *E. coli* heat-labile toxin expressed by *S*. Dublin in a second inoculation. Indeed there was evidence in these experiments that previous exposure may even potentiate the subsequent response. However, contradictory evidence have since been reported (Attridge et al., 1997; Roberts et al., 1999). Preexisting immunity to *S*. Typhimurium and to a lesser extent *S*. Dublin, depressed the humoral immune response to heterologous antigen TetC that was expressed in a *S*. Typhimurium vaccine strain administered 44 days later (Roberts et al., 1999). It is possible that differences in these reports are serotype or strain-specific. These considerations are important if such vaccines are to be used in areas where typhoid is endemic and the target populations are likely to have preexisting exposure to the vector species.

PROSPECTS FOR THE FUTURE

There is reason for considerable optimism for future developments in the prophylaxis of typhoid fever. Improved subunit vaccines based on protein–Vi conjugates have been demonstrated to be safe and highly efficacious in phase II volunteer studies. At least three candidates CVD908-htrA (*aroC*, *aroD*, *htrA*), M01ZH09 (*aroC*, *htrA*), and Ty800 (*crp*, *cya*), are promising live oral vaccine strains and candidates to replace Ty21. At least one of these, *S*. Typhi strain M01ZH09, is soon to be evaluated in bridging trials in preparation for

phase III field trials. Some of the candidate live oral vaccines have already been tested as carriers for heterologous antigens, although further development is required to optimize stability and the elicitation of immune response.

KEY ISSUES

- In the face of a rise in incidence of paratyphoid fever caused by *S*. Paratyphi A, a vaccine effective against this serotype is needed particularly for use in the Asian sub-continent.
- The development of a typhoid conjugant vaccine or live oral vacine safe and efficacious in children under two years of age.
- An understanding of the effect of vaccine programs on bacterial populations targeted by the vaccine and populations of related pathogens. For example, what are the effects of *S*. Typhi vaccination on the population structure of *S*. Typhi and *S*. Paratyphi A.
- The development of a vaccine to combat the rising problem of non-typhoidal *Salmonella* (NTS) in sub-saharan Africa.

Shigellosis

Malabi Venkatesan, Robert W. Kaminski and Ryan T. Ranallo
Department of Pediatrics, Division of Bacterial and Rickettsial Diseases,
Walter Reed Army Institute of Research, Silver Spring, MD, USA

OUTLINE

ABSTRACT

Shigellosis is an acute, inflammatory gastrointestinal disease of humans and primates, characterized by diarrhea, fever, nausea, tenesmus, and often dysentery, which is excretion of bloody, small volume stool with mucus. It is caused by a gram-negative, nonmotile bacterium that is orally ingested in contaminated food and water. There are four major serogroups each with one or more serotypes that are differentiated by the structure of the LPS-linked O antigen. *Shigella* is a Category B pathogen and the ricin-like Shiga toxin produced by *Shigella dysenteriae* 1 strains can cause significant toxicity and sometimes hemolytic uremic syndrome which can be fatal. All virulent strains

of *Shigella* carry a large nonconjugative ~220 kb plasmid, which encodes determinants that induce a phagocytic uptake within the colonic epithelial layer. Invasion is followed by intercellular spread within the tissue, resulting in necrosis and release of proinflammatory cytokines and chemokines. Eventually this leads to an infiltration of neutrophils at the site of inflammation and resolution of infection. *Shigella* infections lead to systemic and mucosal responses that are primarily against the LPS O-antigen polysaccharide. Hence, immunity is serotype-specific although some responses are also seen against the major plasmid-encoded invasion plasmid antigens. Over the last 50 years subunit vaccines based on presenting LPS to the mucosal system as well as live-attenuated noninvasive and invasive vaccines have been tested in Phase I and field trials. Many lessons have been learnt from these trials and today, a more complete understanding of the molecular details of pathogenesis has helped to design specific mutated *Shigella* strains that have shown promise as live oral vaccine candidates. At the same time, novel ways of introducing the LPS antigen to the host strains are being evaluated as subunit vaccine candidates with significant success. Currently, only a single live, noninvasive bivalent *Shigella* vaccine exists in China which provides ~60% efficacy in adults. In the next few years a mixture of the current crop of vaccine candidates, both live and subunit, as well as combinations of the two types of vaccines will undergo testing in Phase I, II, and possibly Phase III trials. Data from these studies is expected to provide for a safe and effective vaccine development strategy that will protect against the predominant circulating serotypes of *Shigella* seen worldwide.

INTRODUCTION

Shigella is an enteroinvasive bacterium, evolved from *Escherichia coli*, and is the etiologic agent of bacillary dysentery and diarrhea. The bacterium is ingested orally through contaminated food and water, and fecal–oral and person-to-person transmission predominate as the primary sources of infection. The symptoms of shigellosis includes a sudden onset of severe abdominal cramping, high-grade fever, vomiting, anorexia, and watery diarrhea, often followed by tenesmus, fecal incontinence, and dysentery which is diarrhea with frank blood (Box 58.1). *S. dysenteriae* 1 strains are capable of epidemic diarrhea, hemorrhagic colitis, and in ~5% of patients, potentially life-threatening hemolytic uremic syndrome (HUS) due to Shiga toxin 1 production. Although the challenge dose in volunteer trials is 500–1000 virulent bacteria, as few as 10 bacteria have been shown to cause dysentery in some volunteers. Since *Shigella* is a food-borne pathogen, it has the potential to be deliberately introduced into the food supply with the intent to harm civilian populations. Thus, *Shigella* has been categorized as a Category B pathogen by the U.S. Center for Disease Control. While antibiotics are used to treat infections the ever-increasing problem of antibiotic resistance necessitates the development of effective vaccines and therapeutics.

Nausea	Colitis
Vomiting	

SHORT HISTORY OF THE DISEASE

An excellent history of diarrheal disease can be obtained in Henock Blaise and Dovie (2007). In the mid-1800s with the isolation of *Vibrio cholerae* as the etiologic agent for cholera, it became recognized that diarrheal diseases had an infectious disease component (Henock Blaise and Dovie, 2007). In 1896, during a severe epidemic of dysentery in Japan, Kiyoshi Shiga (1871–1957) isolated the organism from feces and intestinal walls of 36 dysentery patients. At the time, Kiyoshi Shiga was working as a research assistant in the laboratory of Dr. Shibasaburo Kitasato (discoverer of the tetanus bacillius) at the Institute of Infectious Diseases in Tokyo. The isolated bacillus (originally named *Bacillus dysentericus*, now known as *Shigella dysenteriae*) was shown to be negative by gram-staining, fermented dextrose, was negative in the indole reaction, and did not form acid from mannitol. Dr. Shiga was able to demonstrate the production of Shiga toxin and the agglutination of the organism when exposed to the serum from an infected patient. In the years immediately following Shiga's discovery of the dysentery bacillus, three other groups of similar organisms were isolated and named in honor of the lead scientists investigating their discovery. In 1899, Simon Flexner, a professor of pathological anatomy at the Johns Hopkins University, located in Baltimore, MD, isolated *Bacillus dysenteriae* (now *Shigella flexneri*), during a stay in Manila in the Philippine islands. Mark

Frederick Boyd, an American bacteriologist and epidemiologist isolated *Shigella boydii* in 1900 and *Shigella sonnei* was identified in 1915 by Danish microbiologist Carl Olaf Sonne. The genus was first termed *Shigella* in the 1930 edition of Bergey's Manual of Determinative Bacteriology and in the 1940s, four species of the new genus were recognized, *S. dysenteriae*, *S. flexneri*, *S. boydii*, and *S. sonnei*, also known as *Shigella* subgroups A, B, C, and D, respectively (Ewing, 1949). Since the 1960s, epidemiological surveys instituted by the Centers for Disease Control (CDC in Atlanta, GA) and the World Health Organization (WHO) have contributed significantly toward understanding the prevalence of *Shigella* species in different areas, the age groups most affected, and the socioeconomic factors that increase the risk of infection with *Shigella*.

ETIOLOGIC AGENT(S)

Shigella are gram-negative rods, nonmotile, and facultatively anaerobic. The lack of motility is due to an incomplete set of fimbrial, curli, and flagellar genes found after sequence completion of several *Shigella* genomes (Jin et al., 2002; Wei et al., 2003; Yang et al., 2005). There are very few biochemical reactions with which to distinguish *Shigella* from enteroinvasive *E. coli* (EIEC), which also causes bacillary dysentery. *Shigella* strains typically ferment glucose, cannot ferment sucrose or lactose (mutations and deletions in the *lacZYA* genes), are oxidase negative (lack cytochrome c), urease negative, do not decarboxylate lysine (lack *cadA*), and fail to produce hydrogen sulfide in triple-sugar-iron agar (TSI agar). Unlike the other three serogroups, *S. dysenteriae* (Group A) does not ferment mannitol (lacks *mtlA*, *mtlD*) while unlike *S. sonnei* (group D), the other three serogroups do not give a positive biochemical reaction with ornithine (Melito et al., 2005). *S. sonnei* and *S. dysenteriae* type 1 strains are *O*-nitrophenyl-b-d galactopyranoside (ONPG)-positive (Melito et al., 2005).

Selective media are often used to discriminate between *Shigella* and other enteric bacteria from stool samples. These include *Salmonella–Shigella* agar (SS agar), xylose lysine deoxycholate agar (XLD agar), Hektoen-enteric agar (HE) and MacConkey agar (MAC agar) all of which contain a variety of sugars, dyes, and bile salts to inhibit gram-positive bacteria and differentiate between different organisms based on their metabolic activities. For example, MAC agar contains lactose on which lactose-positive colonies such as most *E. coli* strains are red to pink in color, while lactose-negative strains like *Shigella* are usually transparent. On SS agar, *Shigella*, like Salmonella forms colorless colonies but without black centers (lack of hydrogen sulfide production by *Shigella*). On XLD agar, *Shigella* remains red because it does not ferment xylose or decarboxylate lysine while Salmonella ferments xylose, decarboxylates lysine, and forms hydrogen sulfide from thiosulfate-forming red colonies with black centers. Confirmation of biochemical identity is done serologically with *Shigella* grouping and typing antisera (DuPont et al., 1989).

CLASSIFICATION

Traditionally, the genus *Shigella* has been classified in the Family Enterobacteriaceae, with four major serogroups, each with one or more serotypes and subtypes. *S. dysenteriae* constitutes group A (with 15 serotypes), *S. flexneri* group B (16 serotypes), *S. boydii* is group D (20 serotypes), and *S. sonnei* is group C (one serotype) (Box 58.2). Subdivision into serotypes is based on the O antigen only, because *Shigella* strains lack the flagella H antigen and capsular K antigen also used in typing other *E. coli.* Some O antigens associated with EIEC are identical to those found in *Shigella* spp.

The O-antigen structure is part of the bacterial lipopolysaccharide (LPS), which is a major structural element in the outer membrane of gram-negative

- C. Type 1–20
- D. Type 1

bacteria. Besides the O-antigen, the LPS is composed of the core oligosaccharide and lipid A anchor. The core consists of a single sequence of heptoses and hexoses while the O-antigen is a polysaccharide unit composed of a repetitive sequence of hexoses, further modified by the addition of glucosyl and acetyl groups. The *S. flexneri* serotypes 1 through 5 (subtypes include *S. flexneri* 1a and 1b, 2a and 2b, etc.) are closely related and have a common basic structure encoded by a common O-antigen gene cluster (Cheah et al., 1991; Simmons and Romanowska, 1987). The differences between these serotypes are conferred by modification of the basic structure of glucosyl and/or *O*-acetyl residues generating the diversity of group (group antigens 3, 4, 6, 7, 8) and type antigens (type I–VI) (Huan et al., 1997). *S. flexneri* serotypes 6 and 6a are not genetically similar to the other *S. flexneri* forms, but crossreact with them serologically because of similarity in part of the O-antigen structure (Cheah et al., 1991). The O-antigen repeat of *S. boydii* and *S. dysenteriae* are unique among *Shigella*, although many *S. boydii* and *S. dysenteriae* O antigens are either identical to, or related to, a conventional *E. coli* O antigen (Jonsson et al., 2006; Perepelov et al., 2007; Valvano and Marolda, 1991; Wang et al., 2001). The *S. sonnei* and *S. flexneri* O antigens are not found in *E. coli* (Pupo et al., 2000). So far, approximately 50 serotypes, including subtypes, of *Shigella* have been recognized and the number is expected to grow. Monoclonal antibodies (mAbs) have been generated to help in typing *Shigella* (Carlin et al., 1986, 1989; Carlin and Lindberg, 1987).

Although *Shigella* and *E. coli* have always been known to be very similar, *Shigella* has historically been treated as a different species that is distinct from *E. coli*. This is based primarily on its pathogenic traits and a few metabolic defects that were used to differentiate *Shigella* from *E. coli*. Population genetic studies using multilocus enzyme electrophoresis (MLEE) showed that *Shigella* strains fall within *E. coli*, confirming previous evidence from DNA hybridization data (Ochman et al., 1983; Riley and Anilionis, 1980). More recently, sequencing of eight housekeeping genes in four regions of the chromosome of ~50 *Shigella* strains belonging to the four traditional *Shigella* species indicated that, all but five of the *Shigella* strains (*S. sonnei*, *S. dysenteriae* 1, and *S. flexneri* VIa are three of these five strains) fall into one of three major clusters within *E. coli* species, and these the same strains are in each cluster for all four regions of the chromosome (Pupo et al., 2000). While the strains within each cluster are very similar, there is little in common among the three clusters suggesting that *Shigella* strains, like the other pathogenic forms of *E. coli*, do not have a single evolutionary origin but have multiple origins. By a process of convergent evolution of phenotypic properties, including gene gain (capture of the virulence plasmid) and gene loss or "black holes" (e.g., losses of the chromosomal *cadB* and the *nadB* gene), *Shigella* has uniquely adapted its pathogenic lifestyle within the host (Maurelli, 2007; Pupo et al., 2000).

EPIDEMIOLOGY

Shigellosis affects an estimated 164 million people worldwide and although it is considered a disease of developing countries, over 14,000 laboratory-confirmed cases are reported to occur in the US annually (Kotloff et al., 1999). *Shigella* species are not known to be zoonotic pathogens, and natural infections have been documented only for humans and primates. While the infectious dose for humans is in the range of 100–1000 bacteria, doses of 10^9–10^{10} cfu are required to observe dysentery in rhesus monkeys (DuPont et al., 1989; Formal et al., 1965). Epidemiological and antibiotic resistance data on *Shigella* is typically monitored in travelers returning from developing countries or by in-country, population-based national surveillance systems, such as those found at local hospitals and clinics. The isolates are often typed, subtyped, and characterized using specific antisera, biochemical profile, ribotyping, plasmid analysis, PCR-based epidemiological tools, and antibiotic resistance patterns (Korpela et al., 1995; Materu et al., 1997; Na-Ubol et al., 2006; Navia et al., 1999; Penatti et al., 2007; Taneja et al., 2005; Zafar et al., 2005). A global view of the incidence of shigellosis was estimated from current literature (Fig. 58.1) and indicates that approximately 99% of all shigellosis occurs in developing countries with the highest burden of *Shigella* infection in northern Africa (Chompook et al., 2005; Lee et al., 2005; Ram et al., 2007; von Seidlein et al., 2006). The lowest incidence of shigellosis occurs in the US, Europe, and Australia (Kotloff et al., 1999). As noted by many epidemiological studies, shigellosis incidence data are almost nonexistent in sub-Saharan Africa and represents a significant challenge when estimating the global epidemiology. *S. flexneri* is the most prevalent serotype worldwide and is found most often in the developing countries of Africa and South and East Asia while *S. sonnei* predominates in the US and Europe (Box 58.3). New isolates of each major serogroups are being isolated such as *S. flexneri* 1c, *S. flexneri* 4X, *S. boydii* 20, and *S. dysenterie* type strain KIVI 162 (Grimont et al., 2007; Talukder et al., 2002, 2003, 2006, 2007).

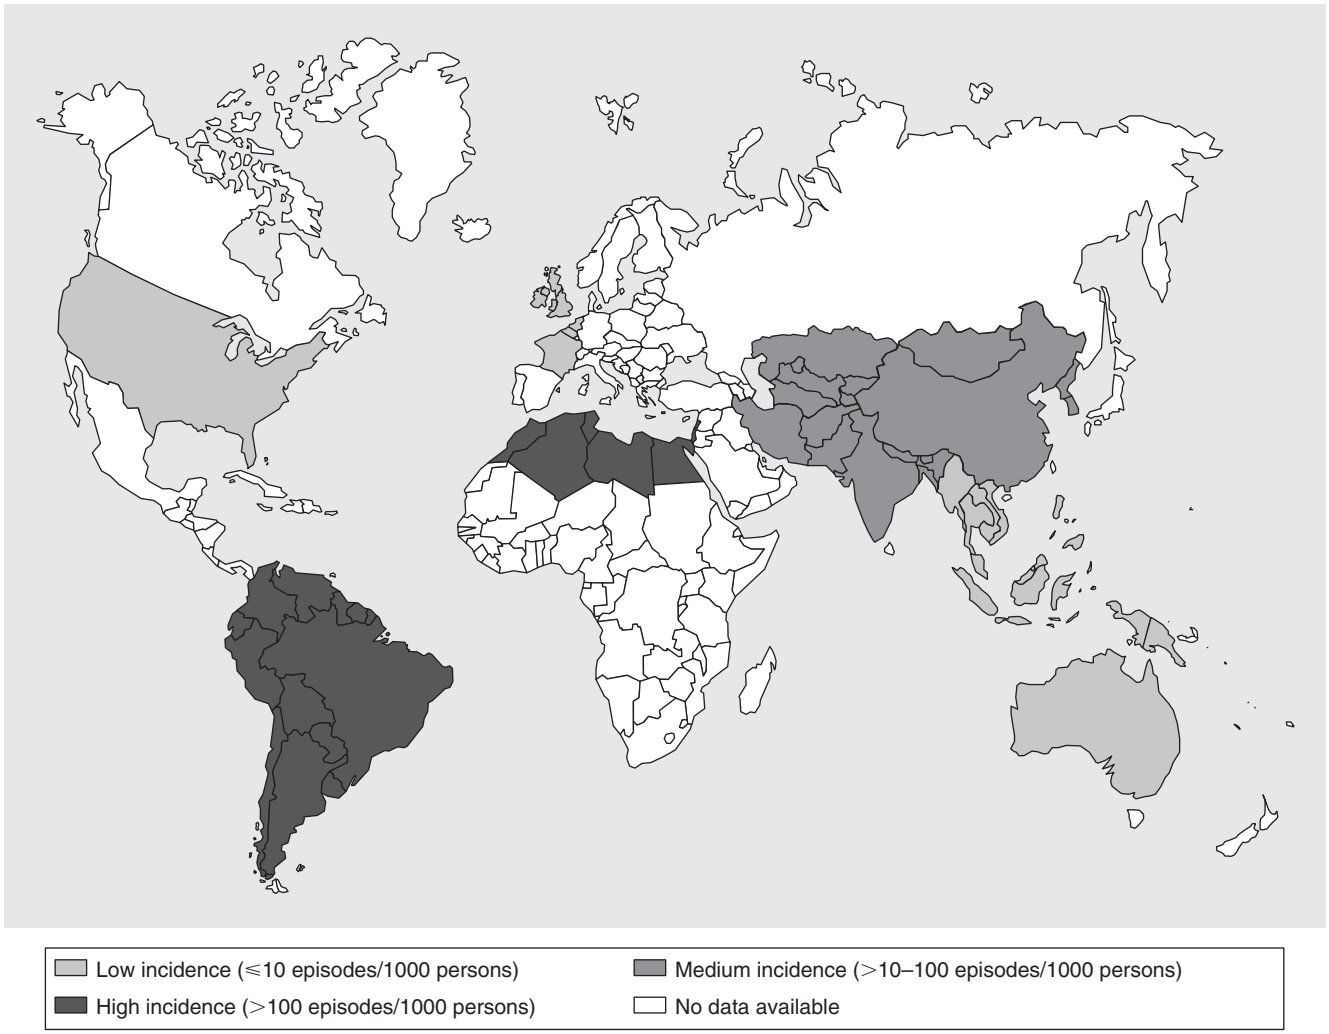

FIGURE 58.1 World incidence of shigellosis.

In developing countries where substandard hygiene and poor water quality persist children under 5 years of age are most at risk (>6 months and <2 years are at highest risk) for developing shigellosis (Elamreen et al., 2007; Faruque et al., 1998; Nguyen et al., 1998). Worldwide, approximately 600,000 deaths occur annually; 60% of such deaths are seen in children under 5 years of age (Sur et al., 2004). The bacteria are primarily transmitted through direct contact with an infected person or by ingestion of contaminated food or water. Several factors increase the risk for shigellosis such as age and socioeconomic status including, sanitation, and malnutrition (Elamreen et al., 2007; Sakdisiwasdi et al., 1982). Flies can serve as mechanical vectors for the transmission of *Shigella* under particularly poor environmental conditions (Bidawid et al., 1978; Chompook et al., 2006; Dupont, 2005).

In the US, *Shigella* infections constitute the third most common cause of gastroenteritis, after *Campylobacter* and *Salmonella* infections. Particularly susceptible are children in day-care centers, migrant workers, travelers to developing countries, and homosexual men (CDC, 2002; Garrett et al., 2006; Monteville et al., 2006; Morgan et al., 2006; Riddle et al., 2006). An association of *Helicobacter pylori* with *Shigella* gastroenteritis in children has also been reported (Shmuely et al., 2004). From 1989 to 2003, a total of 208,368 cases of laboratory-confirmed *Shigella* infections were reported to the Centers for Disease Control and Prevention wherein, *S. sonnei* accounted for the majority of the cases (72%), followed by *S. flexneri* (18%), *S. boydii* (2%), and *S. dysenteriae* (~1%) (Gupta et al., 2004). To compare a different part of the world, in Kolkata, India, 193 *Shigella*

strains were isolated from 2489 hospitalized children from Jan 2001 to August 2004. *S. flexneri* was the most prevalent serogroup (60%) followed by *S. sonnei* (23%), *S. dysenteriae* (10%), and *S. boydii* (6%) (Pazhani et al., 2005). In a recent study in a pediatric population in Egypt, the prevalent serotypes seen were *S. flexneri* 2a (37.1%), 1b (18.6%), 1c (17.5%), and 6 (15.5%), which together comprised over 88.7% of the total isolates. These data also show that *S. flexneri* 1c has emerged as a dominant *S. flexneri* serotype in Egypt (Ahmed et al., 2006).

ANTIBIOTIC RESISTANCE

Wide spread resistance to first line antimicrobials has complicated the selection of drugs for the treatment of shigellosis. A survey of the literature suggests that a majority of *Shigella* isolates from around the world, including the US, demonstrate some resistance to commonly used antibiotics such as ampicillin, chloramphenicol, TMP-SMX, and tetracycline (Ahmed et al., 2006; Al-Moyed et al., 2006; Pan et al., 2006; Replogle et al., 2000; Sivapalasingam et al., 2006; Toro et al., 2005). In fact, multidrug resistance to these antibiotics has made them no longer appropriate for empirical treatment in the US. Resistance to these antimicrobials appears to be even higher in developing countries, like India and China, where resistance to both traditional antibiotics as well as fluoroquinolones (ciprofloxacin) is increasing dramatically (Talukder et al., 2003, 2007). In parts of these countries resistance to nalidixic acid in *S. flexneri* strains can be as high as 92–100% (Haukka and Siitonen, 2007; von Seidlein et al., 2006). In Kolkata, the prevalence of fluoroquinolone resistance has increased to 25% in endemic *S. flexneri* isolates (Pazhani et al., 2005). In a pediatric population in Egypt, marked resistance to ampicillin (87.6%), tetracycline (84.5%), and trimethoprim-sulfamethoxazole (63.9%) was seen among the strains isolated (Ahmed et al., 2006). Increasing resistance to antimicrobials in developing countries highlights the perils of over-the-counter sale and indiscriminate use of antibiotics for treating infectious diseases (Ahmed et al., 2006; Al-Moyed et al., 2006; Pan et al., 2006; Toro et al., 2005).

SIGNIFICANCE AS PUBLIC HEALTH PROBLEM

The low infectious dose, the fecal–oral route of transmission, and the emergence of resistance to multiple antibiotics among *Shigella* isolates poses a major public health problem throughout the developing world. Areas of political upheaval and natural disasters are particularly susceptible to high rates of morbidity and mortality due to diarrheal diseases, in particular, because of the lack of clean water, proper

sanitary conditions, overcrowding in refugee camps and villages. *S. dysenteriae* 1 has the highest mortality rate (as high as 5–15%) of any *Shigella* species due in part to the expression of the ricin-like Shiga toxin which can cause renal complications leading to HUS. Since the late 1960s, pandemics of dysentery, caused by *S. dysenteriae* 1, have occurred in Central America, sub-Saharan Africa, Middle East, and Southeast Asia (Cahill et al., 1966; Gangarosa et al., 1970; Rahaman et al., 1975; Simchen et al., 1991). During a regional epidemic of *Shigella*-based dysentery that swept through Guatemala and neighboring countries in Central America during 1969–1971, an estimated 20,000 cases of dysentery-induced deaths were reported. One particularly disturbing feature was the resistance of the bacteria to the most commonly used antibacterial drugs (Gangarosa et al., 1970). Dysentery spared infants under 6 months of age, the attack rate being highest in the age group 7–23 months and thereafter was more or less equally distributed between the ages and the sexes (Gangarosa et al., 1970). During the civil war in Rwanda that started in mid-1994, among the estimated 500,000–800,000 refugees who crossed over into Goma in neighboring Zaire, an unprecedented number of deaths, ~50,000, were reported during the early months of the emergency situation, between the months of July–August, 1994. Eighty-five to 90% of the mortality rates were ascribed to diarrheal diseases, more specifically due to successive cholera and *S. dysenteriae* 1-induced outbreaks of bloody diarrhea (Legros et al., 2001). International intervention with provision of clean water contributed thereafter to significant reduction in the mortality rates (Legros et al., 2001). *S. dysenteriae* epidemics occur in roughly 10 to 14-year cycles with the most recent outbreak documented in northern India and Bangladesh (Hens et al., 2005; Pazhani et al., 2005; Talukder et al., 2003; Taneja et al., 2005). The most troubling finding from these outbreaks is the emergence of fluoroquinolone-resistant strains capable of clonal spread (Talukder et al., 2006; Taneja et al., 2005).

POTENTIAL AS A BIOTHREAT AGENT

In October 1996, a disgruntled lab worker in Dallas, TX, deliberately infected pastries to be consumed by colleagues with *S. dysenteriae* 2, causing illness in 12 people and sending 4 to the hospital (Kolavic et al., 1997). Such an intentional and malevolent use of a multidrug resistant Shiga toxin-producing *S. dysenteriae* as an agent of food terrorism on a larger scale can pose a huge burden on the public health system and has the potential to disrupt the social, economic, and political stability of the region. "Early detection of disease resulting from covert food terrorism depends on sensitive surveillance systems for communicable disease at the local and national levels, with close cooperation and communication among clinicians, laboratories and public health officials" (World Health Organization, 2002).

CLINICAL DISEASE

During the Guatemalan epidemic in early 1969, the onset of *S. dysenteriae* 1-induced shigellosis in patients was described as follows and typifies the clinical symptoms of the disease: "in patients with Shiga dysentery, diarrhea started abruptly, usually without blood. Three fourths of the patients had fever, generally below 102°F. Twelve to 72 h after onset, blood and pus appeared in the stools. Many patients passed only mucus and blood during the acute phase of the disease. Abdominal pain and cramps were commonly observed. Vomiting was recorded in 47% of cases. The most severely ill had 10–40 evacuations a day and intense tenesmus and rectal pain at the height of illness. The duration of symptoms for most patients was 5–7 days. A few were ill for less than 48 h and others for more than a month" (Mata et al., 1970). Pathology reports of autopsy cases indicated a diffusely inflamed mucosa of the sigmoid colon and shallow ulcers no deeper than the muscularis mucosa. The cause of death was dehydration and exhaustion in most cases.

In endemic areas shigellosis is rare in infants less than 6 months of age, presumably, because antibodies in their mother's milk protect them from infection. Shigellosis in the neonatal period results from mother-to-infant fecal–oral transmission during labor and delivery, usually from asymptomatic carriage. Bloody diarrhea is uncommon, however, intestinal perforation and mortality are more common in this group than in older children. In a postmortem examination of the intestine of 37 Bangladeshi children, ~age 2 years, who died of shigellosis, the regional pattern of lesions ranged from involvement of the rectosigmoid only (3 cases) to the entire colon plus the ileum (20 cases) (Box 58.4) (Butler et al., 1989). Children who died of infections due to *S. dysenteriae* 1 and 2, *S. flexneri*, and *S. boydii*, were also compromised by severe malnutrition, hypoproteinemia, and sometimes hypoglycemia. Pathology reports indicated that the common lesion was erythema and edema denoting congestion and inflammation. Histopathology indicated increased numbers of leukocytes, predominantly mononuclear,

in the lamina propria and sometimes in the submucosa (Butler et al., 1989).

In approximately 5% of *S. dysenteriae* 1 infections, HUS (bloody urine), microangiopathic hemolytic anemia, thrombocytopenia, and renal failure have been reported because of vasculopathy mediated by Shiga toxin or Stx (Tesh and O'Brien, 1991). Shiga toxin belongs to a family of toxins characterized by a receptor binding B subunit (7.7 kDa), which forms a pentameric ring and a single 32 kDa enzymatic A subunit. The B subunit binds to the glycolipid receptor Gb_3 found in the walls of the vascular endothelial cells, allowing entry of the toxin A subunit which is an *N*-glycosidase that cleaves the 28S ribosomal RNA component of ribosomes halting protein synthesis (Tesh and O'Brien, 1991). The ensuing endothelial cell death destroys the lining of the vascular walls leading to hemorrhage. The principal organ affected in shiga toxin-mediated HUS is the kidney where there is abundant baseline expression and high inducibility of the receptor Gb_3 in the glomerular microcirculation. Direct Stx-mediated injury to vascular endothelial cells leads to tissue ischemia and dysfunction and Stx-mediated release of cytokines and chemokines, including IL-6, CXCL8 (IL-8), TNF-α which leads to a systemic inflammatory response. Extraintestinal symptoms have been recorded and include severe headache, lethargy, meningismus, delirium, and seizures, especially with *S. dysenteriae* (Chapel et al., 2005; Islam et al., 1994). Neurologic manifestations during shigellosis have been described and include rarely severe toxic encephalopathy. The pathogenesis of neurologic manifestations during shigellosis is unclear and various bacterial (Stx, LPS) and host factors (TNF-α, IL-1β, corticotrophin releasing hormone, CRH) have been implicated from studies in mice (Yuhas et al., 2002, 2004). Reiter syndrome (arthritis, urethritis, conjunctivitis), a postinfectious sequalae, is commonly observed in adults carrying human leukocyte antigen (HLA)-B27 histocompatibility antigen (Finch et al., 1986) (Box 58.5).

TREATMENT

While most diarrheal episodes should be treated with oral rehydration therapy (ORT), antibiotics are the main drugs for treating shigellosis (Alam and Ashraf, 2003; Khan et al., 1997; King et al., 2003; Sur and Bhattacharya, 2006). An assessment of the antibiotic resistance profiles of circulating strains is important when choosing which antibiotic to use in a particular region (Box 58.6). Fluoroquinolones such as ciprofloxacin, levofloxacin, and norfloxacin introduced in the late 1980s inhibit DNA replication by inhibiting DNA gyrase. These antibiotics seem to be the antibiotics of choice in US adults, however, they are not approved for use in children in the US for whom azithromycin, an azalide antibiotic is the prescribed drug (ciprofloxacin dose 500 mg given bid for 3–5 days) (Bennish et al., 1992; Ehrenpreis and Ehrenpreis, 2001; Murphy et al., 1993). Other antibiotics include trimethoprim-sulfamethoxazole (Bactrim or Septra, adult dose 800 mg

SMX/160 mg of TMP, given orally bid for 5 days) which inhibits bacterial growth by inhibiting synthesis of dihydrofolic acid and third generation cephalosporins such as cefixime and ceftriaxone, which bind to penicillin-binding proteins and disrupt or inhibit bacterial cell wall synthesis (Ehrenpreis and Ehrenpreis, 2001).

Among new developments in this area, Rifaximin, a nonabsorbed oral antibiotic given at 200 mg three times a day for 3 days, protected volunteers from shigellosis after being challenged with virulent *S. flexneri* 2a in a double-blind placebo-controlled study (Taylor et al., 2006a, 2006b). Oral butyrate represents an exciting new treatment for shigellosis. This short-chain fatty acid induces the endogenous cathelicidin CAP-18 in the colonic epithelium, stimulating the release of the active antimicrobial peptide CAP-18, which inhibits *Shigella* (Raqib et al., 2006). Promising effects of zinc, given as a micronutrient to pediatric populations, has also been reported (Roy et al., 2007).

There are currently no FDA-approved therapies or vaccines in the United States to combat or prevent illness from Shiga toxin, which is not only produced by *S. dysenteriae*, but also Shiga toxin-producing *E. coli* (STEC). STEC infections represent a significant problem in the US. Incidentally, STEC strains produce two Shiga toxins, Stx1 (identical to Shiga toxin) and Stx2 (O'Brien et al., 1992). Several different strategies to inhibit Shiga toxin and Shiga toxin-like activity include receptor mimics, active and passive immunization strategies, Stx1 and Stx2 genetic toxoids, a plant-based Stx2 toxoid, and a chimeric StxA2/StxB1 toxoid (Karmali, 2004; Paton et al., 2001; Smith et al., 2006; Tzipori et al., 2004; Wen et al., 2006a, 2006b). Passive immunization strategies utilizing humanized or human monoclonal antibodies that neutralize one or more Stx's are also being evaluated (Sheoran et al., 2005; Tzipori et al., 2004).

PATHOGENESIS

The use of cell culture and different animal models of infection have proven useful for elucidating the primary steps of infection with *Shigella*. Data from each model system has been combined to form the current pathogenic paradigm of shigellosis (Fig. 58.2, A–D) (Parsot, 2005; Sansonetti, 2006). After being orally ingested the bacteria transit through the stomach and small intestine where it survives the gastric acidity and antimicrobial peptides using mechanisms that are not completely understood. At the distal colon and rectal mucosa the bacteria transit through the specialized M cells of the follicle-associated epithelium (FAE) to the subepthelial dome where they are taken up into phagocytic vacuoles by resident phagocytes (macrophages and dendritic cells). *Shigella* rapidly escape from the vacuole and induce a proinflammatory cell death during which the loss of membrane integrity coincides with the release of numerous proinflammatory cytokines (TNF-α, IL-1β, IL-18) (Fig. 58.3) (Haimovic and Venkatesan, 2005; Suzuki et al., 2007).

After escaping the phagocytic cells, *Shigella* invades the adjacent enterocytes at the basolateral surface and are taken up within an endocytic vacuole through the coordinated activities of numerous proteins, which include the products of the *ipa* genes (IpaA, B, C, and D) and the *mxi-spa* genes that form a needle-like complex called the type three secretion system (TTSS) (Buchrieser et al., 2000; Sansonetti, 2006). The *ipa-mxi-spa-loci* comprises a 31 kb coding region located on a large >200 kb virulence plasmid present in all pathogenic isolates of *Shigella*. The IpaB and IpaC proteins are stored in the bacterial cytoplasm complexed with chaperones, such as IpgC, while others such as IpaD form a complex at the tip of the TTSS thereby controlling its secretion activity (Demers et al., 1998; Espina et al., 2006; Parsot et al., 2005; Picking et al., 2005). The invasion plasmid antigen (Ipa) proteins constitute key antigens to which antibodies are seen in serum from infected humans and monkeys

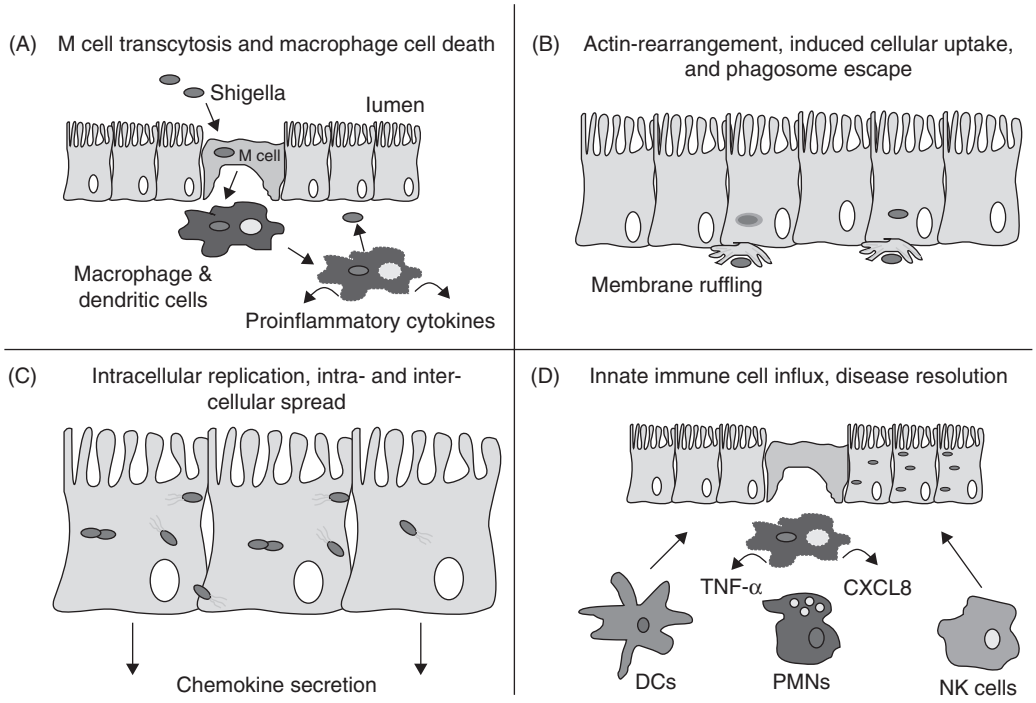

FIGURE 58.2 Major steps of *Shigella* pathogenesis (see color plate section).

(Oaks et al., 1986) (Box 58.7). Upon contact with the surface of epithelial cells, the IpaB and IpaC proteins exit through the TTSS and are believed to form a pore through which a set of type III effector proteins are secreted within the host cell. Secretion of these effectors (IpaA, IpaB, IpaC, IpgB1, IpgD, and VirA) into host cells causes major cytoskeletal rearrangements involving both F-actin and microtubules thus allowing for engulfment of the bacteria within an endocytic vacuole (Sansonetti, 2006; Tran Van Nhieu et al., 2000).

The bacteria lyse the endocytic vacuole, presumably with the help of some of the Ipa proteins, and begin to replicate using host cell metabolites to fulfill energy requirements (Fig. 58.3). Intracellular movement of the bacteria is facilitated by the polar expression of the VirG(IcsA), a critical virulence protein which belongs to the family of type V autotransporters, and mediates localized actin polymerization on one end of the bacteria (Ogawa and Sasakawa, 2006; Wing et al., 2005). VirG(IcsA) mediates intracellular movement by interacting with and activating N-WASP which in turn leads to recruitment and activation of the Arp2/3 complex (Ally et al., 2004; Suzuki and Sasakawa, 2001). VirG(IcsA) deletion mutants remain invasive in epithelial cells but are severely attenuated in plaque formation in cultured cells and in animal models of infection (Fig. 58.4). Therefore the *virG(icsA)* mutation has become a principle attenuating feature of multiple live attenuated vaccine strains (see below).

Intracellular movement is followed by intercellular spread through the enterocytes lining the intestinal mucosa. Replication and cell-to-cell movement within enterocytes results in the secretion of cytokines and chemokines, such as IL-8, a potent chemoattractant that promotes the recruitment of polymorphonuclear leucocytes (PMNLs) and neutrophils to the site of infection (Francois et al., 2000). Secretion of CXCL8 by enterocytes is induced by bacterial products such as LPS and peptidoglycan, which are recognized by host cell pattern-recognition receptors such as Toll-like receptors (TLRs) and nucleotide-oligomerization domain (NOD)-like receptors (NLRs) (Girardin et al., 2001; Viala et al., 2004). The lipid A component of extracellular LPS is recognized by TLR4 through a series of interactions involving LPS binding protein (LBP), soluble and membrane bound forms of CD14, and myeloid differentiation protein 2 (MD-2). The TLRs and NLR's activate central signaling cascades involving mitogen activated protein kinases (MAPKs) pathways and transcription factors, such as NF-kB, leading to upregulation of key cytokine synthesis such

as IL-8 and activation of the innate immune system (Philpott et al., 2000; Viala et al., 2004).

However, recent evidence suggests that invasive bacteria like *Shigella* have evolved counter defenses capable of evading or suppressing, at least temporarily, the innate immune response. For *Shigella* these counter defenses involve the secretion of additional TTSS substrates once the bacterium has entered the host cells. For example, the *Shigella* OspG protein targets host ubiquitin-transfer proteins, thereby blocking IkB degradation and subsequent activation of NF-kB (Kim et al., 2005). OspF has been shown to block NF-kB mediated transcription by targeting MAPKs such as Erk1/2 and p38 by a phosphatase or a phosphothreonine lyase activity, which removes phosphate groups from the phosphothreonine residue in the MAPK activation loop (Arbibe et al., 2007; Li et al., 2007). According to one report, this results in reduced histone H3 phosphorylation, and chromatin remodeling, leading to inaccessibility at the NF-kB regulated IL-8 promoter (Arbibe et al., 2007). Finally, a member of the IpaH family ($IpaH_{9.8}$) has been shown to interact with the mRNA splicing factor $U2AF^{35}$. This interaction appears to affect the expression of both chemokine and cytokine genes (CXCL8, RANTES, IL-β) resulting in the suppression of neutrophil migration (Okuda et al., 2005). In a mouse pulmonary model of infection, $IpaH_{9.8}$ mutants produced more inflammation than wild-type strains (Okuda et al., 2005). As more counter defense mechanisms are elucidated, strategies for utilizing these proteins to improve current vaccine efforts will be forthcoming. These elaborate mechanisms, however, are clearly inadequate to

stop the secretion of IL-8 and other chemokines by the host tissues which results in a massive influx of inflammatory cells (neutrophils) to the site of infection causing increased destruction of the colonic epithelium including loosening of the cell tight junctions, a process that seems to hasten intra- and intercellular spread. The presence of activated neutrophils is an important step in resolving the infection because neutrophils have been shown to efficiently kill *Shigella* {(Francois et al., 2000, Fig. 58.2, panel D)}.

The potency of the lipid A region of the bacterial LPS as an immune stimulant is dependent on structural features such as the number, length, and degree of acyl chain saturation. It has been demonstrated that underacylated lipid A has reduced ability to stimulate endotoxic responses (Clementz et al., 1997; Somerville et al., 1999). In *Shigella* several enzymes (encoded by the *htrB* and *msbB* genes) are responsible for secondary acylation of lipid A (Clementz et al., 1997). *Shigella* has two *msbB* genes, both of which encode late acyltransferases that are required for producing full acyl-oxyacylated lipid A under standard laboratory growth conditions (D'Hauteville et al., 2002). Furthermore *msbB* deletion mutants were found to be attenuated for virulence using animal models making them attractive targets for reducing the endotoxicity of live attenuated vaccines strains (D'Hauteville et al., 2002).

Although advanced shigellosis is usually characterized by low volume stools with blood and mucus, watery or large-volume stools often precede this stage of infection and sometimes can be the only clinical manifestation in mild infections. This stage is often overlooked as a pathogenic step, however, it occurs frequently in patients infected with *Shigella*. A detailed investigation into the cause of watery diarrhea revealed the presence of at least two enterotoxins termed *Shigella* enterotoxin 1 and 2 (ShET1 and ShET2). Both proteins were shown to contribute to enterotoxic activity using ligated rabbit ileal loops and Ussing Chambers (Fasano et al., 1995, 1997; Nataro et al., 1995). ShET1 is uniquely situated in a pathogenicity island (SHI-1) present in all *S. flexneri* 2a isolates, but rarely in other serotypes (Nataro et al., 1995). The two genes that encode ShET1 make up an operon (*setAB*) that is embedded in the opposite DNA strand of a secreted mucinase termed Pic (Behrens et al., 2002). The proteins encoded in these genes most likely form a classic A_1-B_5 oligomer and induce secretion, however, a detailed mechanism remains to be established. The gene that encodes ShET2 (*senA* or *ospD3*) is found on the large invasion plasmid and is present in all *Shigella* serogroups. The protein does not resemble any known toxin and its mechanism of action is completely unknown. Interestingly, at least one other paralog of ShET2 (encoded by *senB* or *ospD2* gene) is also present on the *Shigella* invasion plasmid (Jiang et al., 2005; Venkatesan et al., 2001). The presence of this gene could explain residual enterotoxic activity seen in the absence of both ShET1 and ShET2 (Nataro et al., 1995). The enterotoxic activity of ShET1 and ShET2 was confirmed by results from a recent clinical trial, which compared two different attenuated strains of *S. flexneri* 2a (Kotloff et al., 2004). These data show that deletion of both *senA* and *setAB* dramatically reduces the incidence of watery diarrhea in experimentally infected volunteers, a finding that has significantly advanced our ability to construct safe efficacious live attenuated *Shigella*-based vaccine strains.

Replication within epithelial cells requires multiple systems capable of scavenging limited oxygen and other nutrients found within host cells. For example, *Shigella* has multiple iron acquisition systems, which allow for growth in the iron restricted intracellular environment (Boulette and Payne, 2007; Runyen-Janecky et al., 2003). One of the most well-characterized systems is the aerobactin *iucABCD* operon, which encodes an iron siderophore capable of transporting ferric iron (Fe^{+3}) to the bacteria while in the host cell cytoplasm (Boulette and Payne, 2007). Aerobactin mutants are less virulent when compared to wild-type strains presumably because of the lack of adequate iron levels, which limits intracellular growth (Runyen-Janecky et al., 2003). Indeed deletion of *iuc* has been used as a secondary mutation in the live attenuated *Shigella* vaccine strain SC602 (discussed below). Additional attenuation strategies that take advantage of the limited biosynthetic precursors found inside host cells, include the use of *aroA*, *aroD*, and *guaBA* mutations. The most extensively tested example of such attenuation strategies can be found with the live attenuated *Shigella* vaccines from the University of Maryland Center for Vaccine Development (CVD) in Baltimore, MD. The principle attenuating feature of these strains is a deletion of the *guaBA* operon rendering the cells auxotrophic for purine biosynthesis and attenuated for both invasion and intracellular growth.

IMMUNE RESPONSE AFTER INFECTION

Innate Immune Response

Natural infection with *Shigella* results in a pronounced inflammatory response due to engagement of the innate immune system (Fernandez and Sansonetti,

BOX 58.8

SHIGELLA-SPECIFIC IMMUNE RESPONSES POSTINFECTION

Immune responses to infection with *Shigella*

Innate immune response

The initial inflammatory response induced by the release of IL-1β, IL-6, TNF-α, and IFN-γ from infiltrating PMNs, necrotic macrophages, and other lymphocytes.

Cellular immune response

Although IFN-γ and IL-10 are specifically elevated in patients 21 days after experimental infection T cell responses still remain ill defined.

Humoral immune response

Natural infections induce serum (IgA and IgG) and mucosal (sIgA) immune responses to O-antigen polysaccharide (LPS) and outer membrane proteins like the TTSS-associated invasion plasmid antigen (Ipa) proteins (IpaA, B, C, D) and VirG(IcsA).

2003). Soon after transcytosis across the gut epithelium via M cells (Box 58.8), *Shigella* induce inflammatory cytokine release after interaction with phagocytes (Fernandez-Prada et al., 1997; Viala et al., 2004). In addition, during both acute and convalescent stages of shigellosis, significant levels of IL-1α, IL-1β, TNF-α, IL-6, IL-4, IL-10, and IFN-γ can be found in rectal biopsies (Raqib et al., 1995a, 1995b, 1995c). The release of inflammatory cytokines and chemokines initiates the influx of inflammatory cells, primarily neutrophils and monocytes to the site of infection. Additional release of inflammatory cytokines likely occurs from cellular activation of epithelial cells by both intracellular and extracellular bacterial components, such as LPS. In addition to neutrophils and macrophages, dendritic cells are also recruited to the site of infection. The influx of innate cells to the site of infection largely controls the infection and is responsible for the self-limited disease.

Adaptive Immune Response

Induction of adaptive immunity also occurs after infection with *Shigella*. During acute infection, there is an increase in CD8+ T cells in the surface epithelium, an increase in the number of CD4+ and CD8+ T cells in the lamina propria, and an induction of HLA-DR antigens on the epithelial surface (Raqib et al., 1994). As an intracellular pathogen, *Shigella* induces cell-mediated immunity, both cellular proliferation and secretion of immunomodulatory cytokines, IFN-γ, and IL-10 after infection (Samandari et al., 2000; Way et al., 1998). The humoral response to infection has been well-characterized. Patients infected with *Shigella* respond with robust serum antibody responses to LPS, the Ipa proteins, and VirG (Barzu et al., 1993; Coster et al., 1999; Munoz et al., 1995; Oberhelman et al., 1991; Venkatesan and Ranallo, 2006). Mucosal antibodies, directed to both LPS and the Ipa proteins, have also been demonstrated after natural infection or immunization with live-attenuated vaccine strains in fecal samples, urine, and intestinal secretions (Cohen et al., 1996; Kotloff et al., 2004, 2002; Oberhelman et al., 1991; Van de Verg et al., 1990; Venkatesan and Ranallo, 2006). Subtle changes in the bacterial strain or species prevents full protection from disease in subsequent exposures leading to the notion that immunity is serotype-specific and conferred by LPS structure (Black et al., 1987; Cohen et al., 1997). However, the specific immune mechanisms that mediate resistance to infection have not been clearly defined and are currently being debated. For example, in contrast to anti-LPS antibodies, anti-Ipa antibodies may limit the spread and severity of infection (Oberhelman et al., 1991). Humans and rhesus macaques infected with *Shigella* mount a vigorous serum antibody response to the Ipa proteins (IpaA, IpaB, IpaC, and IpaD) and to the VirG protein (Hayani et al., 1992; Oaks et al., 1986, 1996), which is exposed on the bacterial surface. The strongest responses are generally directed to IpaB and the weakest to IpaD (Li et al., 1994a, 1994b).

VACCINES TO PREVENT SHIGELLOSIS

Early History

Early attempts to make vaccines against *Shigella* used both whole bacterial cells and whole-cell extracts (Tamura, 1967). Whole bacterial cells given parenterally were toxic and caused severe local and systemic reactions. Extracts made with various solvents were also extremely toxic. Saline extracts of acetone dried *Shigella* were highly antigenic but also exhibited considerable toxicity in mice and humans (Tully and Tamura, 1954). Since extracts from stable, colonially smooth *Shigella* was critical to obtain immunogenic extracts, it was suggested that immunity was due to specific somatic antigens, which are present only in smooth colonial types (Box 58.9).

Studies in human volunteers demonstrated that parenteral administration of *Shigella* endotoxin and other products as well as oral administration of whole-cell inactivated vaccines did not afford consistent and significant protection. This led to the concept that live vaccines, that survived in the gastrointestinal tract longer, and prolonged the presentation of the antigen to the intestinal lymphoid tissue would be more protective (Formal et al., 1965). Several noninvasive strains were developed whose principal goal was to deliver the primary immunogen, the O antigen of LPS.

Live, Noninvasive, Shigella-Based Vaccines

Sm-D Vaccines

In the mid-1960s, streptomycin-dependent (Sm-D) strains of *S. flexneri* and *S. sonnei* were used as live, oral vaccine candidates and tested in controlled field trials, in soldiers and children, living in hyperendemic areas in Yugoslavia (Mel et al., 1965a, 1965b). The vaccines were usually administered orally four to five times at high doses ranging from 3×10^{10} to 5×10^{10} cfu, preceded by a bicarbonate solution to neutralize gastric acidity. Following numerous field trials using the Sm-D strains several important observations were made. These included demonstration of (a) serotype-specific protection against shigellosis; (b) a positive correlation between vaccine efficacy and the number of organisms administered; (c) lack of antagonistic effects when two serotypes were combined into a single dose; (d) the safety and efficacy of lyophilized vaccines; (e) the utility of bicarbonate ingestion before vaccination to increase stomach pH and thus intestinal colonization; (f) a direct correlation between reactogenic symptoms and vaccine dose; (g) increasing reactions in children with decreasing age; (h) the requirement of booster doses after primary vaccination to reinforce protection (Mel et al., 1968, 1971). In the United States, a strep-dependent *S. sonnei* live oral vaccine was tested in a double-blind field trial in institutionalized children where *S. sonnei* was endemic (Levine et al., 1976). A causal relationship was observed between vaccination and protection against disease. However, the efficacy was compromised by inadvertent child-to-child vaccine transmission (Levine et al., 1976).

T-32 Istrati (Vadizen)

The live, T-32 Istrati strain is a spontaneous Sereny negative avirulent *S. flexneri* 2a strain that was tested as a live oral vaccine candidate extensively in Romania in several field trials in over 60,000 individuals and in 8000 individuals in China from 1976 to 1980 (Bingrui, 1984; Meitert et al., 1978, 1984a, 1984b). The avirulent status of the vaccine strain was later shown to be due to the loss of the ipa-mxi-spa region on the

invasion plasmid (Venkatesan et al., 1991). The vaccine was initially manufactured at Bucharest as a liquid refrigerated formulation (trade name Vadizen) and administered with buffer in Romanian children and adult collectives. Individuals received five increasing doses of the vaccine, from 5×10^{10} to 2×10^{11} cfu at 3-day intervals. Using historical data for comparison, an efficacy of 81% was calculated against *S. flexneri* 2a and 89% protection against heterologous *Shigella* species, including *S. sonnei* (Meitert et al., 1984b). The vaccine was also manufactured by Lanzhou and Beijing Institute of Biological Products in China as an enteric-coated pill. In seven placebo-controlled field trials, 11,000 individuals were tested with the vaccine or placebo (Bingrui, 1984). The vaccine was safe and demonstrated considerable protection against both homologous and heterologous serotypes (Bingrui, 1984). More recently, a deleted version of the *S. sonnei* plasmid expressing its O-antigen, has been transferred into T-32 Istrati and is used as a licensed bivalent *Shigella* vaccine in China (Levine et al., 2007).

Live, E. coli–Shigella *and* Salmonella–Shigella *Hybrid Vaccines*

Several live invasive, hybrid vaccine candidates were constructed and tested in the 1970s–1980s, with the aim of delivering the primary *Shigella* LPS antigen more effectively to the mucosal immune system. None of these strains are being pursued today; data from these trials are of historical interest.

PGA142-1-15

The first hybrid *Shigella* vaccines were constructed by the conjugal transfer of genetic markers between *E. coli* K-12 and *Shigella*. These hybrid strains were invasive in cultured cells but Sereny negative. One such strain PGA145-1-15 was tested as one or two doses at 3×10^{10} cfu per dose and showed significant colonization of the intestinal lumen. However, immunogenicity was poor and no protection was seen after challenge with virulent *S. flexneri* 2a strain 2457T (Levine et al., 1977). This suggested that colonization alone was not sufficient for protection.

EC104

The identification of the virulence plasmid and its role in promoting invasiveness in cultured cells, led to the design of EC104 which contained the Tn*5*-tagged virulence plasmid (pWR110) of *S. flexneri* 5 in addition to chromosomal markers from *S. flexneri* 2a in an *E. coli* background (Formal et al., 1984; Sansonetti et al., 1981, 1982). EC104 was invasive in cultured cells but negative in the Sereny reaction, which was later shown to be linked to the *kcpA* locus in *E. coli*. Safety trials in human volunteers indicated that doses that were safe and showed colonization of the intestine were not protective (Hale, 1990).

EcSf2a-1 and EcSf2a-2

Two additional derivatives (EcSf2a-1 and EcSf2a-2) were constructed based on conjugal transfer of the *Shigella* virulence plasmid and chromosomal markers into *E. coli*. Like EC104, both EcSf2a-1 and EcSf2a-2 were invasive in cultured cells but negative in the Sereny reaction. EcSf2a-1 was tested in three doses at 10^6–10^9 cfu per dose. The vaccine was shed for 7–12 days and at the highest dose, several volunteers had fever, diarrhea, or dysentery. Although 30–40% of the volunteers indicated significant responses to LPS and Ipa proteins, at the lower dose where the vaccine was safe, no protection was observed between immunized and unimmunized volunteers. Introduction of an *aroD* mutation into EcSf2a-1 resulted in EcSf2a-2 (Kotloff et al., 1992). The *aroD* mutation made EcSf2a-2 dependent upon exogenous PABA for growth, and limited multiplication within epithelial cells. Three doses of EcSf2a-2 at 2×10^9 cfu per dose was fairly safe while two of the four volunteers had dysentery at 10^{10} cfu. In two subsequent efficacy studies the vaccine showed variable efficacy. No correlation was observed between protection and fourfold rises in antibody titers to LPS or the Ipa proteins. An outpatient phase II trial at Fort Ord, CA employing a four-dose regimen of 5×10^8 cfu showed EcSf2a-2 to be safe and immunogenic but in a subsequent trial, vaccine efficacy with the four doses of EcSf2a-2 was only 27% (Kotloff et al., 1995b). Since EcSf2a-1 and EcSf2a-2 occasionally formed tiny plaques, which upon isolation proved to be positive in the Sereny reaction, deletions of the *virG(icsA)* gene was introduced into both strains generating EcSf2a-3 and EcSf2a-5 respectively (Alexander et al., 1996). However, these did not enter clinical trials due to instability of these strains to retain invasiveness in cultured cells (M. Venkatesan, unpublished) and the move away from designing live, *E. coli–Shigella* hybrid vaccines towards constructing *Shigella*-based live vaccines (see below).

Salmonella typhi–S. sonnei *Bivalent Vaccine 5076-1C*

The oral typhoid vaccine Ty21a was also used for the transfer of the *S. sonnei* invasion plasmid generating

the transconjugate 5076-1C. This strain agglutinated with antisera to both *S. typhi* and *S. sonnei,* and chemical analysis indicated that the *S. sonnei* O-antigen repeat unit is transported to the surface of the hybrid strain as a polymer unlinked to the *S. typhi* lipid A core (Formal et al., 1981; Seid et al., 1984; Tramont et al., 1984). The vaccine was initially tested in military personnel as either one or three doses ranging from 10^6 to 10^9 cfu per dose. The vaccine showed good colonization rates but poor immunogenicity (Tramont et al., 1984). Subsequently, several lots of a lyophilized vaccine were tested as three doses at 10^9 cfu per dose. Upon challenge with *S. sonnei*, two of the three vaccine lots tested showed 53% protection against diarrhea and 71% protection against bloody diarrhea. The rates of serum IgG or IgA responses to the protective vaccine lots were similar as the lot that did not protect (Black et al., 1987). To reduce the lot-to-lot variation of the vaccine, a lyophilized seed lot was prepared and used for the production of another three lots of vaccine. These new lots were also not protective (Black et al., 1987). Comparison of protective lots versus nonprotective lot under the EM indicated that the nonprotective lot of 5076-1C strain lacked intact flagella. By systematic changes in the manufacturing process a new vaccine lot was prepared (lot 87-5-1), which resembled the original protective lots biochemically, serologically, and by EM visualization. Vaccination studies showed that although the strain was excreted and showed good immune responses, there was no evidence of protection against challenge with *S. sonnei* (Herrington et al., 1990). 5076-1C was later shown to have deletions in the invasion plasmid. Recently, this hybrid strain has been reengineered, wherein the Ty21a strain has been transformed with a plasmid that encodes the *S. sonnei* O-antigen operon. This new hybrid strain has shown protection in mice and guinea pigs (Xu de et al., 2007; Xu et al., 2002).

Live, *Shigella*-Based Vaccines

Linde's pur-/Rif^r Strains

Purine auxotrophs (*pur*) carrying RNA polymerase mutants (Rifampicin resistance) in *S. flexneri* 2a, strain Pur-/Rif vc77 and *S. sonnei* strain Pur-/Rif vc3359 were tested in adult volunteers and children in Sofia, Bulgaria (Linde et al., 1990). These strains retained invasiveness, displayed attenuated Sereny reaction, and showed no fluid production in rabbit ileal loops. The volunteers received one, two, or three doses of increasing amounts of the vaccines from 3×10^8 to 3×10^{10} cfu, spaced 4–5 days apart. None of the vaccinees had dysentery or any major reactions. Of four vc77-immunized volunteers, two volunteers with fecal antibody titers of >1:40, did not contract the disease after challenge with the *S. flexneri* 2a virulent strain suggesting a correlation between fecal antibody titers and immunity. In general, the vaccine was shed for 2–3 days after doses of 3×10^{10} cfu and no revertants were found. The vaccines appeared safe in a larger group of children aged 2–17 years, who were given a total dose of 3–5 $\times 10^8$ cfu of either vc77 or vc3359, but no excretion of the vaccine was observed (Dentchev et al., 1990).

aroD *and* aroA-*based Vaccines*

Two *aroD*-based live attenuated vaccines, SFL124 and SFL1070 were made in the late 1980s by investigators at the Karolinska Institute in Sweden (Karnell et al., 1992). The *aroD* gene codes for a 3-dehydroquinase enzyme that catalyzes the conversion of dehydroquinate to dehydroshikimate, a metabolite on the pathway to PABA biosynthesis. *aroD* mutants are therefore, auxotrophic for PABA, a precursor of folic acid, which is a cofactor in multiple essential biochemical reactions including the de novo biosynthesis pathway of purines. Since eukaryotic cells do not contain PABA, a *Shigella aroD* mutant is expected to invade epithelial cells but undergo limited multiplication. SFL124, was derived from a *S. flexneri* serotype Y strain background which contains the common repeating tetrasaccharide unit of the O-antigen of the *S. flexneri* serotypes (except *S. flexneri* 6) (Karnell et al., 1992). The *S. flexneri* Y strain also expresses the group 3:4 antigen and recently has been shown to have originated from a *S. flexneri* 2a strain (Roberts et al., 2005). Besides providing cross protection against other *S. flexneri* serotypes, the *S. flexneri* Y strain can be modified by glucosylating and acetylating phages to form other serotypes (Verma et al., 1991). SFL1070 has the same *aroD* mutation, however, a more virulent wild-type *S. flexneri* 2a isolate was used as the parent strain (Karnell et al., 1995). SFL124 was initially given orally to Swedish volunteers in one or three doses at 2×10^9 cfu per dose and proved to be safe and immunogenic (Li et al., 1992). In general, more volunteers responded with ASCs and local sIgA production against both LPS and Ipa than with serum antibodies. Compared to Swedish volunteers, SFL124 was both less reactogenic and less immunogenic in Vietnamese adult volunteers, probably because most of these volunteers had higher prevaccination serum anti-LPS and anti-Ipa titers (Li et al., 1993). Nonetheless, there was evidence of strong LPS-specific ASC response after primary vaccination. In addition, there were increases in sIgA to LPS and to

the Ipa antigens after booster doses as well as stimulation of mucosal memory functions that may have contributed to lower excretion rates after the booster dose. In three groups of Vietnamese children, aged 9–14 years, SFL124 was given in a single dose at 10^7–10^9 cfu (Li et al., 1994a). A dose-dependent LPS-specific ASC response as well as sIgA response was seen in 50–90% of the vaccinated children. Since the children had high preexisting antibody titers to *S. flexneri* Y LPS and water extract, modest, insignificant serum antibody responses were noted. SFL1070 was tested in adult Swedish volunteers at 10^5, 10^7, 10^8, and 10^9 cfu (Karnell et al., 1995). At 10^8 cfu the vaccine was safe but at 10^9 cfu the vaccine was quite reactogenic. A vigorous LPS-specific and water extract-specific IgA ASC response, intestinal sIgA responses, and serum IgA, IgG, and IgM responses was seen at the two highest doses. The requirement for multiple high doses of these vaccines made further development unfeasible. However, based on the safety and immunogenicity of the *aroD* vaccine strains, investigators at the CVD, introduced an *aroA* and a *virG(icsA)* deletion in the virulent *S. flexneri* 2a strain 2457T (Kotloff et al., 1996; Noriega et al., 1996). Like SFL124 and SFL1070, CVD 1203 was auxotrophic for PABA. CVD1203 was tested at a single dose of 10^6 cfu and at two doses each at 10^8 and 10^9 cfu. The strain colonized 80–95% of the volunteers at the two highest doses, however, reactogenicity was also evident (Kotloff et al., 1996). Like SFL124 and SFL1070, more volunteers responded with LPS-specific sIgA and ASCs than serum antibodies and 90–100% of the volunteers had elevated levels of serum TNF-α. In more current CVD constructs the *aroA* mutant background has been replaced with deletions in the *guaBA* genes (see below).

VACCINES IN DEVELOPMENT

Challenge Dose for Efficacy Trials of *Shigella* Vaccines

In earlier studies in naive US volunteers, doses of 100–200 cfu of 2457T, produced illness in 25–40% of the volunteers while doses ranging from 5×10^3 to 5×10^8 cfu produced illness in ~60% of the volunteers with no clear relationship between cfu given and illness (DuPont et al., 1989). *S. dysenteriae* 1, strain M-131 produced illness in 75% of the volunteers when given doses from 2×10^3 to 1×10^4 cfu, although a dose of 10 cfu caused 1 out of 10 volunteers to get sick (DuPont et al., 1989). *S. sonnei* strain 53G given at 5×10^3 cfu in this study produced illness in 35% of the volunteers (DuPont et al., 1989). In order to obtain a more consistent attack rate, volunteers were given 120 ml of bicarbonate buffer to neutralize gastric acidity prior to ingesting the 2457T challenge strain (Kotloff et al., 1995a). This time the attack rate for a 1×10^3 dose of 2457T was 92% in naive controls. In ongoing vaccine trials, administration of the vaccine is usually preceded by ingestion of a bicarbonate solution to neutralize gastric acidity.

Several subunit and live vaccines are in different stages of development (Table 58.1) and are described below.

Parenteral Vaccines

Ribosomal Shigella *Vaccines*

Crude endotoxin from *S. flexneri* was used extensively as a parenteral vaccine in the Russian army

TABLE 58.1 Developmental stage of current *Shigella vaccines*

during second world war but was subsequently shown to be nonprotective (mentioned in Levenson et al., 1991). Based on published reports of protection with ribosomal preparations from *M. tuberculosis*, *Salmonella*, *Streptococcus mutans*, and *Candida albicans*, several studies using a ribosomal vaccine preparation from *Shigella* were described between the years 1978 and 1988, including a clinical trial in human volunteers in 1985 in Russia (Gregory, 1986). In the US, ribosomal *Shigella* vaccine preparations (SRV) were isolated from fermenter cultures of avirulent strains of Form I *S. sonnei* and *S. flexneri* 2b. After sonication the ribosomes were collected by ultracentrifugation or precipitation. After further processing, the SRV was shown to consist of RNA (~55%) and protein (37%) with 0.2% by weight of LPS based on O-antigen neutralizing capacity. Since the SRV O-specific component was devoid of lipid A and KDO, that are characteristic of classical LPS, it is believed to be composed of polymerized O-side chains that constitute cytoplasmic precursors of LPS, that are noncovalently linked to the ribosomal vector in SRV preparations (Levenson and Egorova, 1990). One to two injections of 100–1000 μg of SRV given subcutaneously (s.c.) to mice, guinea pigs, or monkeys resulted in high levels of serum O-antibodies. Immunized animals were protected against intraperitoneal (mice on day 7), ocular (guinea pig on day 14), or oral challenge (monkeys at 4–20 weeks) with live virulent strain that caused disease in unimmunized animals. No correlation was seen between individual O-antibody titers and the resistance to challenge in guinea pigs (Levenson et al., 1991).

More recently, a ribosomal *Shigella* vaccine has been manufactured by the International Vaccine Institute (IVI) at Seoul, Korea for field testing in developing countries (Shim et al., 2007). Mice were immunized with a ribosomal preparation containing 2.5 μg dose of O-antigen, on days 0, 1, either intranasally (i.n.) or s.c. and compared with SC602 (a virG(icsA) and iuc mutant of *S. flexneri* 2a, see below) given i.n. Both routes of administration yielded high levels of antigen-specific serum IgG. Intranasal administration also showed high levels of IgA in mucosal secretions such as nasal washes, saliva, vaginal washes, and fecal extracts and the values were similar to that seen with SC602. Also, i.n. administration elicited significantly higher numbers of IgA ASCs in the mononuclear cells isolated from nasal passage, lung, and submandibular gland tissues than s.c. administration or SC602 given i.n. The serum and ASCs levels were maintained up to 28 weeks past immunization. Mice immunized i.n. were protected to a greater extent than those immunized s.c. after challenge with virulent strains 1 week after immunization (Shim et al., 2007). Mice with knockouts in MyD88, TLR2, TLR4, and TLR5 and immunized i.n. with SRV resulted in induction of significant levels of serum IgG and IgA as well as IgA antibodies in nasal washes similar to wild-type mice. In contrast, levels of serum IgA and IgA ASCs were significantly lower in the lung, saliva, and fecal extracts of MyD88 and TLR2 knockouts (Shim et al., 2007). Using polymeric immunoglobulin receptor knockout mice (pIgR−/−) immunized i.n. with SRV, significant levels of IgG and IgA antibodies were detected in serum and lung lavage samples, but not in saliva and fecal extracts and such mice were poorly protected after i.n. challenge with virulent strains. This indicates that sIgA induced after i.n. administration is critical for protection against *Shigella* infection (Shim et al., 2007).

Conjugate Shigella *Vaccines*

These vaccine candidates were designed based on the role of the O-antigen as the major protective antigen during natural infections of *Shigella* or during immunization with attenuated strains (Formal et al., 1989). Furthermore, prospective studies in recruits in Israel Defense Forces (IDF) showed that LPS-specific serum IgG correlated with resistance to shigellosis (Cohen et al., 1991; Robbins et al., 1992). In initial studies, LPS from *S. dysenteriae* 1 strain 1617, *S. flexneri* 2a strain 2457T, and *S. sonnei* strain 53G were extracted using hot phenol extraction and ethanol precipitation and then treated with 1% boiling glacial acetic acid to extract O-antigen-specific polysaccharides (O-SP). These O-SP products were derivatized using adipic acid hydrazide as a linker and initially conjugated to tetanus toxoid (TT) (Chu et al., 1991). Since *S. sonnei* does not stably express the O-SP, later versions of *S. sonnei* conjugate vaccines used the LPS from *Pleisomonas shigelloides*, which has an identical O-specific structure as *S. sonnei*. Injection of 25 μg of *S. dysenteriae* 1, *S. flexneri* 2a, and *P. shigelloides* conjugates into adult volunteers elicited mild local reactions only. Each conjugate induced a significant rise of the geometric mean LPS-specific serum IgG, IgM, and IgA levels (Taylor et al., 1993). A second injection 6 weeks later did not elicit booster responses, and adsorption of the conjugates onto alum did not enhance their immunogenicity. Conjugate-induced levels of IgA, but not IgG or IgM, declined to preimmunization levels at day 56. The levels of postimmunization antibodies of the three immunoglobulin classes were similar to or higher than those of recruits in the IDF following shigellosis caused by *S. flexneri* type 2a or *S. sonnei*. In later versions the O-SP was conjugated to recombinant mutant exoprotein A of *Pseudomonas aeruginosa* (rEPA) (Cohen et al., 1997). A *S. sonnei*-rEPA was

given to recruits of the IDF who were at increased risk of shigellosis under field conditions (Cohen et al., 1997). The vaccine was given as a single 0.5 ml dose intramuscularly (i.m.) (contains 25 μg of polysaccharide, 75 μg protein in saline with 0.01% thimerosal). In this study, the control group comprised volunteers who received either four oral doses of EcSf2a-2 ($5–9 \times 10^8$ cfu, given on days 0, 3, 14, 17) or a parenteral tetravalent meningococcal vaccine. Overall 559 recruits received the *S. sonnei*-rEPA conjugate and 839 recruits served as controls. The overall attack rate of *S. sonnei* shigellosis was 2.2% in recipients of *S. sonnei*-rEPA, compared with 8.6% in controls indicating an efficacy of 74%. *S. sonnei*-rEPA recipients who developed culture positive shigellosis had lower geometric mean titers of serum IgG and IgA to *S. sonnei* LPS and a lower proportion of such recruits showed a fourfold or higher increase in antibody titers (Cohen et al., 1997). In 4 to 7-year old children, *S. sonnei* and *S. flexneri* 2a conjugate vaccines elicited significant LPS-specific serum IgG titers against the homologous serotypes, which were boosted after a second dose at 6 weeks and remained high for up to 6 months after vaccination (Ashkenazi et al., 1999). Succinylation of the carrier protein was shown to improve the immunogenicity of the conjugates in mice and therefore a clinical trial of O-SP conjugates of *S. sonnei* and *S. flexneri* 2a bound to succinylated rEPA (rEPAsucc) or native or succinylated *Corynebacterium diphtheriae* toxin mutant (CRM9 or CRM9succ) was conducted in healthy adults in Israel (Passwell et al., 2001). All three conjugates of *S. sonnei* elicited significant rises of GMT of IgG anti-LPS within 1 week of injection that remained high up to 26 weeks while the *S. flexneri* 2a-rEPAsucc elicited significantly higher titers to LPS than those elicited by *S. flexneri* 2a-rCRM-9succ. Both conjugates elicited statistically significant rises of serum antibodies to the injected carrier protein. A similar profile of immunogenicity was also observed in healthy 1- to 4-year-old children given two 0.5-ml i.m. injections 6 weeks apart of either *S. sonnei*-CRM9 or *S. flexneri* 2a-rEPAsucc (Passwell et al., 2003). Five to 10% of the children had low transient fever lasting 24–48 h. *S. sonnei*-CRM9 elicited a >fourfold rise in IgG anti-LPS in 92% of the immunized children and *S. flexneri* 2a-rEPA(succ) in 85% of the children after the second injection; both conjugates elicited type-specific booster responses (Passwell et al., 2003). At 2 years the geometric mean concentrations of IgG anti-LPS were significantly higher than preimmunization levels. A >4-fold rise of IgG anti-diphtheria (66%) and IgG anti-EPA (78%) was also observed. A study of these newer derivatives of conjugate vaccines in infants is ongoing (Passwell et al., 2003).

Intranasal *Shigella* Vaccines

LPS-proteosomes

This product was developed by combining purified preparations of outer membrane proteins (OMPs) from Group B *Neisseria meningitides* that form multimolecular vesicular structures with purified antigen. In the case of *Shigella* the antigen is purified LPS and the antigen is noncovalently bound to the OMP complex in approximately equimolar proportion. In an initial clinical trial the *S. flexneri* 2a proteosome preparation was given in two i.n. doses ranging from 0.1 to 1.5 mg, with a spray device. The primary symptoms seen in most volunteers were mild-to-moderate rhinorrhea and headache, which did not appear to interfere with daily activity. All dose groups demonstrated a significant ASC response in all antibody isotypes (50% of the volunteers had LPS-specific IgA ASCs of 20–25 per 10^6 PBMCs at the 1 and 1.5 mg doses). *S. flexneri* 2a LPS-specific serum IgG and IgA rose sharply between days 0 and 14 with 40% of the volunteers showing ~5-fold increases in IgG titers at the 1 mg dose. A >twofold increase in IgG geometric mean titers to LPS in stools were seen in 50–80% of the volunteers at all doses. A subsequent challenge study failed to show adequate protection (TL Hale, unpublished communication).

Invaplex Subunit Vaccine

The *Shigella* invasin complex or Invaplex is a subcellular, macromolecular complex isolated from water extracts of virulent, intact, viable *Shigella* using step gradients of NaCl on an FPLC ion-exchange column (Turbyfill et al., 2008). Fractions eluting from the column using either 0.24 or 0.5 M NaCl and containing LPS, IpaB, and IpaC are pooled to form Invaplex 24 or Invaplex 50, respectively. Both Invaplex 24 and Invaplex 50 contain LPS, IpaB, IpaC, and IpaD, whereas only Invaplex 50 contains a truncated form of VirG and IpaA. Invaplex has been isolated from each of the four species of *Shigella* and is void of major OMPs (Turbyfill et al., 2000). Although Invaplex contains several unknown proteins, many of which are nonimmunogenic, recent work has isolated and defined the constituents responsible for the immunogenicity and protective efficacy to be LPS, IpaB, and IpaC. Significant work is currently underway to generate Invaplex from the individual components, potentially resulting in a more defined product that can be customized.

Invaplex is delivered i.n. to mice, guinea pigs, and humans and induces both systemic and mucosal antibody responses. Invaplex is not delivered with an adjuvant. In fact, Invaplex functions as a mucosal adjuvant

with both protein-based and DNA-based vaccines, highlighting its potential use with other enteric vaccine antigens for use in a combination vaccine (Kaminski et al., 2006). In mice, the mucosal immune response is induced at sites both proximal (lungs) and distal (intestines) to the site of immunization. The serum antibody response is directed primarily to LPS, IpaB, and IpaC. *Shigella*-specific cell-mediated immune responses are also induced, which have been phenotyped as primarily Th2, with high levels of antigen-specific IgG1 and the secretion of IL-4, IL-5, and IL-10 after *in vitro* restimulation of immune cells. There also is a Th1 component to the immune response, indicated with high levels of IFN-gamma secretion. Serotype-specific, homologous protective efficacy is achieved in both the mouse pulmonary and guinea pig keratoconjunctitis models (Turbyfill et al., 2000). The subunit Invaplex approach is highly adaptable to creating a multivalent vaccine, by simply combining the necessary monovalent vaccines prior to immunization (Oaks and Turbyfill, 2006).

Shigella flexneri 2a Invaplex 50 has been evaluated in Phase 1 safety and immunogenicity trials using a dose-escalation study design. Human volunteers were administered three i.n. vaccinations, separated by 2 weeks, of either 10, 50, 240, or 480 μg. No severe adverse reactions were noted in any of the dose groups. Immunization with ≥50 μg was immunogenic, with ≥240 μg induced mucosal and systemic immune responses with increased frequency and magnitude (Tribble, 2007). Positive immunogenicity results combined with an excellent safety record from the first clinical trial has warranted further evaluation in humans, which is currently underway.

Oral Vaccines

Inactivated Whole-Cell Vaccine

An inactivated *S. sonnei* whole-cell vaccine candidate SsWC, was recently tested in seven volunteers with three placebo recipients, in a Phase 1 clinical trial (McKenzie et al., 2006). To increase the expression of Ipa proteins, the strain was grown in BHI broth supplemented with 0.1% sodium deoxycholate. In vitro studies previously indicated that growth in the presence of bile salts increased invasiveness of *Shigella* (Pope et al., 1995). The cell pellet obtained after harvesting the fermentation culture was inactivated by 1% formaldehyde. The vaccine was formulated at a concentration of 2×10^{10} bacterial cells/ml in phosphate buffered saline, which also constituted a single dose. Volunteers were given either a three does (on days 0, 14, 28) or a five-dose regimen (0, 2, 4, 6, 28) with one group serving as placebo controls. One volunteer in the three-dose group had moderate abdominal pain, mild diarrhea, and one episode of vomiting after the first, second, and third dose respectively, while one volunteer in the five-dose group had moderate nausea after the fourth dose. No significant differences were seen between the two dosing groups in the mean antibody levels and each of the seven volunteers developed a fourfold or greater rise in serum IgG or IgA to at least two of the three antigens: six had significant response to SsWC, five to IpaC, and four to LPS. Five vaccines also had significant rises in fecal IgA to SsG and three volunteers to LPS and IpaC. One placebo recipient seroconverted and also had 7.5-fold rise in fecal IgA to LPS.

guaBA-*Based Vaccines Developed at CVD*

A series of live attenuated *Shigella* vaccines are being developed at the CVD based on alterations of genes associated with the biosynthesis of guanine nucleotides (*guaBA*) with additional deletions in *virG(icsA)*, enterotoxin genes *sen* and *set*. CVD 1204 contains a specific 918 bp deletion in the *guaBA* operon. The *guaBA* operon is part of the purine metabolic pathway (Noriega et al., 1994). *guaB* encodes IMP dehydrogenase and converts inosinic acid (IMP) to XMP. *guaA* encodes GMP synthetase and converts XMP to GMP. In HeLa cells CVD 1204 was less invasive than the parent strain 2457T. Additional loss of the *virG(icsA)* gene generated CVD 1205. Further suicide-vector-based deletions in the chromosomal gene *setAB*, encoding *Shigella* enterotoxin 1 (ShET1, 459 bp deletion in *set*A encoding the subunit with putative enzymatic activity) and the plasmid gene *senA*, encoding *Shigella* enterotoxin 2 (ShET2, 397 bp deletion in *senA*) resulted in CVD 1207 (Kotloff et al., 2000). Immunization with CVD 1207 was protective against challenge in guinea pigs by the ocular route even though it was significantly less invasive in HeLa cells and Sereny reaction negative. Groups of three to seven volunteers were given a single oral dose of CVD 1207 starting at 1×10^6 cfu and increasing the dose, in 10-fold increments, to 10^{10} cfu (Kotloff et al., 2000). No subject experienced fever or dysentery, although at the two highest doses a small percentage of volunteers experienced diarrhea and emesis. All of the volunteers receiving 10^8–10^{10} cfu excreted the vaccine strain for an average of 1–3 days, and 65–100% of these volunteers also demonstrated a positive ASC response to LPS. The magnitude of the LPS-specific IgA ASC responses (35 per 10^6 PBMCs) was modest compared to the response following virulent infection (239 per 10^6 PBMCs). Serum antibody responses to LPS and the

Ipa proteins were modest. In a subset of volunteers tested, increases in IFN-γ, IL-10, and TGF-β indicated a Th1 response and proliferative responses to IpaC and IpaD were also observed in a few volunteers.

More recently, CVD 1204 (*guaBA*) was compared with CVD 1208 (*guaBA*, *set*, *sen*) in groups of 16–18 volunteers who received sequentially a single oral dose of 10^7, 10^8, or 10^9 cfu of either of the two vaccine strains or placebo (Kotloff et al., 2004). While 8 of 23 recipients ingesting CVD 1204 had an adverse clinical reaction, only 1 of 21 recipients receiving CVD 1208 had mild fever, and only at the highest dose. Both vaccines elicited significant LPS-specific ASC responses while responses to the Ipa proteins were lower in magnitude and less frequent. Significant serum antibody responses to LPS and to the IpaB protein were measured with both vaccine strains, and >4-fold increases in fecal IgA to LPS were seen in 100 and 86% of volunteers at the highest dose. These results established the association of *senA* and *setAB* enterotoxins with diarrheal symptoms previously observed with live vaccines (Kotloff et al., 2004). It is anticipated that further studies with CVD 1208 will confirm its safety and immunogenicity profile.

virG(icsA)-*Based Vaccines being Developed at Walter Reed Army Institute for Research (WRAIR)*

A series of vaccine candidates based on loss of VirG(IcsA) have been tested by investigators at WRAIR and shown to be both immunogenic and in one case, efficacious against dysentery. SC602 was derived from *S. flexneri* 2a, strain 454, and constructed at the Institut Pasteur, Paris, France. In addition to the loss of the *virG(icsA)* gene, SC602 also contained a deletion in the chromosomal *iuc* gene encoding aerobactin. By itself, an *iuc* mutant gives a slightly attenuated Sereny reaction as well as a compromised reaction in rabbit ileal loops. SC602 was manufactured as a lyophilized product and orally administered in a single dose to volunteers after ingestion of a bicarbonate solution. Initially, groups of three volunteers (and three placebo controls) were vaccinated sequentially, with increasing doses from 10^2 to 10^8 cfu. There were no cases of dysentery at any dose (Coster et al., 1999). At the highest dose, two of three volunteers got diarrhea, fever, and severe constitutional symptoms. A follow-up expanded study was carried out in 15 volunteers at the 10^6 cfu dose. This time 47% of volunteers had diarrhea, 33% had fever, 40% had severe intestinal problems, and 40% had severe constitutional symptoms. An additional cohort of 12 volunteers was vaccinated with 10^4 cfu. Only one volunteer's symptoms met the criteria of diarrhea while 10–30% of the volunteers reported mild-to-moderate intestinal and constitutional symptoms. Robust and prolonged colonization was seen, as measured by excretion of the SC602, which was proportional to the dose given (Coster et al., 1999). For example 100 and 90% of the volunteers fed 10^6 and 10^4 cfu respectively, excreted the vaccine for 7 days. Seven of 12 volunteers given 10^4 cfu had significant peak IgA ASCs. Four of the seven volunteers had fourfold or greater rises in serum and urine IgA titer to LPS. Fewer volunteers showed response to the Ipa proteins. An efficacy study was performed using seven SC602-vaccinated volunteers from the 10^4 cfu dose study, and challenged with 2457T two months after immunization along with seven unvaccinated controls (Coster et al., 1999). Four of the vaccinated volunteers showed no symptoms of the disease while three volunteers met the clinical definition of diarrhea that lasted for 24 h. Three of the four volunteers who were completely protected had demonstrated significant LPS-specific IgA ASCs and had greater than fourfold increase in serum and urine LPS-specific IgA titers. Of the three vaccinated volunteers who had diarrhea after challenge, two lacked an LPS-specific IgA ASC response as well as an adequate increase in serum or urine IgA titer after vaccination. These results indicate that the immune correlates of protection must include a combination of LPS-specific ASC responses, along with three to fourfold increases in LPS-specific serum antibody titers. Fecal IgA responses were not measured in this study. In contrast to SC602-vaccinated volunteers, six of seven control volunteers developed shigellosis after 2457T challenge that included diarrhea, fever, severe gastrointestinal and constitutional symptoms, and dysentery. Thus, vaccination with SC602 was efficacious against disease. A community-based evaluation of SC602 was carried out in 12 inpatient and 34 outpatient volunteers in the 10^3–10^4 cfu dose range. Approximately 15% of the volunteers had transient fever and diarrhea while headache and abdominal cramps appeared to be the main constitutional symptoms reported. Approximately 50% of the volunteers had a threefold serum IgA ELISA response to LPS, and approximately 75% had an ASC response to the same antigen confirming earlier trial data with this vaccine candidate (Katz et al., 2004).

WRSS1 was derived from a stable *S. sonnei* strain, Moseley, and contains a 212 bp deletion in the *virG(icsA)* gene (Hartman and Venkatesan, 1998). WRSS1 was manufactured as a lyophilized product and the protocol for administering it to volunteers was similar to that followed with SC602. WRSS1 was tested in a placebo-controlled dose escalating study in 27 volunteers who received a single oral dose of either

10^3, 10^4 10^5, or 10^6 cfu (Kotloff et al., 2002). No volunteer receiving WRSS1 had dysentery or a fever >102°F. Approximately 30% of the volunteers in the two highest doses developed diarrhea and low-grade fever. At the highest dose tested, the vaccine was excreted for at least a week showing robust colonization, which elicited strong LPS-specific IgA ASCs, serum antibodies, and fecal IgA antibodies. An increase in IFN-γ production was seen in response to purified Ipa proteins, IpaB, IpaC, and IpaD at the two highest doses in some of the volunteers. In general, WRSS1 was considered safe given as a single oral dose in the range of 10^3–10^4 cfu. A community-based study at 10^3, 10^4, and 10^5 cfu dose of WRSS1 was carried out in Israeli volunteers (Orr et al., 2005). At the 10^5 cfu dose, approximately 30% of the volunteers had mild fever and/or diarrhea whereas the 10^3–10^4 cfu dose was well tolerated, with no reported fever and one report of moderate diarrhea for 1 day. The vaccine was excreted for an average of 5 days by 80% of the volunteers ingesting the 10^3–10^4 dose, and induced robust LPS-specific IgA ASCs and increases in serum IgA titers. Most importantly, in spite of the strong colonization seen with WRSS1, the vaccine was not transmitted to household contacts. The low but consistent rate of fever and diarrhea that was seen with SC602 and WRSS1 at the 10^4 cfu dose suggests that, further attenuation is needed to reduce these symptoms.

In a recent Phase 1 trial, a *virG(icsA)*-based *S. dysenteriae* 1 vaccine strain WRSd1 was fed to five groups of eight subjects who were given escalating doses from 10^3 to 10^7 cfu at the Johns Hopkins Medical Center in Baltimore, MD. The parent strain, 1617, was obtained from a 1960s epidemic dysentery outbreak in Guatemala. WRSd1 contained a 10 kb deletion on the plasmid that included the loss of the *virG(icsA)* gene, and an additional ~20 kb deletion on the chromosome, that eliminated not only the *stxAB* genes but also an important transcriptional regulator of anaerobic gene expression, the *fnr* gene, among others (Venkatesan et al., 2002). WRSd1 is invasive in Hela cells but Sereny negative, and it was less immunogenic than SC602 and WRSS1 in guinea pigs. In the Phase I trial no subject developed fever or abdominal pain. Fecal shedding of the vaccine strain was poor and identified in 9 of 40 subjects (23%) and 8 of these 9 had anti-LPS IgA ASC responses (McKenzie, 2007). About one-third of the volunteers showed a serum anti-LPS IgA response. Eight of the 40 subjects (20%) had diarrhea, and 2 subjects in the 10^4 CFU group passed a single loose, stool containing blood without any other constitutional symptoms. The rate and severity of diarrhea were not related to the dose of the vaccine. Poor colonization may have resulted from the lack of the *fnr* gene since it has been implicated to play a critical role in the gastrointestinal colonization of *E. coli* in a rat model.

Based on these trials, second generation *virG (icsA)* vaccine strains have been constructed with retention of the *fnr* gene and deletion of additional genes with a goal of improving colonization, tolerability, and immunogenicity. The presence of the *setAB* gene (encoding ShET1) on the chromosome of SC602, the *senA* gene (encoding ShET2-1), and *senB* gene (encoding ShET2-2) on the invasion plasmid of SC602, WRSS1, and WRSd1 indicate that deletions of enterotoxin genes may alleviate the reactogenic symptoms seen with these vaccine candidates (Fasano et al., 1995, 1997; Nataro et al., 1995). Additionally, loss of the *msbB* gene on the plasmid (*msbB2*) has been incorporated into the design of the second generation *virG*(*icsA*)-based vaccines to reduce the febrile reactions seen with the earlier vaccines. A *S. flexneri* 2a strain WRSf2G11 with deletion of the *virG*(*icsA*), *setAB* and *senA* genes has been shown to be immunogenic and protective in a guinea pig model. Further deletion of the *senB* gene (WRSf2G12) as well as the *msbB2* gene (WRSf2G15) have been constructed and are being tested in animal models (Ranallo et al., 2007). Similar derivatives have been designed and constructed in *S. sonnei* and *S. dysenteriae* 1 background and have been shown to be immunogenic and protective in animal models (Ranallo, 2007; Ranallo et al., 2006; Venkatesan and Ranallo, 2006). These newer derivatives await manufacture and testing in Phase 1 trials.

Current Licensed Vaccines

FS Bivalent Vaccine

Currently this is the only licensed oral, live noninvasive *Shigella* vaccine, and is used in China (Levine et al., 2007). It was constructed by mobilizing a spontaneously modified deleted form of the *S. sonnei* invasion plasmid, tagged with Tn5, into the *S. flexneri* 2a vaccine strain T32-ISTRATI. The FS vaccine strain is a bivalent vaccine designed to provide protection against both *S. sonnei* and *S. flexneri* 2a. Initial testing in humans with freshly harvested bacteria provided safety colonization and immunogenicity data at three doses of $2–5 \times 10^{10}$ cfu. The vaccine was excreted for 1–3 days by 65–75% of the volunteers. A lyophilized form of the vaccine was then tested in field studies in 17,500 adults and children and similar numbers of placebo controls in Changge City, China. Passive surveillance for the next 5–6 months indicated 61–65% protective efficacy (PE) against *S. flexneri*, 50–72% against *S. sonnei*, and 48–52% against other *Shigella*

species. Similar data is currently unavailable in infants and toddlers.

PROSPECTS FOR THE FUTURE

Several live attenuated vaccines are being developed. At the same time several new approaches to subunit vaccines are also being evaluated. A combination of live and subunit vaccines should be tested in animal models for immunogenicity and efficacy. Phase 1 trials will be needed to determine the value of individual vaccine candidates. Such trials should also incorporate bivalent and multivalent mixtures of vaccines. Challenge studies can take the place of large-scale field trials to show efficacy. Dose–response studies in endemic populations will determine the range to be tested for effectiveness in these groups. Information about the geographical distribution of *Shigella* serotypes will be needed to determine the vaccine serotypes to be tested in a particular region of the world.

KEY ISSUES

- Protection is serotype-specific, therefore an effective vaccine, whether live or subunit, will have to incorporate components of several serotypes.
- Development and application of a *Shigella* vaccine should consider the diversity of *Shigella* serotypes within a geographical region.
- The vaccine must be easy to manufacture so that it is cost effective, especially if it is to be used in developing countries.
- Delivery of the vaccine should be needle free, if possible.
- The technology for making and manufacturing the vaccine must be user friendly.
- Reliance on a cold chain for storage of the vaccine must be minimized.
- The vaccine should be immunogenic in endemic populations.
- Engagement of local health care policy makers, scientists, and technicians must be carried out prior to testing vaccines in endemic regions of the world.

Syphilis

Lorenzo Giacani, Sheila Lukehart and Arturo Centurion-Lara
Department of Medicine, School of Medicine, University of Washington, Seattle, WA, USA

OUTLINE

ABSTRACT

Syphilis continues to be a common and serious disease, affecting at least 25 million persons worldwide. It is a recognized cofactor in the transmission and acquisition of human immunodeficiency virus, and is a major cause of stillbirth and perinatal morbidity in the developing world. Despite the availability of safe, effective, and inexpensive diagnostic tools and treatment, syphilis is still uncontrolled or has reemerged in many areas of the world, thus demonstrating the failure of conventional efforts to control transmission and emphasizing the need for an effective and practical vaccine. The peculiar biology of *Treponema pallidum*, along with the inability to continuously grow this pathogen in vitro, has hindered progress in this field. The public health importance of syphilis prompted numerous vaccination attempts with whole cell vaccines in the mid-1900s. Only one protective vaccine has been described which, though completely protective in the rabbit model, cannot be translated for human use. The availability of new tools such as genomics, proteomics, and recombinant DNA technology permits today's investigators to focus on the identification of surface-exposed antigens and other virulence factors to target their vaccine efforts. The combination of modern in silico analysis tools and biological assays has led to the identification of several promising candidate antigens, including the members of the Tpr family, newly identified adhesin molecules, lipoproteins, and other putative outer membrane proteins. While early subunit vaccine studies have not yielded complete protection, a number of antigens have induced sufficient immunity to significantly alter disease progression following infectious challenge. These encouraging results serve as the basis for a renewed interest in syphilis vaccine development.

Syphilis has long been a topic of controversy, consternation, and fascination by historians who argue about its origin, physicians who marvel and despair at its protean clinical manifestations, and scientists who struggle to unravel the secrets of its causative agent *Treponema pallidum* subsp. *pallidum* (*T. pallidum*). Although effective therapy with penicillin has significantly decreased the burden of syphilis in developed countries, this infection still results in significant morbidity and mortality, especially in the developing world. The seeming dichotomy of a fragile and metabolically crippled bacterium that is able to cause lifelong and potentially destructive infection has yet to be resolved. This chapter reviews our current understanding of *T. pallidum* and the disease process, then focuses on efforts to develop a practical and effective vaccine.

HISTORY

The first definitive clinical descriptions of syphilis resulted from the outbreak of an apparently new disease in Italy following the Siege of Naples by the French in 1495. The sexually transmissible nature of the infection was recognized early, and the infection was dubbed "the French Disease" and later the "Great Pox" (to distinguish it from smallpox). Because of the coincidence of this outbreak with the return of Columbus and his sailors from the New World, it has been speculated that syphilis was brought to Europe by these men. Others believe that syphilis had existed in Europe and Asia before 1492, and that the sudden widespread recognition of the disease was the result of increased movement of armies throughout Europe and the greater dissemination of information at the end of the Middle Ages.

Regardless of its origin, syphilis became a common disease, with an estimated ~10% of the population of Europe and the United States being infected in the early 20th century. Before the discovery of penicillin, fear of the destructive late manifestations of syphilis, including insanity, paralysis, blindness, and death, led to the use of a number of dangerous treatments, including the use of hotboxes to raise the body temperature, fever induced by intentional malaria infection, and mercury salves and vapors.

ETIOLOGIC AGENT

Treponema pallidum is a spiral organism with a structure similar to gram-negative bacteria. The organism has both an outer membrane (OM) and a cytoplasmic membrane, with a periplasmic space containing the periplasmic (or endo-) flagella (Fig. 59.1). The lipid-rich OM of *T. pallidum* has an unusually small number of integral membrane proteins (Radolf et al., 1989b; Walker et al., 1989) and is very fragile, complicating physical and biochemical analyses of surface structures. At this writing, there is no consensus about the identity of any surface-exposed protein on the organism. The genome sequence of *T. pallidum* (Fraser et al., 1998) revealed an organism with significant metabolic limitations, including the inability to synthesize lipids, nucleotides, and most amino acids de novo; a lack of Kreb's cycle enzymes; and no evidence for oxidative phosphorylation. This renders the organism highly dependent on the host for nutrients, and efforts to propagate *T. pallidum* in vitro in continuous culture have been unsuccessful.

CLASSIFICATION

T. pallidum is one of four recognized human pathogens within the genus *Treponema*: *T. pallidum* subsp.

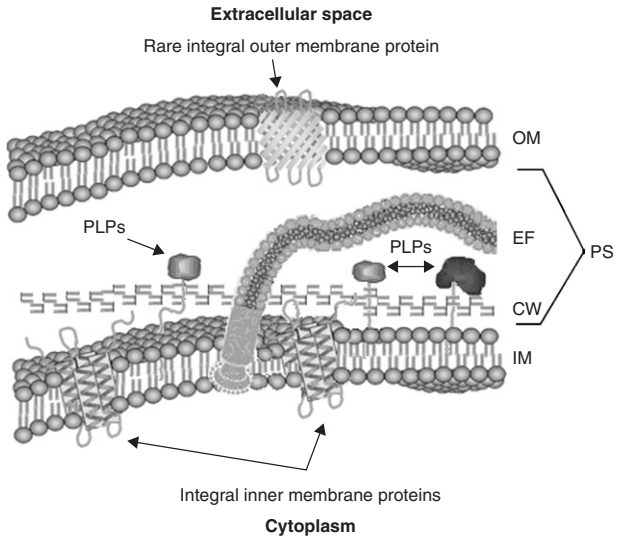

FIGURE 59.1 A schematic representation of the *T. pallidum* cell envelope. Similar to conventional Gram-negative bacteria, the outer membrane (OM) separates the internal cellular compartments from the extracellular space and, along with the inner membrane (IM), defines the periplasmic space (PS). Unlike conventional Gram-negative bacteria, *T. pallidum* OM does not contain LPS, and has only rare integral membrane proteins compared to the IM. Furthermore, in *T. pallidum*, the peptidoglycan layer (cell wall, CW) overlies the cytoplasmic membrane rather than being associated with the inner leaflet of the outer membrane. The most antigenic *T. pallidum* proteins, such as the components of the endoflagella (EF) and the periplasmic lipoproteins (PLPs, anchored to the IM by a lipidic moiety) are found within the PS. Adapted with permission from Mary S. Lipton (www.PNL.gov/biology/programs/MSD/characterization.stm).

pallidum (syphilis), *T. pallidum* subsp. *pertenue* (yaws), *T. pallidum* subsp. *endemicum* (bejel), and *T. carateum* (pinta). The infections caused by these organisms are similar in that they appear in distinct clinical stages, are chronic, and can cause serious destructive late sequelae. The *Treponema* also include oral treponemes that are associated with periodontal disease, *Treponema paraluiscuniculi* which causes a venereal disease in rabbits, a group of organisms (including *Treponema brennaborense*) associated with papillomatous digital dermatitis and ulcerative mammary dermatitis in cattle and sheep (Stamm et al., 2002), and symbionts of the termite hindgut (Lilburn et al., 2001).

ANTIGENS

A number of antigens have been identified in *T. pallidum* using biochemical and genetic tools. Of the 1039 predicted proteins in the *T. pallidum* genome, 882 were expressed and tested for reactivity with antisera from rabbits infected with syphilis; of these, 106 antigens were recognized by the antisera. (McKevitt et al., 2005). Antisera from humans with syphilis showed significant reactivity to 34 of 908 peptides tested (Brinkman et al., 2006). These genome-wide screens undoubtedly underestimate the actual number of *T. pallidum* antigens, possibly because of the inability to express some *T. pallidum* antigens in *Escherichia coli*. Major classes of *T. pallidum* antigens are introduced briefly below, and are then discussed in more detail as they relate to vaccine studies.

Lipoproteins

Three of the major antigens of *T. pallidum* with molecular masses of approximately 47, 17, and 15 kDa are now recognized as lipoproteins (Chamberlain et al., 1989a; Purcell et al., 1990), as are TmpA, B, and C (Schouls et al., 1989b, 1991). The genome predicts 22 lipoproteins, including roughly one-third of those antigens that were highly reactive with rabbit and human syphilis sera above. Lipoproteins are not only highly immunogenic, but the lipid moiety has been demonstrated to be recognized by toll-like receptor (TLR) 2, thus implicating these in induction of the innate immune response (Aliprantis et al., 1999; Lien et al., 1999; Salazar et al., 2002) and in early induction of adaptive immunity.

Endoflagella

The major structural components of the endoflagella (37, 34.5, 33, and 30 kDa) and associated flagellar proteins are readily recognized by immune serum from rabbits and humans. The sheath protein (37 kDa) is unique to the pathogenic treponemes while the core proteins (34.5, 33, and 30 kDa) share cross-reactive epitopes with the cultivable treponemes (Lukehart et al., 1982, 1985).

Tpr Family

Most of the members of the 12-member Tpr family (TprA–TprL) have been shown to induce the production of antibodies during infection in rabbits (Leader et al., 2003; Sun et al., 2004). The most uniformly immunogenic are TprK, TprC, TprD, TprF, and TprI. These have predicted cleavable signal peptides and may therefore be OM associated (Centurion-Lara et al., 1999); these *tpr* genes are highly transcribed (Giacani et al., 2007b), consistent with their expression during infection. Mechanisms of transcriptional regulation of several of the *tpr* genes have recently been identified (Giacani et al., 2007a).

Lipids

Lipids also induce immune responses during syphilis infection. The VDRL and RPR serological tests are widely used in syphilis diagnosis, and these tests detect antibodies to cardiolipin, phosphatidylcholine, and cholesterol complexes. The presence of these lipids on the surface of *T. pallidum* is suggested by the demonstration that antibodies raised against VDRL antigen can effectively opsonize *T. pallidum* for phagocytosis (Baker-Zander et al., 1993b).

PROTECTIVE IMMUNE RESPONSES

Immunity to *T. pallidum* does develop during infection, but the level of protection against reinfection depends on the length of the initial infection. Physicians have long recognized that persons treated for early syphilis can be repeatedly reinfected. Numerous reinfection studies have been conducted in humans (reviewed in Magnuson et al., 1956) but the most definitive work was conducted at Sing Sing prison in the 1950s (Magnuson et al., 1956). In this study, persons with various stages of treated and untreated syphilis (and uninfected controls) were inoculated on the forearm with an infectious dose of *T. pallidum* Nichols strain. Infection was defined as development of a lesion at the challenge site or by an increase in antibody titer. After a 4-month observation period (or earlier if the subjects developed lesions), all subjects were treated with the then-recommended dose of penicillin. Only those persons with late latent syphilis prior to challenge showed significant levels of protection against reinfection: none of 5 with untreated, and 10 of 26 with treated, late latent syphilis showed evidence of reinfection, while the majority of subjects with earlier stages of treated syphilis were reinfected upon challenge. This study clearly demonstrates that prolonged antigen exposure is required for protective immunity.

The rabbit provides an excellent model for investigation of protective immunity. As in humans, infection immunity develops only after lengthy infections (Turner and Hollander, 1957). This model also provides the opportunity to examine the development of immunity to heterologous strains of *T. pallidum*; intensive studies conducted by Turner and others, reviewed in Turner and Hollander (1957), demonstrated that, while homologous immunity was uniformly seen, immunity to symptomatic infection with other strains is variable. These data suggest that the "protective antigen(s)" of *T. pallidum* may not be conserved or may be differentially expressed across strains.

The specific mechanisms that contribute to the protective immune response have not been defined, although it is widely accepted that organisms are cleared from the early lesions of syphilis via phagocytosis and killing of opsonized *T. pallidum* by interferon-γ (IFNγ)- activated macrophages (Lukehart et al., 1980a; Baker-Zander and Lukehart, 1992; Baker-Zander et al., 1993a). This process requires the production of antibodies that react with surface-exposed antigens (opsonization), as well as secretion of IFNγ by specifically sensitized CD4+ and CD8+ T lymphocytes.

Humoral Immunity

Specific anti-treponemal antibodies first become demonstrable during the primary stage in human infection (Hanff et al., 1982; Baker-Zander et al., 1985), and within 1–2 weeks of infection in the rabbit model of syphilis (Lukehart et al., 1986). Titers generally peak during the secondary stage in humans and during healing of the primary lesion in rabbits. Both IgG and IgM are generally detectable through untreated infection, even in infections of several years duration. Despite the existence of high titers of antibodies during primary and secondary syphilis, some organisms escape and persist for decades within the untreated host.

Serological testing is a major tool in diagnosis of syphilis and in screening settings. Antibodies can be measured using the lipoidal tests (e.g., VDRL, RPR) or treponemal tests such as the TPPA, FTA-ABS, and recombinant-based immunochromatographic and ELISA tests. The identified functions of anti-*T. pallidum* antibodies include complement-mediated immobilization (Nelson and Mayer, 1949) or neutralization (Bishop and Miller, 1976b), opsonization (Lukehart and Miller, 1978; Baker-Zander et al., 1993a), and inhibition of attachment to host cells (Fitzgerald et al., 1984). The molecular targets of these immune functions have not been definitively identified, although opsonic and anti-attachment antibodies are likely to be directed against surface antigens. Blanco et al. (2005) recently demonstrated that a monoclonal antibody with specificity for a phosphorylcholine lipid moiety has immobilizing activity against *T. pallidum* in vitro in the presence of complement. The antibody response alone, however, does not protect against infection per se (Bishop and Miller, 1976a) suggesting that a cellular component is also necessary for protective immunity in vivo.

Cell-Mediated Immunity

Primary and secondary lesions in humans (Tosca et al., 1988; Van Voorhis et al., 1996b) and rabbits

(Lukehart et al., 1980a; Leader et al., 2007) show an impressive T lymphocyte infiltration (comprised of both CD4+ and CD8+ lymphocytes) with variable numbers of infiltrating B lymphocytes. RT-PCR analysis of human (Van Voorhis et al., 1996a) and rabbit (Godornes et al., 2007; Leader et al., 2007) lesions demonstrates a Th1 cytokine milieu, with significant IFN-γ production and very little detectable IL-4.

Specifically sensitized T lymphocytes can be demonstrated in infected rabbits within a few days of infection (Lukehart et al., 1980b); these recognize a variety of *T. pallidum* antigens (Baker-Zander et al., 1988; Giacani et al., 2007b). Stimulation of lymphocytes in vitro with *T. pallidum* antigens results in production of IFN-γ (Arroll et al., 1999). Macrophages appear just prior to the clearance of treponemes from the lesions, and treponemal antigens can be seen within macrophages in healing lesions (Lukehart et al., 1980a; Sell et al., 1982). These data suggest that activated macrophages are the primary effector cell in bacterial clearance, and that the phagocytosis and killing of *T. pallidum* that is demonstrable in vitro mimics the activities of macrophages in vivo.

EPIDEMIOLOGY

Syphilis is a leading cause of genital ulcers worldwide and is a cofactor for acquisition of HIV (CDC, 1998). In 1998, the World Health Organization estimated 12 million new cases per year, with an overall prevalence of at least 25 million, mostly in developing countries (Gerbase et al., 1998). The highest prevalence is found in developing nations and among people with limited or no access to health care; globally, sub-Saharan Africa, Southeast Asia, and Latin America have the highest incidence of syphilis (Fig. 59.2). Naturally, prevalence rates vary among countries and populations. During the past 25 years, prevalence rates in regions of sub-Saharan Africa have ranged from 2.5 to 12.5% in antenatal women (Ratnam et al., 1982; Creek et al., 2005; Pham et al., 2005; Potter et al., 2006). In South America, seropositivity rates in female commercial sex workers were 3.2, 13, and 28% in Peru, urban Guyana, and Buenos Aires, respectively (Zapiola et al., 1996; Persaud et al., 1999; Trujillo et al., 1999). After the dissolution of the Soviet Union, there was a dramatic increase in syphilis and other sexually transmitted infections in the newly independent states (Renton et al., 1998), and emigration carried syphilis to many eastern European countries that previously had very low rates of syphilis. In all high-prevalence areas of the world, congenital syphilis is a major cause of preventable miscarriage, perinatal morbidity and mortality (Watson-Jones et al., 2002).

In the United States and Europe, the past decade has shown a significant increase in new cases, affecting primarily men who have sex with men (MSM). The incidence of primary and secondary syphilis in U.S. males doubled from 2000 to 2005 (CDC, 2006b), and provisional data suggest a continuing increase of 5–8% per year since that time. Similar outbreaks of syphilis have been reported in MSM in Western Europe (Cowan, 2004; Marcus et al., 2004; Righarts et al., 2004; Sasse et al., 2004). In the United States, racial differences in syphilis prevalence still persist, but an important decline of syphilis in African Americans has been observed in the last decade, due, at least in part, to the efforts of the Centers for Disease Control (CDC)-sponsored Syphilis Elimination Program (Hook, 1998; CDC, 1999) which focused on areas of the southeastern United States where rates in African Americans were very high. The last decade has also brought a dramatic increase in syphilis in China, with rates increasing from 0.2 to 5.7 cases per 100,000 between 1993 and 2005 (Chen et al., 2007). Recent studies report very high prevalence among incarcerated Chinese female sex workers (15.7%) (Ruan et al., 2006), drug users (7–15.6%) (Liu et al., 2006), and MSM (13.5%) (Choi et al., 2007). These recent examples of new outbreaks of this readily curable infection demonstrate the failure of efforts for controlling transmission and highlight the urgent need for the development of a syphilis vaccine.

NATURAL HISTORY AND PATHOGENESIS

Syphilis is transmitted primarily during sexual contact with an infected individual when treponemes breach the mucosal surfaces or skin of an uninfected host. The infection can also be transmitted transplacentally to the fetus (congenital syphilis), or rarely through blood transfusion or organ transplantation. *T. pallidum* is a highly invasive organism that can reach virtually any tissue in the human body, resulting in a multitude of possible clinical presentations. If untreated, syphilis can result in serious cardiovascular and neurological complications or even death.

Clinically, syphilis is characterized by episodes of active disease interrupted by periods of asymptomatic, latent infection. *T. pallidum* multiplies at the site of contact (entry) and an ulcerative lesion (chancre) develops, containing millions of spirochetes per gram

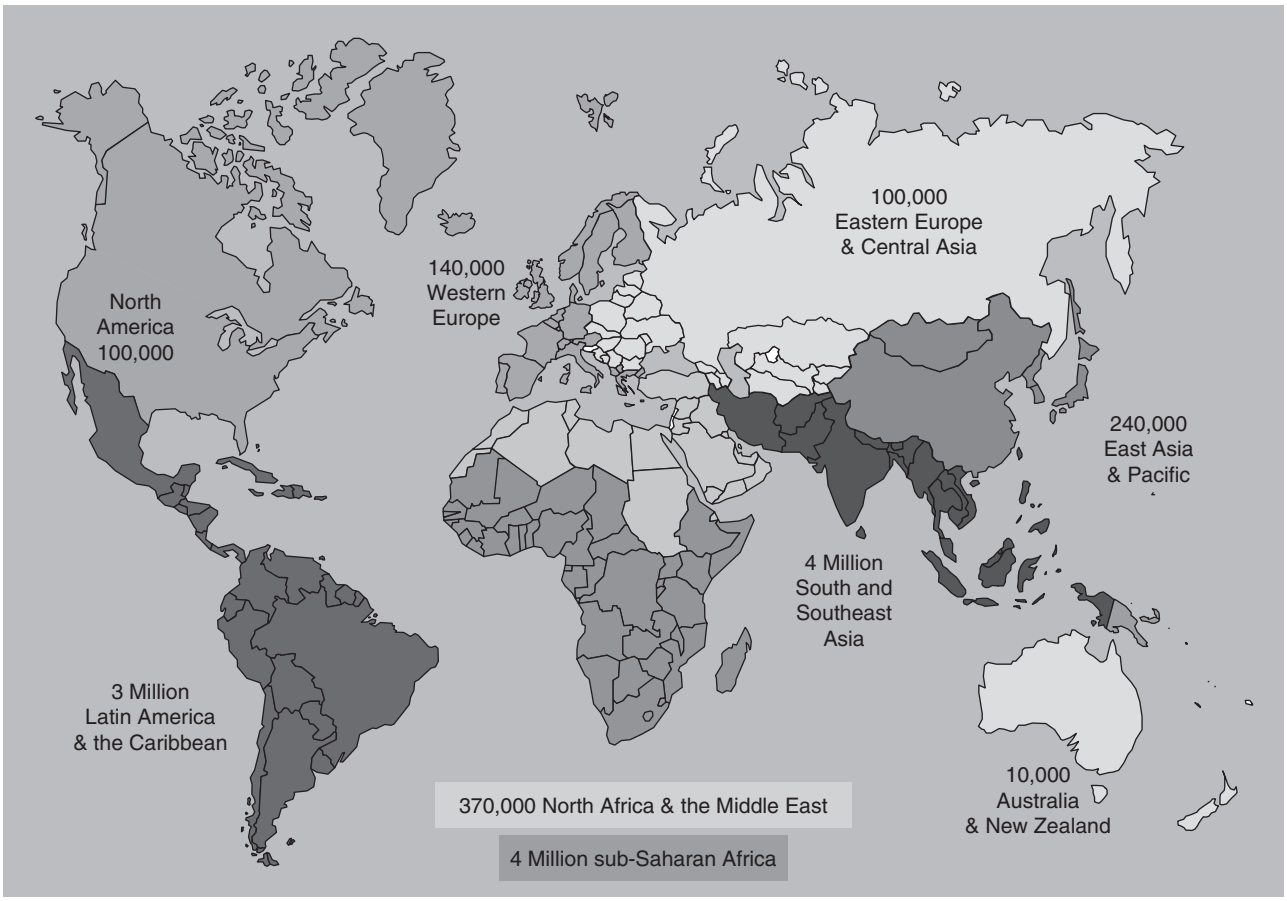

FIGURE 59.2 The incidence of syphilis in different regions of the world. The World Health Organization estimated in 1998 that there are 12 million new cases of venereal syphilis annually worldwide. Over 90% of these new cases are in developing countries in Latin America and sub-Saharan Africa, although increasing numbers of cases were reported in Eastern Europe, Central Asia, and East Asia. Outbreaks have been reported in several cities in Western Europe and North America among men who have sex with men. In the United States, a program for the elimination of syphilis was proposed in the late 1990s, but the number of reported cases has increased in the past 5 years.

of tissue. Concurrently, treponemes gain access to the circulation and rapidly disseminate throughout the body seeding many tissues, including the central nervous system. After several weeks, the chancre heals spontaneously and infection is next manifest by the secondary stage, characterized by disseminated skin lesions; these also resolve spontaneously over a period of several weeks or months. During primary and secondary syphilis, a strong host humoral and cellular immune response eliminates the great majority of treponemes, but a small population of organisms escapes to cause persistent infection. The untreated host then enters the latent stage, which can persist for decades or a lifetime; few or no treponemes can be detected during the latent stage of infection. A small minority of untreated persons will develop the serious manifestations of tertiary syphilis, including tabes dorsalis, general paresis, or aortic aneurysm.

The role of the inflammatory and immune responses in pathogenesis of syphilis is now better understood. Salazar et al. (2002) has proposed that inflammation driven by *T. pallidum* lipoproteins leads to the unique histopathological changes observed in syphilis. *T. pallidum* lipoproteins act as potent proinflammatory agonists (Radolf et al., 1991, 1995a; Salazar et al., 2002) and they stimulate dendritic and other cells via interactions with CD14, TLR1, and TLR2 expressed by monocytes/macrophages and dendritic cells (Lien et al., 1999). These cells then serve to present antigen to CD4+ lymphocytes which orchestrate the production of cytokines and signaling factors that result in the production of specific antibodies and the activation of both CD4+ and CD8+ lymphocytes and macrophages. The role of IFN-γ, activated macrophages, and opsonic antibodies in clearance of *T. pallidum* from early lesions is described above.

Primary Syphilis

T. pallidum establishes infection when it penetrates skin through intact mucosa or microabrasions at the site of contact, likely by attaching first to host cells via surface antigens (Fitzgerald et al., 1977a, 1977b). The treponeme has also been shown to bind to serum components, cell membranes, and several extracellular matrix (ECM) components, including fibronectin (Peterson et al., 1983; Thomas et al., 1985b), laminin, collagen I, and hyaluronic acid (Fitzgerald et al., 1984). Recently, Cameron et al. (2004) have identified *T. pallidum* proteins that bind fibronectin and laminin (Cameron, 2003); binding to ECM may serve as a bridge for *T. pallidum* to attach to host cells prior to invasion and dissemination to different tissues. The bacteria multiply at the site of contact and trigger the innate and acquired immune responses, resulting in lymphocyte and macrophage infiltration of the local site to form a chancre. The histopathology of the lesions shows proliferation of endothelial cells in small vessels, with infiltrating CD4+ and CD8+ lymphocytes and plasma cells. Macrophages infiltrate just prior to bacterial clearance, and phagocytosis of opsonized *T. pallidum* by activated macrophages is thought to be the main mechanism of bacterial clearance (LaFond and Lukehart, 2006).

During the early stages of infection, *T. pallidum* disseminates rapidly through the body. It is still unclear which strategies *T. pallidum* uses to survive without being eliminated by the host; however, the chronicity of this infection suggests intricate mechanisms for adaptation and immune evasion. Several mechanisms have been postulated including localization in immunologically privileged tissues (Medici, 1972), intracellular location in non-phagocytic cells (Azar et al., 1970; Sykes and Miller, 1971; Sykes et al., 1974), the presence of a protective outer coat of host origin masking the bacterial surface (Christiansen, 1963; Alderete and Baseman, 1979), a poorly antigenic OM (Radolf et al., 1989b; Radolf, 1994), and antigenic variation (Centurion-Lara et al., 2004; LaFond et al., 2006b).

Secondary Syphilis

Hematogenous dissemination of *T. pallidum* during primary infection leads to development of the systemic secondary stage, which is accompanied by malaise, generalized lymphadenopathy, and a disseminated macular or papular mucocutaneous rash (Chapel, 1980; Baughn and Musher, 2005). Signs and symptoms usually appear 4–10 weeks after the primary lesion has disappeared. The clinical presentation of secondary syphilis varies from inconspicuous lesions to lues maligna with massive necrosis (Baughn and Musher, 2005). Other manifestations include condylomata lata, mucous patches, gastric and renal involvement, and hepatitis (Chapel, 1980).

It is thought that the distribution of skin lesions on palms and soles reflects the preference of *T. pallidum* for lower temperatures. Although mucocutaneous lesions are the hallmark of secondary syphilis, this stage involves virtually any organ or tissue, and bacterial burden is thought to be high. The relatively mild systemic response to the presence of viable organisms is presumably due to the lack of lipopolysaccharide (LPS) (Hardy and Levin, 1983; Fraser et al., 1998) in *T. pallidum*; however, following antibiotic treatment for primary and secondary syphilis, the release of treponemal lipoproteins likely triggers the relatively common Jarisch-Herxheimer reaction. The histopathology of secondary and primary syphilis is very similar. As in primary syphilis, the immune response of the host is again able to clear the great majority of treponemes from lesions by macrophage-mediated phagocytosis. Measurement of cytokine mRNA in skin samples from infected individuals shows a Th1 cytokine pattern (Van Voorhis et al., 1996a), consistent with this immune mechanism.

Latent and Tertiary Syphilis

After resolution of secondary syphilis, the infected individual enters the latent stage, in which infection is subclinical and may last for the lifetime of the patient. In the pre-antibiotic era, approximately 30% of untreated individuals with latent infection developed tertiary syphilis after years or decades of infection (Gjestland, 1955). The manifestations of tertiary syphilis include gummas, cardiovascular syphilis, and late neurosyphilis, but these are rarely seen today.

Gummas are granulomatous lesions with a central area of necrosis affecting skin, bones, liver, heart, brain, stomach, or upper respiratory tract. In a few cases, spirochetes have been demonstrated in these lesions (Handsfield et al., 1983). In cardiovascular syphilis, the ascending aorta is typically affected. Recently, DNA amplification demonstrated the presence of *T. pallidum* in an aortic aneurysm (O'Regan et al., 2002), indicating that an active infection may result in tissue damage. Preexisting atheromatous conditions of the aorta might facilitate adhesion of treponemes to exposed ECM components (Cameron, 2003; Cameron et al., 2004).

Neurosyphilis is classified as asymptomatic, meningeal, meningovascular, or parenchymatous. In the absence of treatment, asymptomatic neurosyphilis

either resolves spontaneously or progresses to symptomatic disease (Moore and Hopkins, 1930). Vasculitis of the small vessels and proliferative endarteritis are the hallmarks of meningeal and meningovascular syndromes. The parenchymatous syndromes (generalized paresis and tabes dorsalis) involve neuronal loss, demyelination, and astrocyte proliferation with gliosis. The mechanisms that give rise to these lesions are unknown to date.

Treatment

Penicillin G is the preferred drug for the treatment of all stages of syphilis (CDC, 2006a), and no penicillin resistance has been documented. The long-acting forms, such as benzathine penicillin G, are widely used for all forms except neurosyphilis, which is treated with aqueous crystalline or aqueous procaine penicillin G to ensure sufficient penicillin levels in the cerebrospinal fluid. Other classes of antibiotics with efficacy against *T. pallidum* include the tetracyclines and macrolides. Azythromycin, a macrolide compound that can be administered orally, has been shown to be effective for treatment of early syphilis and for sexual contacts of infected patients (Mashkilleyson et al., 1996; Hook et al., 1999, 2002). Unfortunately, macrolide resistance associated with a point mutation in the 23S rRNA genes (Stamm and Bergen, 2000) has been documented in the United States, Canada, and Ireland (Lukehart et al., 2004; Morshed and Jones, 2006). Although azythromycin may be a safe and effective alternative to benzathine penicillin in areas without resistant strains of *T. pallidum* and where proper clinical evaluation and follow-up can be guaranteed, penicillin remains the cornerstone of syphilis treatment.

VACCINE STUDIES TO DATE

Although remarkable efforts have been made in the last two decades to unravel the complex pathogenesis and immunology of syphilis, allowing the identification of a wide variety of treponemal antigens, a practical and effective vaccine is still unavailable. Furthermore, the recently discovered ability of *T. pallidum* to use antigenic variation to evade the host immune response complicates vaccine development. In the remaining part of this chapter, the rationale for the choice of past and current syphilis vaccine candidates will be critically reviewed in light of our current understanding of the peculiar *T. pallidum* ultrastructure and the difficulty in definitive identification of surface-exposed antigens. We will also describe how the most recent advances in vaccinology could benefit and improve our ability to control this too often neglected disease.

The Rationale for a Syphilis Vaccine

Syphilis is a disease whose characteristics make it amenable to control by vaccination. Importantly, like smallpox, there is no known animal reservoir for syphilis. Although it is a chronic infection, syphilis is transmissible only during the early symptomatic stages, so the period of transmissibility is limited. Readily available and simple serological tests make it possible to determine the prevalence of infection in specific populations or geographical regions, so that interventions can be focused appropriately. Moreover, the relatively low incidence of syphilis with respect to other curable sexually transmitted infections (Gerbase et al., 1998), the ease and low cost of diagnosis and treatment (Larsen et al., 1995; CDC, 2002), and the concentration of this infection in somewhat marginalized populations, likely reduce the focus on syphilis vaccine development in the United States. Syphilis is still a major health problem, however, in many countries and a vaccine could provide the means for a global syphilis eradication effort similar to the U.S. Syphilis Elimination Program initiated in 1999 (CDC, 1999). Globally, mass or focused treatment could be combined with immunization in the areas where syphilis incidence is high while, in regions where the disease is mainly restricted to defined social categories (e.g., MSM and intravenous drug users in North America and Europe), vaccination could selectively target individuals at higher risk.

Impediments to the Identification of Putative Protective Surface Antigens

Several major limitations hamper the ability of scientists to apply standard biochemical and immunological approaches to identification of putative candidate vaccine antigens in *T. pallidum*. First, the syphilis spirochete cannot be propagated in vitro, and the bacterial cells rapidly die outside of a susceptible host. The New Zealand white rabbit (*Oryctolagus cuniculus*) is used for in vivo propagation of *T. pallidum* and has become the preferred animal model for syphilis in that, following experimental infection, the clinical and pathological manifestations of the disease and immune response to the pathogen closely resemble those seen during natural infection in humans (Turner and Hollander, 1957; Sell and Norris, 1983). The slow growth rate of *T. pallidum* (generation time is ~30–33 h) (Magnuson et al.,

1948; Cumberland and Turner, 1949), along with the rapid onset of both innate and adaptive host immune response in the rabbit, make it possible to recover only limited numbers of organisms from an infected animal, prohibiting any experimental approach that requires large amounts of bacterial cells. The failure to maintain *T. pallidum* viability in culture (Fieldsteel et al., 1982; Riley and Cox, 1988; Cox et al., 1990) also precludes any kind of genetic manipulation, limiting the direct analysis of potential virulence factors. The ability to functionally inactivate, delete, and complement genes would in fact provide important information on which determinants *T. pallidum* requires to survive and persist in its host; such an approach would likely be particularly useful in the setting of the very small *T. pallidum* genome (Fraser et al., 1998), where the low number of genes potentially allows only limited functional redundancy.

The ongoing quest for vaccine candidate antigens finds its major obstacle in the biochemical composition and structural organization of the *T. pallidum* membrane systems (Fig. 59.1). Unlike more conventional gram-negative bacteria, the *T. pallidum* OM does not contain LPS (Hardy and Levin, 1983; Penn et al., 1985; Radolf and Norgard, 1988; Belisle et al., 1994; Fraser et al., 1998; Weinstock et al., 1998), and there is close chemical similarity between the lipid composition of the outer and inner membranes (Radolf et al., 1995b). Furthermore, while in most gram-negative bacteria, the peptidoglycan layer is physically associated with the inner leaflet of the OM, this layer overlies the cytoplasmic membrane in *T. pallidum* (Hovind-Hougen, 1983; Radolf et al., 1989a). These characteristics result in the extremely fragile nature of the *T. pallidum* OM, and difficulty in applying common immunological methods (i.e., surface immunofluorescence staining or immunoelectron microscopy) without compromising the OM integrity and exposing internal antigens to the immunological probes. Further, the substantial chemical homogeneity between the outer and inner membranes (Radolf et al., 1995b) discourages the use of separation techniques (i.e., sucrose density centrifugation) to isolate OM from the protoplasmic cylinder, in that such methods repeatedly result in contamination of the OM fractions with periplasmic antigens (Chamberlain et al., 1989a).

Criteria for Measuring Post-Challenge Protection against Syphilis Infection

The rabbit model provides a straightforward and relevant method for assessing post-immunization protection against infection. After the last immunization, test and control rabbits are challenged by intradermal injection of infectious *T. pallidum* on their shaved backs; multiple sites can be injected per animal. Lesion appearance, development, and progression (to ulceration) in control rabbits closely resemble that of primary chancres in humans, and the degree of alteration of this course in immunized rabbits is proportional to the level of immunity, with complete immunity resulting in no clinical or serological evidence of infection post-challenge. Partial immunity may be manifest as development of atypical lesions, such as delayed lesion appearance, flat nonprogressive lesions, a lower proportion of challenge sites progressing to ulceration (Fig. 59.3), and fewer challenge sites containing *T. pallidum* cells demonstrable by darkfield microscopy. Partial protection, however, does not prevent the establishment of the infection or seroconversion of the animals. In addition to monitoring lesion development, rabbit infectivity tests (RITs) can be performed for detection of inapparent infection of lymph nodes or other tissues in asymptomatic rabbits (Turner et al., 1969), particularly when the employment of whole-cell vaccines does not allow monitoring of seroconversion in the challenged animals. In this practice, a tissue sample from the test animal is injected into a naïve rabbit, and the eventual seroconversion of the recipient confirms infection in the tissue donor. Overall, vaccination with a partially protective antigen attenuates the symptoms of the disease, and

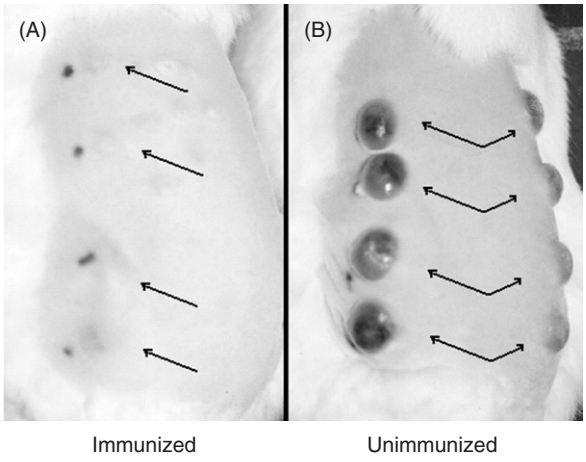

FIGURE 59.3 An example of altered lesion development following intradermal infectious challenge in rabbits immunized with a chimeric Tpr protein containing the NH_2-terminus of Tpr F/I and the TprG central region (Panel A) compared to unimmunized animals (Panel B). In immunized rabbits, small flat and non-ulcerative lesions (indicated by arrows in Panel A), containing few or no detectable treponemes, were observed compared to typical large ulcerative lesions in control animals at the same time post-challenge. In both animals, black ink dots mark the left of the injection site to facilitate lesion identification.

vaccinees may not develop ulcerative lesions, even though becoming infected. It is unclear whether individuals lacking ulcerative lesions could transmit the infection to others.

First-Generation Syphilis Vaccines: Whole Cell Approaches

The only successful vaccination ever reported to have induced durable sterile immunity against syphilis was described by Miller (1973). In this experiment, Miller immunized Dutch Belt rabbits intravenously with 3.7×10^9 γ-irradiated *T. pallidum* (Nichols strain) cells over a period of 37 weeks, with injections of weekly or semiweekly frequency. Ten days after the last immunization, 24 rabbits were challenged intradermally with 10^3 or 10^6 homologous *T. pallidum* cells, without developing any visible lesions in the following 3-month observation period. Asymptomatic infection was excluded by the negative outcome of the RITs performed using testicular tissue and lymph nodes from the challenged animals. A second group of 11 rabbits was challenged with 800 virulent *T. pallidum* cells one year after the immunization procedure, showing the durability of sterile immunity in these animals (Miller, 1973). Although this study was never independently confirmed due to its laborious nature, it clearly provides proof of concept for successful development of protective immunity against syphilis following immunization.

Although Miller's experiment represents the only success over a very long series of failed attempts to protect rabbits and other animals using killed or attenuated *T. pallidum*, reviewed previously by Lukehart (1985), Miller himself recognized that such a demanding procedure could not be easily translated from animals into humans. In addition to the exhausting immunization protocol, the inability to adequately separate *T. pallidum* cells from the rabbit tissue in which the bacteria were grown, and the fact that the serologic reactivity induced by the vaccination protocol would be difficult to distinguish from that caused by active syphilis infection, are major obstacles. Nonetheless, Miller's success provides important fundamental concepts that can guide those involved today in the search for a syphilis vaccine. First, a key aspect in the antigen preparation was the preservation of the native structure of the antigens inducing sterile immunity. His use of a physical (γ-irradiation) rather than chemical method to inactivate *T. pallidum* targeted the microorganism's genetic material, rather than its antigens, thus preserving molecules that could stimulate protective immunity in the host. In addition, the series of studies preceding Miller's successful vaccination suggest that the preservation of the fragile OM of *T. pallidum* (e.g., no centrifugation, etc.) was essential to success. It is still unclear whether the protective antigen(s) are protein, carbohydrate, or lipid, but it seems apparent that they are readily removed from the intact organism. The use of a high dose of treponemes (3.7×10^9 treponemes), in combination with a prolonged immunization cycle ($\sim$60 injections per rabbit), strongly suggests that the antigens able to elicit protective immunity are minimally expressed in *T. pallidum* or are weakly immunogenic. In previous attempts using lower doses of γ-irradiated treponemes and shorter immunization periods, either absent or partial protection was observed (Miller, 1967). In a subsequent attempt to reproduce the original results with a less demanding immunization schedule, Miller (1976) increased the immunizing dose to 12×10^9 *T. pallidum* cells administrated over 9 weeks vs. 37 weeks, and obtained only partial protection. Lastly, the durable sterile immunity demonstrated by Miller was not dependent on the development of immobilizing antibody. No other antibody functions (e.g., opsonization, neutralization) or cellular mechanisms of immunity were measured in the immunized animals, so the immune correlates of protection remain elusive.

The most recent vaccination experiments using whole-cell preparations were attempted in the early 1990s by Fitzgerald (1992), who endorsed the now-discounted theory that *T. pallidum*'s ability to escape clearance during early lesion resolution could be facilitated by a premature down-regulation of the initial Th1-mediated response in favor of Th2. Fitzgerald's hypothesized association between a premature Th1/Th2 switch and *T. pallidum*'s ability to establish a chronic infection was supported by the perceived parallels between the immune response to early syphilis and other chronic infections such as leishmaniasis (Boom et al., 1990; Scott, 1991), and trypanosomiasis (Reed, 1988; Silva et al., 1992). Fitzgerald immunized rabbits with a single injection of heat-inactivated *T. pallidum* cells and supported the Th1-type response with the administration of cyclophosphamide, monophosphoryl lipid A, and indomethacin (Fitzgerald, 1991; Fitzgerald et al., 1991). Despite the significant increase in the number of atypical lesions in the challenged animals, this approach did not prove effective in inducing sterile immunity, and in fact increased dissemination of organisms to distant sites (Fitzgerald, 1991; Fitzgerald et al., 1991).

Syphilis vaccinology has also known a remarkable number of attempts to immunize with different species of the genus *Treponema*, based on their antigenic

relatedness to *T. pallidum* and their ability to be grown in vitro. All immunizations with *Treponema phagedenis* (Reiter strain) (Gelperin, 1951; Al-Samarrai and Henderson, 1976), *Treponema refringens* (Izzat et al., 1970; Al-Samarrai and Henderson, 1976), *Treponema minutum*, *Treponema ambiguum*, *Treponema microdentium* (Al-Samarrai and Henderson, 1976), *T. paraluiscuniculi* (Graves, 1981), and *Spirochaeta aurantia* (Graves et al., 1984) resulted, however, in absent, partial, or questionable protection after challenge with *T. pallidum* (reviewed by Lukehart, 1985).

Second-Generation Syphilis Vaccines: Subunit Immunogens

The increasing understanding of antigenic relatedness among different treponemal species and the application of DNA engineering techniques quickly fostered the use of individual subcellular fractions and recombinant proteins as experimental vaccines (Table 59.1) instead of whole-cell preparations. For example, in their work, Hindersson et al. (1985) immunized rabbits with purified endoflagella from *T. phagedenis* in the attempt to induce sterile immunity against syphilis. The outcome of the experiment showed no alteration of lesion development following challenge with virulent *T. pallidum*; nonetheless, the rationale for selecting such antigen was justified by the presence of shared epitopes between the *T. phagedenis* and *T. pallidum* homologous peptides (Blanco et al., 1986). To increase the specificity of the immune response, a similar experiment was attempted by Champion et al. (1990) with purified *T. pallidum* endoflagella; in this case, infection occurred although lesions were atypical in the immunized animals. These two examples are noteworthy in that both groups tried to induce sterile immunity against syphilis with an antigen already known to be located in the *T. pallidum* periplasm and therefore lacking any surface exposure. Based on the disappointing results of these studies, contrasted with the success of Miller's studies described above, the general concept emerged that antigens exposed on the *T. pallidum* surface would be the most likely targets to induce sterile immunity; this launched an active effort in many laboratories to identify surface-exposed antigens of *T. pallidum*.

In the 1980s, supported by the introduction of recombinant DNA technology in syphilis research, the identification of putative *T. pallidum* integral membrane proteins seemed to be easily achieved. Libraries were constructed with *T. pallidum* genomic DNA and propagated in *E. coli* strains suitable for the expression of exogenous antigens, and *T. pallidum*'s major immunogens began to be identified based on the reactivity of *E. coli* colonies with immune sera from experimentally infected rabbits or syphilitic patients (Walfield et al., 1982; Norgard and Miller, 1983; van Embden et al., 1983). The *Treponema* membrane protein A (TmpA, or TpN44.5), B (TmpB) (Hansen et al., 1985), and C (TmpC, TpN35) (Schouls et al., 1991) were among the antigens first isolated with this newly introduced approach, and their membrane location was supported by the evidence that these antigens were synthesized in *E. coli* as larger precursors, that the amino terminal sequence was predicted to contain a signal peptide, and finally that fractionation studies of *E. coli* cells expressing the Tmp proteins showed the tendency of these antigens to localize in the hydrophobic phase containing the cell membranes. Surprisingly, however, only partial or absent protection were reported following immunization with recombinant antigens based on the Tmp protein sequences (Wicher et al., 1989; Wicher et al., 1991) (Table 59.1); later studies of radiolabeled fatty acid incorporation into *T. pallidum* membranes lead to the conclusion that these antigens are lipoproteins whose characteristics of hydrophobicity, previously attributed to membrane-spanning domains, are due to protein acylation with lipid moieties, responsible for the anchoring of the antigens to the periplasmic side of the cellular membrane (Chamberlain et al., 1989a; Schouls et al., 1989a). The 47 kDa antigen of *T. pallidum* was also cloned early and, similarly, is a lipoprotein (Norgard et al., 1986a; Chamberlain et al., 1989a, 1989b).

The list of *T. pallidum* lipoproteins initially mistaken for OM antigens is quite extensive (Fehniger et al., 1986a, 1986b; Norgard et al., 1986a, 1986b; Radolf et al., 1986; Cunningham et al., 1988; Chamberlain et al., 1989a, 1989b; Schouls et al., 1989a; Swancutt et al., 1990). Although these proteolipids represent major *T. pallidum* immunogens, all have uniformly failed to induce sterile immunity against syphilis when used in immunization/challenge experiments (Table 59.1) (Borenstein et al., 1988; Centurion-Lara et al., 1997), similar to the previously attempted immunization with preparations of periplasmic endoflagella (Champion et al., 1990). Unpublished studies from our laboratories have failed to demonstrate any protective immunity following immunization with the 47 kDa antigen.

THE *T. PALLIDUM* OUTER MEMBRANE AND THE QUEST FOR SURFACE-EXPOSED ANTIGENS

In the last two decades, the desire to deepen the study of the *T. pallidum* OM and unravel some of its

[d] Total dose of immunogen administered.
[e] Protection is defined as resistance to challenge with *T. pallidum*. Partial, significantly altered lesion progression or asymptomatic infection; None, lesion development equivalent to that in unimmunized control animals.

peculiar characteristics prompted a series of pivotal investigations that demonstrated the OM to be poorly antigenic and almost devoid of integral membrane proteins. The perceived poor immunologic reactivity of the outer surface of *T. pallidum* is based on the evidence that the binding activity of syphilitic sera to undamaged *T. pallidum* cells is modest, while binding is highly enhanced by any intervention which damages the OM integrity (Penn and Rhodes, 1982; Robertson et al., 1982; Fehniger et al., 1986b; Radolf et al., 1986; Stamm et al., 1987; Cox et al., 1992). Furthermore, complement-mediated killing (immobilization and neutralization) and phagocytosis of opsonized *T. pallidum* cells have been shown to occur only upon use of high concentrations of antisera and extended incubation times (Nelson and Mayer, 1949; Bishop and Miller, 1976b; Lukehart and Miller, 1978; Alder et al., 1989, 1990). One long-standing hypothesis to explain the limited reactivity of intact *T. pallidum* with antibodies has been the ability of *T. pallidum* to gather proteins from the host to form a self-like protective shield surrounding the OM; although this hypothesis has not been completely disregarded, it became a less-plausible explanation when freeze fracture electron microscopy studies revealed that the *T. pallidum* OM possesses an extremely low density of integral membrane proteins (Radolf et al., 1989b; Walker et al., 1989, 1991). More specifically, the outer and inner leaflets of the OM were calculated to harbor 70 and 100 membrane particles per μm^2 (Walker et al., 1989), approximately 1% of the number found in the *E. coli* inner and outer leaflets of the OM, respectively. These fascinating discoveries provided the first plausible explanation to the fact that conventional methods to identify putative surface exposed epitopes (e.g., immunofluorescence, immunoelectron microscopy, or surface protein radiolabeling) find very limited application in *T. pallidum*. Equally interestingly, *T. pallidum*'s surface proteins were shown to have a nonuniform but ordinate distribution throughout the bacterial surface, and to be capable of only limited mobility within the lipid bilayer (Radolf et al., 1989b; Blanco et al., 1990; Bourell et al., 1994), which might correlate with the limited ability of immune sera to cross-link these antigens and the very slow rate at which complement-mediated killing of *T. pallidum* occurs (Nelson and Mayer, 1949; Bishop and Miller, 1976b).

The modest immunological reactivity and the protein-poor content of the *T. pallidum* OM have not discouraged investigators from attempting alternative experimental routes to identify surface-exposed antigens. These methods can be generally classified into two groups, according to the use of a direct or indirect identification approach. Direct approaches encompass all of the biochemical methodologies aimed to selectively isolate the *T. pallidum* OM after detaching it from the underlying cellular structures (endoflagella, peptidoglycan, and the cytoplasmic membrane with its array of proteolipids) which could constitute a source of contaminating proteins. A generic hypertonic plasmolysis of the OM, using a sucrose gradient followed by isopycnic centrifugation to recover the OM fractions (Radolf et al., 1995b; Shevchenko et al., 1997, 1999), and subsequent analysis of the protein constituents by two-dimensional electrophoresis and immunoblotting, identified at least two new plausible candidates, p30.5 (Tp0453) and GPD/GlpQ (Shevchenko et al., 1997). In addition, at least three known periplasmic lipoproteins were also represented on the immunoblot, underlining how direct isolation of OM fragments is fraught with contamination by proteins from other cellular compartments.

It is by indirect analytical methods, however, that the majority of the *T. pallidum* putative surface antigens have been identified, mostly using in silico analysis of the Nichols strain genome. The initial search for homology between *T. pallidum* predicted proteins and previously characterized OM proteins of related bacteria, has allowed the identification of a first group of candidates. These include the twelve genes encoding for the Tpr proteins, which are homologous to the major sheath protein of the oral spirochete *Treponema denticola* (Weinstock et al., 1998; Centurion-Lara et al., 1999), and Tp0326 (Tp92), which is homologous to the Omp85/D15 antigens described in many pathogenic bacteria (Cameron et al., 2000). The combination of bioinformatics tools for prediction of signal peptides, membrane spanning domains, and protein cellular location has also led to the identification of three proteins which, in a series of intensive experiments, were shown to encode for laminin-binding (Tp0751) (Cameron, 2003) and fibronectin-binding (Tp0483 and Tp0155) proteins (Cameron et al., 2004). These proteins are likely to be surface exposed and involved in the attachment of *T. pallidum* to the host cells and ECM.

Many of the hypothetical *T. pallidum* OM proteins identified on the basis of the methods described above have been the subject of intensive investigation to confirm or refute the original hypotheses suggested by the in silico analysis of their sequences. Although none of those antigens has been unequivocally shown to reside within the OM, and immunoprotection assays have thus far failed to induce sterile immunity, very promising immunization studies have been performed. The ample knowledge accumulated on these proteins has strongly renewed the interest in the study of this elusive pathogen and has provided new analytical instruments to further investigate the

pathogenesis of syphilis. An increasing body of information is available today on these proteins regarding their immunogenic capabilities during experimental or natural infection, their functions, their structures, the conservation of their genes among *T. pallidum* strains, subspecies and treponemal species, their gene organization into transcription units, their transcriptional patterns, and mechanisms of transcriptional regulation. This knowledge will eventually help in the characterization of these and other antigens that could serve as more effective immunogens for inducing protective immunity.

Tpr Antigens

The recognition of the gene-family coding for the *T. pallidum* repeat (Tpr) antigens is one of the major findings of the *T. pallidum* genome project (Fraser et al., 1998), in that these hypothetical proteins were immediately identified as potential virulence factors and vaccine candidates (Weinstock et al., 1998; Centurion-Lara et al., 1999). Several of these genes had been identified earlier using other methods (Hardham, 1995; Centurion-Lara et al., 1999), but the existence of a 12-member family (named *tprA-tprL*) was not anticipated until the genome sequence was analyzed. The encoded antigens share homology with the major sheath protein (Msp) of *T. denticola* (Weinstock et al., 1998), a virulence factor reported to be surface exposed and to have both porin and adhesin proprieties (Fenno et al., 1996; Mathers et al., 1996). These *tpr* genes account for a high percentage (~2%) of the very sparse *T. pallidum* genome (Centurion-Lara et al., 1999), suggesting an important role for these antigens in the survival of an organism that has lost many biosynthetic capabilities during evolution (Fraser et al., 1998). The Tpr antigens are divided into three subfamilies by their predicted amino acid homology: Subfamily I (TprC, D, F, and I), Subfamily II (TprE, G, and J), and Subfamily III (TprA, B, H, K, and L) (Centurion-Lara et al., 1999). The Subfamily I members, along with Tpr J and K, are predicted to have cleavable signal sequences and possible OM localization (Centurion-Lara et al., 1999; Giacani et al., 2007b), although definitive localization studies have not yet been performed. Within the Subfamily I and Subfamily II members, the proteins have conserved NH_2- and COOH-terminal regions, with central domains that are variable in sequence and length, allowing the differentiation of the individual proteins (Centurion-Lara et al., 1999). In the Nichols strain, where the Tprs were first characterized, Subfamily I TprC and D are identical in sequence but their genes reside in two distinct genomic loci, and TprF is predicted to lack the conserved COOH-terminal region and part of the central variable domain due to a deletion and frame-shift mutation in the coding sequence (Fraser et al., 1998; Centurion-Lara et al., 1999).

A comparison of the *tpr* genes among different *T. pallidum* isolates has revealed strain-to-strain sequence variability in several members of this gene family. Because the Tpr proteins stimulate humoral and cellular immune responses during infection (Morgan et al., 2002b; Leader et al., 2003; Sun et al., 2004; Giacani et al., 2007b), variations in the gene sequence has potential ramifications for immune function and cross-immunity, which is relevant to the development of a broadly effective syphilis vaccine. Among Subfamily I members, an alternative allele, named *tprD2*, can be found within the *tprD* locus in about 50% of syphilis isolates tested (Centurion-Lara et al., 2000b). Diversity was described also for the *tprC* gene locus, in that all of the strains analyzed so far with the *tprD* sequence in the D locus also harbor an identical sequence in the C locus (as in the Nichols strain); in contrast, strains in which a *tprD2* allele is found in the D locus, contain a *tprC* allele containing a variable number of base changes resulting in new predicted amino acids at those sites (Sun et al., 2004). Sequences for *tprF*, *tprI,* and *tprE* have not yet been found to vary among syphilis strains (Sun et al., 2004). In the Sea 81-4 strain, the central region of Subfamily II *tprJ* has been replaced by the corresponding region of *tprG*, resulting into a hybrid *tprG-J* gene in the J locus (Giacani et al., 2005a). In this same isolate, a frameshift in the G locus predicts a premature termination of TprG (Giacani et al., 2005a). Among Subfamily III members, the Nichols strain *tprA* contains a frame-shift mutation resulting in a premature stop codon which is absent in the Sea 81-4 strain and in the rabbit treponeme *T. paraluiscuniculi* (Giacani et al., 200, 2007b). Interestingly, in the Nichols strain, the *tprA* frame-shift is caused by a deletion of a dinucleotide (CT) located in a region containing three dinucleotide repeats; conversely, in the Sea 81-4 strain, the presence of four CT repeats at this location reverts the frame shift and generates a full length *tprA* open reading frame (ORF) (Giacani et al., 2007b).

Among Subfamily III members, however, the greatest degree of sequence heterogeneity has been reported for the *tprK* gene which, among human isolates, undergoes extensive sequence diversification shown to accumulate during the course of infection (Centurion-Lara et al., 2000a; LaFond et al., 2003, 2006a; Morgan et al., 2003). Among all of the Tpr proteins, TprK is the most highly expressed (Giacani et al., 2007b), induces the earliest and most vigorous immune response in the infected host (Leader et al.,

2003; Giacani et al., 2007b), and has been reported to be a target for opsonic antibody (Centurion-Lara et al., 1999), suggesting possible surface exposure of this antigen. This sequence variation in TprK is the first antigenic variation mechanism for *T. pallidum*. Although the function and location of TprK have not been finally resolved (Hazlett et al., 2001), this variation is hypothesized to provide an efficient way for the organism to evade the host immune response, leading to persistence and chronic infection despite a vigorous immune response.

In more detail, *tprK* heterogeneity is restricted to seven discrete variable regions (named V1–V7) (Centurion-Lara et al., 2000a), mostly located in the COOH-terminal half of the gene; these regions are flanked by conserved sequences, and variability is generated by a nonreciprocal gene conversion-like mechanism which mediates the recombination of a DNA template (called a donor cassette) into the expression site. Over 50 identified donor cassettes are located in two regions distant from the expression site on the chromosome (Centurion-Lara et al., 2004). Morgan et al. (2002b) demonstrated that antibodies arising in infected rabbits are directed against the V regions of TprK, while cellular immune responses are focused on the conserved regions. This segregation of epitopes is consistent with a major role for antibody in the immune response to *T. pallidum*. Morgan also demonstrated a correlation between the level of protection following immunization and the specificity of the induced V region antibodies (Morgan et al., 2003). In an intensive series of experiments, LaFond et al. (2006b) demonstrated that new variant V region sequences arising during infection are not recognized by antibodies developed against V regions of the infecting strain. These results strongly support not only the involvement of this gene in the generation of antigenic diversity as mechanism of immune escape, but also the TprK OM location. It is difficult to imagine why *T. pallidum* has evolved such a complex mechanism to generate so many TprK antigenic variants if portions of the protein are not exposed to the host immune system.

The surface exposure of TprK and other Tprs, however, is still the object of some debate: surface exposure for TprK and several other Tpr antigens is supported by experimental evidence, PSORTb (http://www.psort.org/psortb) analysis (Giacani et al., 2007b), and predicted cleavable signal peptides in TprF, I and K. Antibodies elicited against TprK have been shown to exert opsonic activity (Centurion-Lara et al., 1999) suggesting that at least some TprK epitopes are surface exposed; this result, however, has not been reproduced by others (Hazlett et al., 2001). TprI's cellular location has been investigated using electron microscopy after colloidal gold labeling using a polyclonal antiserum raised against the recombinant full-length antigen (Giacani et al., 2005b); although gold particles were shown to label the *T. pallidum* OM, the periplasm was also targeted.

Rabbits inoculated with different *T. pallidum* strains develop antibody (Leader et al., 2003) and CD4+ reactivity (Giacani et al., 2007b) in varying magnitudes to different repertoires of the Tpr antigens. This is likely to be a consequence of the differential expression of the *tpr*s during infection. Recent data on transcriptional analysis of the *tpr* genes using quantitative real time RT-PCR, confirmed that the *tpr* genes are differentially expressed within and among *T. pallidum* isolates (Giacani et al., 2007b), suggesting the existence of transcriptional regulatory mechanisms. Subfamily I and II *tpr* expression is regulated, at least in part, by the variable length of homopolymeric G-repeat sequences immediately upstream of the transcriptional start site (Giacani et al., 2007a); this resembles the phase variation mechanism described for *Neisseria meningitidis opc* genes (van der Ende et al., 1995; van der Woude and Baumler, 2004; Cullen and Cameron, 2006). Tight control of transcription initiation is a recognized feature of virulence factors, and the hypothesis that Subfamily I and II *tpr*s could, in addition to TprK, contribute to the antigenic diversity of the *T. pallidum* surface cannot be excluded. Both the sequence variation and the differential expression of individual Tpr among strains of *T. pallidum* have important ramifications for the design of a broadly protective syphilis vaccine.

Tpr Proteins as Vaccine Candidates

Given the impressive and steadily growing body of information concerning the Tpr antigens, these were naturally selected for immunization trials and studies were independently performed in different laboratories (Table 59.1). In all of these studies, adult male rabbits were immunized with purified *E. coli* expressed recombinant peptides, often representing only a portion of the predicted protein antigen; these rabbits were then challenged intradermally with virulent *T. pallidum* (differing doses) and observed for lesion development. Although none of these immunizations yielded sterile immunity, several studies demonstrated significant alterations in the appearance, progression (to ulceration), and content of detectable *T. pallidum* (i.e., presence or absence of *T. pallidum* in darkfield microscopic examination of lesion aspirates) following infectious challenge with the Nichols strain. Antigens examined include peptides from

TprK (Centurion-Lara et al., 1999; Hazlett et al., 2001; Morgan et al., 2002a), TprI (Giacani et al., 2005b) and F full-length peptides (Sun et al., 2004), the TprC/D and J central unique regions (unpublished data), the NH_2 conserved region of Subfamily I Tprs, and the COOH-terminal domain of Subfamily I members (Sun et al., 2004). Further studies identified the NH_2-terminal portion of the TprK antigen as the fragment inducing the highest level of protection, compared to the central and COOH-terminal regions (Morgan et al., 2002a). One independent study reported lack of protective activity (Hazlett et al., 2001) upon immunization with a mixture of full-length TprK plus a peptide analogous to that reported by Centurion-Lara et al. (1999). No alteration of disease progression was seen upon immunization with TprA, B, and H full-length peptides, and the TprI, E, and G central regions, while significant alteration of lesion development was seen upon immunization with the Subfamily II COOH-terminal domain (unpublished data from the authors' laboratory) (Table 59.1). TprL could not be expressed in our laboratory as a recombinant peptide, and no results are available in the literature on the protective capability of this antigen.

There is reason to be enthusiastic about Tpr antigens as vaccine candidates, and studies are in progress to refine the antigens and the immunization protocols. The preliminary studies described above strongly suggest that significant levels of immunity are induced by the NH_2-terminal regions of TprK and the Subfamily I, and the central region of Tpr C/D. Ongoing work in the authors' laboratories is focused on the development of chimeric peptides, including selected regions of Tpr antigens in a single larger recombinant peptide. Given the expected limited exposure of epitopes on the surface of *T. pallidum*, it is hoped that the chimeric immunogens, inducing antibodies to carefully selected regions of multiple antigens, may yield increased levels of protection.

Adhesins

For *T. pallidum*, as for many bacterial pathogens, attachment to host cells or tissue components is a crucial first step in the pathogenic process that will eventually lead to the establishment of infection in the host. *T. pallidum*'s ability to attach to various cultured mammalian cell types was first reported in the 1970s (Fitzgerald et al., 1975, 1977a; Quist et al., 1983), and subsequent studies noted the ability of *T. pallidum* to bind to a variety of components of the ECM, including fibronectin, laminin, and collagen (Baseman and Hayes, 1980; Peterson et al., 1983; Fitzgerald et al., 1984; Fitzgerald and Repesh, 1985; Thomas et al., 1985a, 1985b). Only recently, however, has such interaction been attributed to specific, receptor-mediated attachment through the identification of three ORFs coding for *T. pallidum* ECM-binding proteins: Tp0751 was found to bind laminin (Cameron, 2003) and Tp0155 and Tp0483 were shown to specifically recognize fibronectin (Cameron, 2003; Cameron et al., 2004). Studies by Cameron et al. demonstrated the attachment of viable *T. pallidum* to fibronectin- or laminin-coated surfaces, with specific inhibition of that activity by the respective recombinant proteins. These functional studies argue strongly for surface exposure of the proteins and, correspondingly, for the plausibility of these antigens to induce a protective immune response. Immunization experiments involving the ECM-binding proteins are currently in progress (Cullen and Cameron, 2006).

Lipoproteins

Past attempts to induce protective immunity using major *T. pallidum* lipoproteins, discussed above, have been ineffective. In more recent years, however, the identification of a lipoprotein likely to be associated with *T. pallidum* OM has stimulated a reexploration of this category of antigens in immunoprotection assays. Among these, the proteolipid encoded by the Tp0453 ORF is currently being examined (Cullen and Cameron, 2006). Tp0453 encodes for a 30.5 kDa protein previously identified in *T. pallidum* OM fractions (Shevchenko et al., 1997), but only recently characterized at the genetic, structural, and functional level by Hazlett et al. (2005). Structural and functional analysis showed that, even in absence of its lipid anchor, Tp0453 retains its amphiphilicity and possesses an intriguing ability to destabilize artificial membranes. Such evidence induced the authors to hypothesize that Tp0453, although physically located in the periplasmic space, is able to reversibly increase the permeability of the OM, perhaps functioning as a hidden porin that would allow the pathogen to acquire nutrients from the external environment in a nonselective way without exposing any potential epitope to the host immune system.

Similarly to Tp0453, the *T. pallidum* lipoprotein molecule glycerophosphodiester phosphodiesterase (also called Gpd or GlpQ) may also be associated with the OM. This antigen was initially identified both by screening a *T. pallidum* expression library with opsonizing antibodies (Stebeck et al., 1997; Cameron et al., 1998), and also by reverse genomics applied to protein constituents purified after OM isolation

(Shevchenko et al., 1997); subsequently, its proteolipid nature was shown by its resistance to N-terminal Edman degradation and by protein labeling studies using radioactive fatty acids (Shevchenko et al., 1997). The evidence that Gpd binds the Fc portion of some classes of human immunoglobulins, that anti-Gpd immune sera show decreased reactivity with lysates *T. pallidum* lacking the OM, and the high similarity between the *T. pallidum* Gpd sequence (Tp0257) and its surface-exposed homologs in *Borrelia hermsii* (Gpd) and *Hemophilus influenzae* (Hpd, or Protein D) (Ruan et al., 1990; Janson et al., 1992; Shang et al., 1997), clearly support the hypothesis that Gpd is associated with the *T. pallidum* OM (Cameron et al., 1998). Conversely, however, attempts to identify Gpd in *T. pallidum* using surface immunofluorescence and opsonophagocytosis assays were unsuccessful, thus questioning the association between this antigen and the OM (Shevchenko et al., 1999). Immunoprotection assays using recombinant *T. pallidum* Gpd independently performed in the two laboratories in which the antigen was characterized (Cameron et al., 1998; Shevchenko et al., 1999) were also discordant, one showing significant alteration in lesions following challenge, and the other showing no effect of immunization.

Tp92

As with Gpd, Tp92 (encoded by the Tp0326 ORF) was initially identified both by differential antibody screening of a *T. pallidum* genomic library (using opsonizing and non-opsonizing rabbit immune sera) and by in silico analysis of the Nichols strain genome (Cameron et al., 2000). Tp92 is predicted by PSORT analysis to contain a cleavable signal peptide and to have a significant likelihood of localizing in the bacterial OM. Experimental evidence supporting OM location of Tp92 was provided by the absence of immunoblot reactivity of Tp92-specific antiserum against washed treponemal cells (in which the OM had likely been sheared off), and by the opsonizing capability of antisera from Tp92-immunized rabbits (Cameron et al., 2000). The function of Tp92 has not been determined in *T. pallidum*, but homologous antigens are widely present among gram-negative bacteria. The Tp92 homolog Omp85, described in both *N. meningitidis* and *Neisseria gonorrheae* (Manning et al., 1998), has been shown to be surface exposed, and functional characterization studies performed on *N. meningitidis* Omp85 (Voulhoux et al., 2003; Bos and Tommassen, 2004; Voulhoux and Tommassen, 2004) strongly suggest that this protein is part of a multi-subunit complex involved in correct OM protein sorting and assembly. Furthermore, immunization with the Tp92-homologs of *H. influenzae* and *Pasteurella multocida* (called D15 and Oma87, respectively) were shown to be protective against infection in animal models (Flack et al., 1995; Ruffolo and Adler, 1996). Protection experiments with *T. pallidum* Tp92, however, induced partial protection in immunized rabbits which developed atypical lesions but did show seroconversion for syphilis after infectious challenge (Cameron et al., 2000).

GENOMICS AND RECOMBINANT DNA TECHNOLOGY: GREAT HELP WITH SOME LIMITATIONS

The new sciences of genomics, proteomics, and recombinant DNA technology have revolutionized modern microbiology and are important allies in the challenging path to vaccine development. Given the great potential of these techniques, it might seem surprising that since their introduction, only three vaccines against bacterial pathogens (*Bordetella pertussis*, *Vibrio cholerae*, and *Borrelia burgdorferi*) (Grandi, 2001) have been developed using recombinant DNA technologies. Although DNA engineering provides a virtually unlimited availability of recombinant antigens, there are significant limitations of the application of these methods for production of membrane proteins. Because of their chemical nature, membrane proteins most often are produced in the insoluble (sometimes membrane-associated) fraction of the recombinant host, and the harsh chemical procedures (often 6 M urea) needed to solubilize the material for purification of the single recombinant protein destroys native conformation. Reestablishment of native conformation prior to use in immunization requires tedious application of multiple refolding protocols, most often in a setting where the native conformation is completely unknown. As proposed by Cullen and Cameron (2006), experimental methods that might be utilized include limiting the level of expression of a recombinant antigen to favor production of soluble recombinant protein, and promotion of antigen transport to the *E. coli* OM by replacing the *T. pallidum* signal sequences with those of *E. coli* OM proteins. These approaches may offer improvements but may not be the full answer. Antibody-mediated protective immunity in many cases is directed at conformational epitopes formed by the proteins as they loop in and out of the OM, and purified proteins may or may not form such epitopes in the absence of an environment mimicking the OM.

ANIMAL MODELS AND ADJUVANT SELECTION

The rabbit is the most widely used animal model to study experimental syphilis (Turner and Hollander, 1957), and has advantages over guinea pigs, hamsters, mice, and nonhuman primates because of the many parallels between the experimental infection in rabbits and natural human infection. Similar to humans, rabbits are highly susceptible to *T. pallidum*, with an equivalent ID_{50} (Magnuson et al., 1948, 1956), and develop skin lesions following infection that are clinically and histologically very similar to human primary chancres (Turner and Hollander, 1957; Sell and Norris, 1983). In rabbit and humans, similarities also include the repertoire of antigens recognized by humoral immune responses, the IFNγ-predominant cytokine milieu at the sites of infection, and the ultimate development of immunity to reinfection (Turner and Hollander, 1957; Sell and Norris, 1983). As in humans, rabbits remain chronically infected for a lifetime unless adequately treated (Turner and Hollander, 1957), and infectious organisms can be detected in lymph nodes and other tissues (via transfer of tissue to a susceptible rabbit) even after years of latent infection. Secondary lesions are sometimes seen in infected rabbits if the fur is kept clipped to reduce the temperature of the skin surface, but manifestations of tertiary syphilis are not observed in syphilitic rabbits (Turner and Hollander, 1957). In rabbits, *T. pallidum* disseminates via the bloodstream and lymphatic circulation to distant organs, including the central nervous system, similar to human infection. The disadvantages of the rabbit model include the high cost of the animals, the lack of inbred strains, and the lack of species-specific immunological reagents. The rabbit genome sequence is being completed (http://www.ncbi.nlm.nih.gov/projects/genome/guide/rabbit/) which will facilitate development of reagents. With regard to rabbit strains, it may be worth noting that the successful immunization experiment by Miller (1973) was conducted in Dutch Belt rabbits, while current investigators use the New Zealand White strain; the possible effect of this change on modern immunization studies is unexplored.

Hamsters and guinea pigs have been used as alternative models (Schell et al., 1980; Schell, 1983; Wicher and Wicher, 1989) because inbred strains are available; however, hamsters have reduced susceptibility to the syphilis spirochete compared to the other *T. pallidum* subspecies (subsp. *endemicum* and *pertenue*, the causative agents of endemic syphilis and yaws, respectively), and guinea pigs require inoculation of extraordinarily high numbers of treponemes to induce the development of ulcerative lesions (Wicher and Wicher, 1989). The documented immunological differences between guinea pigs and humans (i.e., absence of production of Th1 cytokines during experimental infection) and the different histopathology of skin lesions also disfavor this animal model with respect to rabbit. Although infection can be experimentally achieved in mice, these animals do not develop clinical syphilis, and therefore the model has not been deemed adequate (Schell et al., 1975; Folds et al., 1983).

Although the vast majority of immunoprotection experiments have been performed in rabbits (except for the TmpA, B, and C immunizations performed in guinea pigs) (Wicher et al., 1989; Wicher et al., 1991), there has been wide variability in the immunization protocols used (Table 59.1), particularly with regard to duration of immunization, dose of antigen, and route of immunization. These factors are critical to successful immunization studies, yet optimal protocols are determined almost completely empirically. There is no effective way to determine the correct combination of these parameters without actually conducting the lengthy and labor-intensive experiments. Adjuvant selection is another critical experimental variable and, in the absence of knowledge of known markers of protective immunity, little guidance can be offered. Many recent immunization studies performed in the authors' laboratories have used the Ribi adjuvant, which contains monophosphoryl lipid A (a TLR4 agonist), synthetic trehalose dicorynomycolate, and cell wall (CW) skeleton. This adjuvant, which enhances the development of cellular immunity in addition to antibody, has not been commercially available for several years, but is soon to become available again. Other than complete or incomplete Freund's adjuvant, other more modern adjuvants have not been explored with *T. pallidum* vaccine candidate antigens.

ALTERNATIVE IMMUNIZATION APPROACHES

DNA vaccination and live attenuated bacterial (LAB) vaccines constitute two very promising branches of modern vaccinology (Ulmer et al., 2006) whose application has not been reported yet for syphilis. Unpublished studies from our laboratories, conducted in collaboration with Cameron, using a DNA vaccination approach for Gpd immunization, failed to induce significant protection. Although at the present time DNA vaccination has no practical use in humans (so far no clinical trial for DNA vaccines have gone beyond Phase I/II) (Liu and Ulmer, 2005; Laddy and Weiner,

2006), their efficacy in many animal models has been widely documented (Ulmer et al., 2006). It is encouraging that DNA vaccination stimulates both branches of the immune response, and that the initial limitations due to poor delivery of the antigen-encoding DNA are gradually being overcome by many innovative DNA delivery systems (including the employment of microparticles targeting antigen-presenting cells, electroporation, and intradermal DNA "tattooing") (O'Hagan et al., 2006; Ulmer et al., 2006). Furthermore, the employment of DNA-vaccine adjuvant (i.e., CpG motifs in the vector backbone to activate intracellular TLR and accessory genes coding for cytokines and chemokines) (Coban et al., 2005) has greatly improved the effective immunogenicity of these vaccines. Particularly interesting is also the evidence seen in recent studies that DNA priming followed by protein boosting can increase the level of protection above that obtained with the protein alone (Hall et al., 2002); this may be an interesting approach to enhance the immune response against many *T. pallidum* antigens already shown to induce partial protection.

The use of LAB vaccines is another interesting strategy (Daudel et al., 2007), though not yet reported for syphilis; the administration of *T. pallidum* antigens using a living carrier, rather than a coding sequence as in DNA vaccination, could provide many advantages, including the mimicry of a natural infection, the natural adjuvant proprieties of bacterial components, and potentially better immunogen conformation. Live bacterial vaccines might also be administered orally or nasally through aerosolization, with the advantage of stimulating mucosal immunity, which is not achieved by the more traditional immunization practices discussed so far. Although very appealing, this technique also has potential hazards that will need to be addressed carefully before the application of LAB vaccines to humans, including the possibility of systemic infection, reversion of the carrier bacterial strain from attenuated to virulent, generic perturbation of the natural flora of the gastrointestinal or respiratory tracts, and accidental transfer of genetically modified organisms to unimmunized individuals (Detmer and Glenting, 2006).

CONCLUSIONS

It is clear today that syphilis pathogenesis involves a very complex strategy that *T. pallidum* uses to evade the immune response of the host. This strategy exploits the limited surface immunogenicity due to a remarkable paucity of integral OM proteins, the rapid generation of antigenic variants of TprK, and probably additional yet-unidentified mechanisms. The recognition of these multi-faceted strategies has strongly underlined the necessity to identify those rare surface-exposed antigens in the attempt to develop more effective vaccines. While the extreme fragility of the *T. pallidum* OM and the absence of a host-free cultivation system impede that search, significant progress has been made in the past decade in our understanding of *T. pallidum* and its antigenic structure. Even with cheap and effective therapy, syphilis is uncontrolled throughout much of the world; a vaccine is the best hope for disease control and eradication. The improvement of existing molecular and immunological methodologies, the promise of even more sophisticated advances in vaccinology, and the public health need for a syphilis vaccine continually serve to bolster the enthusiasm and resolve of the investigators who tackle this difficult organism.

KEY ISSUES

- Syphilis is a major public health problem globally, with the highest burden in developing countries. In addition to adult infection, syphilis is responsible for a high proportion of stillbirth, spontaneous abortion, and neonatal morbidity and mortality in developing countries.
- Cheap and effective diagnosis and treatment of syphilis are available, yet the disease burden remains high. Lack of access to medical care in many countries and failure of traditional disease control methods to eliminate syphilis underscore the need for a vaccine.
- The frequent and prolonged administration of *T. pallidum* attenuated by gamma-irradiation has been shown to provide complete and long-lasting protection against infectious challenge in the rabbit model. This approach, however, cannot be adapted for human studies.
- Because *T. pallidum* cannot be genetically manipulated or grown in culture, and its OM is extraordinarily fragile, its protective antigen(s) have not been identified. The availability of the *T. pallidum* genome sequence, however, has facilitated the identification of key putative surface -exposed proteins involved in attachment and antigenic variation. Many of these have been tested for their ability to induce protective immunity.
- Immunization studies in rabbits using recombinant antigens have demonstrated significant attenuation of lesion development and progression following

infectious challenge, but have not provided complete protection against infection.
- The TprK antigen, which undergoes antigenic variation, and likely contributes to *T. pallidum*'s ability to evade the host immune response, is among the most promising targets for the development of a vaccine against syphilis infection. Production of a broadly protective TprK-based vaccine, however, will likely require immunization with cocktails of peptides representing the variable regions.
- New approaches to immunization under investigation include DNA prime/protein boost strategies and development of chimeric recombinant proteins.

ACKNOWLEDGMENTS

The authors are grateful to Elizabeth Robertson for manuscript preparation. We thank Christa Castro, Barbara Molini, Charmie Godornes and Lynn Barrett for technical assistance with previously unpublished studies. This work was supported by grants AI 34616, AI 42143, and AI 63940 from the National Institutes of Health.

OUTLINE

ABSTRACT

Tuberculosis (TB) is one of the most prevalent infectious diseases worldwide and accounts for a large portion of all preventable deaths. Latent TB infection is also extremely common, affecting as many as one-third of humans alive today. Fortunately, only about 10% of TB infection leads to active TB disease. TB is curable with proper treatment, but treatment programs are labor intensive and increasingly threatened by drug resistance. Furthermore, the long treatment regimen poses compliance problems, and lack of access to TB care is common. As a consequence of these combined factors, TB continues to claim 2 million lives per year. An effective vaccine reliably preventing TB disease in adults would significantly reduce the number of deaths due to TB; however, no such vaccine is available. A live attenuated strain of *Mycobacterium bovis*, bacille Calmette–Guérin (BCG), is used with variable efficacy to vaccinate children against TB in many countries throughout the world. Because BCG protects against meningeal TB in children and against leprosy in adults, it will be difficult to justify replacing BCG with a new TB vaccine unless that vaccine is an improved version of BCG, which may take decades to develop and test. Effective vaccines that could be administered against a background of BCG immunization and/or preexisting *Mycobacterium tuberculosis* (Mtb) infection ("postinfection" vaccines) stand to make the greatest and most immediate impact on TB control. This chapter highlights the most recent history of TB vaccine development and describes TB vaccines that are in the research and clinical pipelines.

INTRODUCTION

About one in every three persons alive carries the tuberculosis (TB) infection and is at risk for TB disease (9 million new cases of TB per year) and death (2 million deaths per year) (WHO, 2007a, 2007b). Most cases of active TB occur in regions of Africa and Asia, where TB case finding is difficult or nonexistent and treatment monitoring is unavailable (Fig. 60.1); thus the actual impact of TB in those regions is underestimated in the World Health Organization (WHO) global TB program reports (WHO, 2007). TB is a treatable disease; however, it remains one of the most prevalent diseases because of the critical disconnect between the need for care and access to it. Sub-Saharan Africa, which has the highest rate of TB, reports the lowest treatment completion rate in the world: of those cases identified and placed in treatment programs, less than 75% complete treatment.

One of the reasons that very few individuals complete treatment is that TB treatment takes at least 6 months, and strict adherence to treatment is essential to achieve a cure. Completion rates differ dramatically between TB control programs in the developed and developing world. Both prompt diagnosis and effective treatment require trained and motivated staff, fully functioning laboratories, and reliable drug supplies. Despite some improvements since the late 1990s, the WHO reported in 2007 that every national treatment program in the world experienced ruptures in TB drug supply, too few laboratories, weak quality control, and limited facilities to carry out culture and drug-susceptibility testing. In most countries, even where TB treatment is free or low cost, physicians on the front line lack the most basic means of testing for active TB infection [the ability to perform a sputum smear for acid-fast bacilli (AFB)].

At the level of patient care, difficulties associated with adherence to a course of therapy over 6 months result in the development of drug resistance. Drug-resistant TB has become more common: multidrug-resistant (MDR) TB accounted for 1 million of the 8 million new cases of TB identified in 2004, the latest date for which the international statistics were compiled, and extensively drug-resistant TB (XDR TB) has emerged. Providing patient monitoring and continuous access to TB medications is a significant challenge for TB programs that globally face a funding shortfall of $1 billion for the next few years (Feuer, 2007).

Despite these figures, some gains have been made in recent years. Indeed, a "leveling off" of global TB incidence was reported (WHO, 2007). However, it is unlikely that widespread access to TB treatment alone will solve the problem of TB. The only possible intervention for TB that does not require extended treatment over 6–9 months, trained clinical personnel, careful monitoring of adherence, and uninterrupted supply chains is a TB vaccine.

Currently, there is no effective vaccine for reliably preventing TB in adults (Colditz et al., 1994; Sepkowitz, 2001). A live attenuated strain of *Mycobacterium bovis*, bacille Calmette–Guérin (BCG), is used with variable efficacy to vaccinate children against TB in many countries (Fine, 1995). Because BCG protects against meningeal TB in children and leprosy in adults and is very widely used in children, it will be difficult to perform studies that justify replacing BCG with a new TB vaccine unless that vaccine is an improved version of BCG. Because of the chronology of TB infection and disease (10–20 years, or more), a replacement vaccine for BCG will take

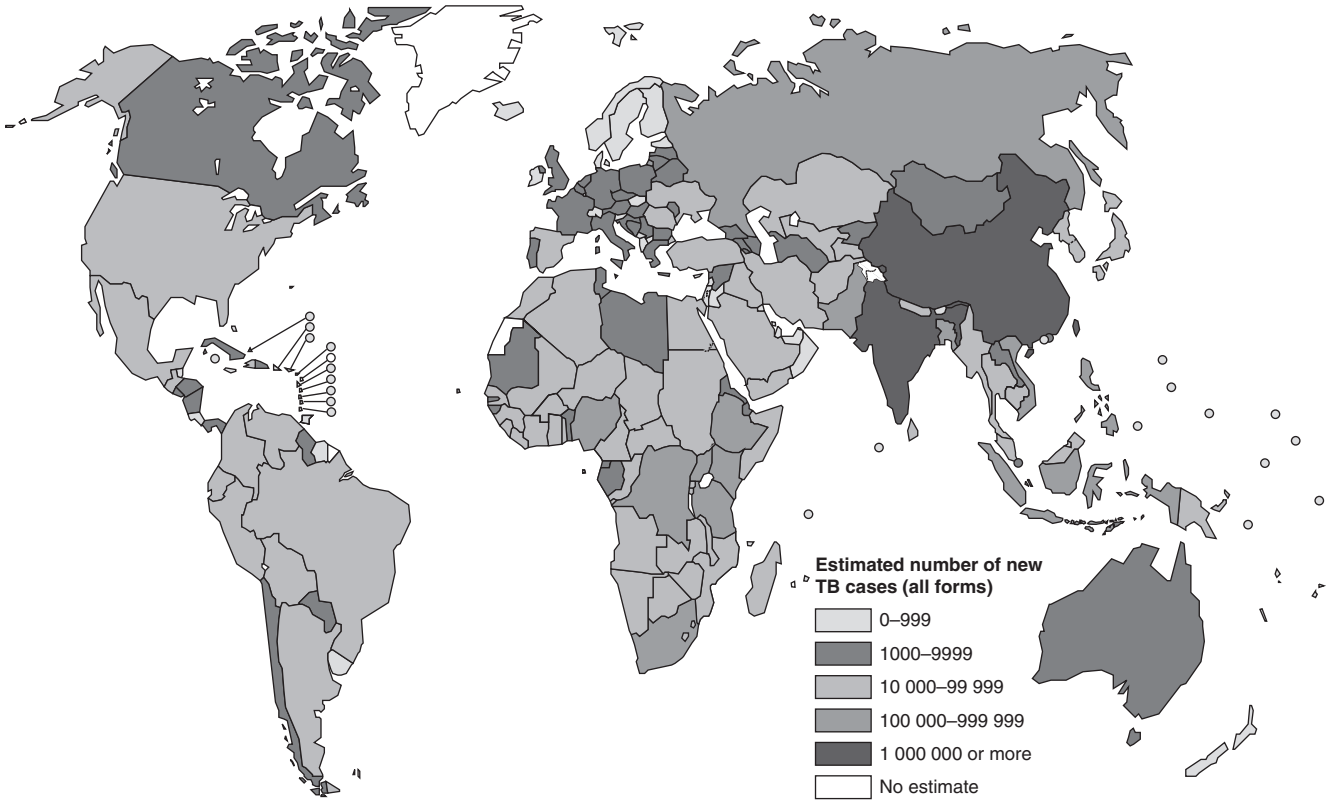

FIGURE 60.1 Estimated TB incidence rates, 2005. Reproduced with permission from the 2007 WHO report, Global Tuberculosis Control: Surveillance, Planning, Financing.

decades to develop and test. As illustrated in this chapter, TB is an extremely successful and robust pathogen for which several vaccine attempts have failed. However, if an effective vaccine can be developed, it could have a substantial impact on TB control, even if the efficacy is limited to delaying disease outbreak and transmission. In particular, vaccines that could be administered against a background of BCG immunization and/or preexisting *Mycobacterium tuberculosis* (Mtb) infection ("postinfection" vaccines) stand to have the greatest and most immediate impact (Nacy and Sacksteder, 2002; Young and Stewart, 2002).

SHORT HISTORY OF THE DISEASE

Paleomicrobiologists date the earliest evidence of TB back to the Pleistocene epoch, according to a study that detected the pathogen in 17,000-year-old bison remains (Rothschild et al., 2001). How and when TB became a human disease remains unclear, although evidence from Egyptian mummies from BC 2400 provides an estimate of the latest point it reached humans (Zink et al., 2003). Only in 1882 was the causative agent, Mtb, isolated by Robert Koch with the advice of Fanny Hesse, who recommended that he cultured bacteria in agar instead of a gelatin-based medium. Isolation of Mtb heralded the beginning of the fight against TB, which still continues today. Vaccine and drug approaches, intensely pursued over the years, have yielded products for disease prevention or treatment. Most notably, the BCG vaccine, developed in the early 1900s, has provided billions of people worldwide with protection from childhood TB, meningeal TB, and leprosy. Because BCG does not adequately protect against adult pulmonary TB, efforts to develop a better vaccine continue. The emergence of MDR TB and the increased risk of TB in persons coinfected with HIV have raised awareness of the importance of TB vaccine development.

ETIOLOGIC AGENT

Classification

Mtb is the causative agent of TB. It is a facultative intracellular, nonmotile, non-sporulating, and rod-shaped

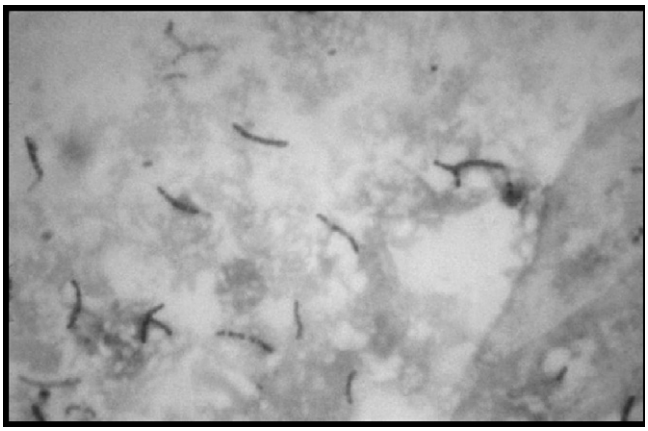

FIGURE 60.2 This photomicrograph reveals Mtb bacteria using acid-fast Ziehl–Neelsen stain; magnified 1000× . The acid-fast stains depend on the ability of mycobacteria to retain dye when treated with mineral acid or an acid–alcohol solution, such as the Ziehl–Neelsen or the Kinyoun stains that are carbolfuchsin methods specific for Mtb. *Source*: phil.cdc.gov CDC-PHIL ID #5789; Date: created 1979; *Author*: CDC/Dr. George P. Kubica. bacterium (Fig. 60.2). Interestingly, this obligate aerobe is neither classified as gram-positive nor gram-negative as its cell wall structure, being rich in mycolic acids and lipids, is atypical of either class (Prescott et al., 1996). *Mycobacterium* is a member of the Mycobacteriaceae family in the Actinobacteria phylum. It is classified into several major groups for diagnosis and treatment. Members of the Mtb complex that can cause TB include *M. tuberculosis*, *M. bovis*, *Mycobacterium africanum*, and *Mycobacterium microti*. Nontuberculous mycobacteria (NTM) can cause pulmonary disease resembling TB, lymphadenitis, skin disease, or disseminated disease. *Mycobacterium leprae* causes Hansen's disease or leprosy. *Mycobacterium avium* complex is a group of mycobacterial species that are a significant cause of death in patients who are immunocompromised. Species in this complex include *M. avium silvaticum*, *M. avium hominissuis*, and *M. avium*. *M. avium paratuberculosis* has been implicated in Crohn's disease in humans and Johne's disease in sheep.

Antigens

Sequencing and annotation is complete for Mtb H37Rv and Mtb CDC1551 as well as for closely related mycobacteria, including *M. bovis*, *M. leprae*, and *M. avium*. Mtb H37Rv encodes 3995 proteins of which 2058 (52%) have functional annotations based on sequence homology and 376 putative proteins that may be unique to Mtb (Camus et al., 2002). The CDC1551 genome contains 4189 protein-coding genes of which 2235 (53%) have a matching database entry (Fleischmann et al., 2002). A complete genome comparison between H37Rv and CDC1551 has identified polymorphic sequences related to pathogenesis and immunity (Fleischmann et al., 2002).

Antigens that are secreted by Mtb have been the focus of several TB vaccine development efforts since these antigens have been shown to induce potent immune responses in humans (Andersen, 1994, 1997; Boesen et al., 1995; Horwitz et al., 2000). Additionally, some studies have shown that responses to secreted TB antigens have been greater than to those antigens of cytosolic origin (Mustafa et al., 1998). Secreted antigens have been shown to elicit significant protection (in animal models), equal in magnitude to BCG, while also priming responses to a wider range of the antigens than BCG does (Andersen, 1994; Boesen et al., 1995; Demissie et al., 1999; Sonnenberg and Belisle 1997). Despite the evidence that these proteins are involved in protection, no single protein or group of proteins has yet been shown to protect against the development of active TB infection. When considering that there are more than 3000 open reading frames in the average mycobacterial genome, it becomes clear that much remains to be done to discover proteins that might contribute to vaccine development. Many of the proteins being considered for vaccine development are summarized in Table 60.1.

Young et al. (1985) have successfully made expression libraries of TB proteins and identified antigens that are reactogenic with serum and/or peripheral blood mononuclear cells (PBMC) from animals and humans exposed to TB. Several of the antigens have been epitope mapped, using overlapping peptides, and while many of these antigen-derived peptides have been confirmed as epitopes, some such epitopes have been confirmed as being immunodominant (Mustafa, 1994, 1995).

Yet another approach to antigen discovery for TB vaccines has been to emphasize Mtb-unique proteins that are upregulated during the growth of Mtb under stress conditions. Mtb thrives in the most oxygenated parts of the body and, when reactivated, preferentially establishes infection in the upper lobes of the lungs (Adler and Rose, 1996). During infection, Mtb bacilli are inhaled and then phagocytosed by alveolar macrophages. Before the host macrophages become immunologically active, Mtb blocks the development of a phagosome into a phagolysosome and establishes long-term residence (Russell, 2001). In order to survive under the hypoxic conditions of

TABLE 60.1 Selected antigens under consideration for TB vaccine development

	Description	Relevant literature	Vaccines in development	Developers
Ag85A and 85B	These *Mycobacterium tuberculosis* proteins were among the first to be defined and elicit responses in healthy individuals who are exposed to *M. tuberculosis*. However, the BCG vaccine already expresses these proteins, as do all environmental mycobacteria, so the relevance of these proteins for boosting responses in developing countries is under evaluation.	Goonetilleke et al., 2003; McShane et al., 2004; Horwitz and Harth, 2003	Modified vaccinia virus Ankara that expresses antigen 85: this might be given to individuals who have already been vaccinated with BCG in infancy to boost both CD4+ and cytotoxic CD8+ T cell responses. Recombinant BCG that over-expresses antigen 85B: this aims to boost responses to antigen 85 to a greater extent than BCG usually does.	85A: University of Oxford with funding from the Wellcome Trust and the European Commission 85B: Marcus Horwitz and Aeras Vaccine Foundation
ESAT-6	ESAT-6 is one of the low-molecular-weight proteins that is unique to Mtb. For that reason, it appears to be a critical antigen for protective immune response, but the use in vaccines is controversial as the protein is now used in special Mtb-specific diagnostic tests.	Skjot et al., 2000; Okkels et al., 2003	Fusion protein of early secretory antigenic target 6 (ESAT-6) and antigen 85B: this aims to prime or boost the interferon response to these proteins, which are immunogenic antigens that are secreted by *M. tuberculosis*.	Peter Anderson, Statens Serum Institute, Intercell and Aeras
TB10.4	ESAT-6 homologue, low-molecular-weight protein of Mtb	Dietrich et al., 2005; Skjot et al., 2002	Included in perfringen vaccine as described by Sadoff (2005)	Aeras
Mtb32 and 39 and recombinant fusion protein Mtb72F	These are immunogenic proteins from *M. tuberculosis* that are recognized by T cells from infants who have been vaccinated with BCG and from healthy individuals who live in regions in which tuberculosis (TB) is endemic.	Skeiky et al., 2004 Alderson et al., 2000	Mtb72F is a 72-kDa polyprotein that consists of Mtb32 and Mtb39.	Steve Reed, GlaxoSmithKline and Aeras
Mtb19	The 19-kDa antigen is a cell wall-associated lipoprotein present in *M. tuberculosis* and in BCG vaccine strains. The 19-kDa protein has a detrimental effect on the efficacy of vaccination with live mycobacteria.	Yeremeev et al., 2000	Targeted elimination of the 19-kDa gene (by RNAi) is one consideration for live Mtb vaccines.	No known vaccines in development
CFP-10	10-kDa culture filtrate protein	Mustafa et al., 2002	Focus has been placed on CFP-10 for diagnostic purposes.	No known vaccines in development
HSP 65	HSPs are important target antigens and have poorly understood immunoregulatory properties.	Johansen et al., 2006	DNA vaccine that encodes HSP65: this induces CD4+ and CD8+ T-cell responses, and it downregulates Th2 cell responses in animal models of TB78.	Doug Lowrie
16-kDa alpha crystallin	Sherman et al., 2001	Agrewala and Wilkinson, 1998		Ken Huygen
Mtb39a-e	These antigens were found primarily in the cell lysate with low levels detected in the culture filtrate.	Dillon et al., 1999.		No known vaccines in development
Mtb9.9				
LppX	LppX is a lipoprotein required for the translocation of phthiocerol dimycocerosates to the surface of *M. tuberculosis*.	Lefevre et al., 2000	Sheep immunized with the recombinant LppX of paratuberculosis analog mounted cellular and humoral responses.	No known human vaccines in development
MPT64	The MPT64 protein and its homologues form a highly conserved family of secreted proteins with unknown function that are found within the pathogenic Mtb genus.	Bhigjee et al., 2007; Cai et al., 2005	Focus has been more recently placed on MPT64 for diagnostic purposes, although it is still being investigated as a vaccine in animal models.	No known human vaccines in development

the macrophage phagosome, Mtb alters its metabolism and gene expression to reflect the conditions of the organelle (Schnappinger et al., 2003). Culturing Mtb under hypoxic conditions is one way to mimic the metabolic state of latent TB infection (LTBI) such that RNA can be isolated and used to generate cDNA probes for microarray analysis (Sherman et al., 2001). Proteins that upregulated under these conditions may be important for effective containment of the LTBI.

PROTECTIVE IMMUNE RESPONSE

Antibody

The role of antibody in the protection against TB is still under study. A recent study by Chambers et al. (2004) showed that the monoclonal antibody MBS43 (IgG2b isotype) to MPB83 protected mice against both high- and low-dose challenge with *M. bovis*. Other studies have shown that passive transfer of antibodies in animal models does not confer protection against Mtb (Dunlap and Briles, 1993). There is a correlation between specific antibody profiles and TB state in humans. In one study, antibody levels to six Mtb antigens were evaluated in serum derived from human subjects grouped into four diagnostic categories: active disease, inactive (past) TB, latent infection without radiographic chest abnormalities, and infection free (Davidow et al., 2005). Statistical data analyses showed that the latter two groups were serologically indistinguishable and active TB and inactive TB were characterized by different antibody profiles. Antibodies to the 38-kDa antigen, alanine dehydrogenase, and Rv2626c were associated with active TB, while antibodies to the 16-kDa antigen, ferredoxin A, and ESAT-6 were associated with inactive TB. This finding has been disputed more recently in studies performed in populations living in TB-endemic regions of the world (Hoff et al., 2007).

Some of the disparities among studies may be due to chronological differences in the expression of the protein antigens. Bacterial transcription profiling has been used to explore the correlation between antigen production and infection stage in human macrophages (Cappelli et al., 2006). Whether these fluctuations in antigen presentation might influence immune response, and thereby need to be considered in vaccine development, is unknown.

CMI

In contrast with antibody response, adoptive transfer of T cells does confer protection from TB in the mouse model (Lefford, 1975). In humans, induction of broad T-cell-mediated immunity to Mtb requires the involvement of type 1 cytokines: interleukin (IL)-2, interferon (IFN)-gamma, and tumor necrosis factor (TNF)-alpha (Kaufmann and Hess, 1999). In addition, it is clear that CD4+ T cells are involved: The rate of TB reactivation in HIV-infected individuals is inversely correlated with the number of circulating CD4+ T cells (Shen et al., 2001). It is believed that this is due to the gradual depletion of T cell clones specific for the coinfecting pathogen, which in turn is due to HIV-mediated destruction of activated T cell clones (Hirsch et al., 2001; Kovacs et al., 2001; Lawn et al., 2001; Moriuchi et al., 2000). By extension, activation of immune response increases susceptibility to HIV (Garrait et al., 1997). Based on the level of immune compromise at which TB begins to develop relatively early in HIV infection, CD4+ T cells are likely to be the critical component of cell-mediated immunity to LTBI. Importantly, T-helper-1 (Th1)-mediated immune responses have been demonstrated in mouse protection studies as well (Cooper et al., 1993; Flynn et al., 1993; Scanga et al., 2000). Some studies have shown that high levels of antigen-specific IFN-gamma production are found in subjects with active minimal disease as compared with lower levels in subjects with advanced disease (Boesen et al., 1995; Sodhi et al., 1997). Similarly, as compared with active TB patients, household contacts of these patients were shown to have greater reactivity to the antigen 85 (Ag85) complex (Torres et al., 1998). However, these studies do not establish a causal link between IFN-gamma production levels and progression to active disease. Levels of TB-specific IFN-gamma production vary considerably between those in the periphery and those at the site of disease (Barnes et al., 1993).

IFN-gamma plays a role in activating specific macrophages and increasing natural killer (NK) cell activity, both of which are host protective. Th1-biased T cell responses to Mtb epitopes not contained in BCG may help control immune response in latently infected individuals. While Th1 cytokines are essential for protection, their levels of production do not alone explain the immunity–susceptibility dichotomy. The spatial and temporal complexity of the TB granuloma has a significant bearing on the nature and effectiveness of the cytokine response. The dynamics of granuloma formation and maintenance are reviewed in Russell (2007).

CD8+ T cells also play a significant role in TB immunity (Serbina and Flynn 2001; Serbina et al., 2001). Importantly, studies of human CD8+ -restricted responses to Mtb antigens have revealed that these cells play an important role in the control of Mtb replication in the alveolar macrophage (Canaday et al., 2001;

Lewinsohn et al., 2007). Indeed, CD8+ T cells specific for Mtb antigens were derived from peripheral blood samples obtained from Mtb-immune donors (Cho et al., 2000). CD8+ T cells may play an important role in the clearance of Mtb as alveolar macrophages have been shown to be effective targets of CD8+ T cells (Tan et al., 1997). Ag85A-specific CD8+ T cell responses have also been identified in patients who have active pulmonary TB (Weichold et al., 2007). Taken together, these data suggest that stimulation of Th1-biased and CD8+ T cell responses to Mtb epitopes may control immune responses in latently infected individuals.

Tregs

Recently, several authors have proposed that the immune responses to latent and active TB also involve regulatory T cells (Guerkov et al., 2003; Boussiotis et al., 2000). T regulatory cells (Tregs) express both CD4+ and CD25+ on their cell surfaces, express the regulatory T-cell-associated transcription factor forkhead box P3 (FOXP3), and produce Th1 suppressive cytokines, such as IL-10 and TGF-beta (Bluestone and Abbas, 2003). $CD4^{+}CD25^{high}FOXP3^{+}$ T cells have been shown to be elevated in peripheral blood of individuals diagnosed with active TB disease in comparison with uninfected control subjects or LTBI individuals (Guyot-Revol et al., 2006; Hougardy et al., 2007). Ex vivo depletion of Tregs from peripheral blood of active TB patients, but not LTBI subjects, increases Mtb antigen-specific IFN-gamma responses (Guyot-Revol et al., 2006; Hougardy et al., 2007; Ribeiro-Rodrigues et al., 2006). This regulatory phenotype is also expressed on the cytokine level as the Th1 suppressive cytokines IL-10 and TGF-beta suppress T cell responses in active TB patients (Boussiotis et al., 2000; Hirsch et al., 1996). A large population-based study in Ethiopia found that TB patients have decreased levels of Th1 cytokines and increased levels of IL-10, when compared with healthy infected and noninfected controls (Demissie et al., 2004). While active TB and LTBI exhibit different regulatory T cell responses, it has not yet been determined if this difference is the cause, or result, of disease.

Regulatory T cells may also explain anergy in patients with TB who respond negatively to a skin test with tuberculin (an Mtb-derived antigen) and whose T cells secrete the regulatory cytokine IL-10 but release little IL-2 or IFN-gamma in response to Mtb (Delgado et al., 2002). Some T cells that secrete IFN-gamma in the lungs of patients with TB also secrete IL-10 (Gerosa et al., 1999), which indicates that they may be regulatory T cells, instead of true Th1 cells.

These data corroborate similar observations made in murine studies. Transgenic mice that overexpress IL-10 show evidence of reactivation of chronic TB with a significant increase in bacterial numbers in the lungs (Turner et al., 2002). Studies using FOXP3-GFP (green fluorescent protein) mice illustrate that Tregs suppress immune responses and contribute to higher bacterial burden upon aerosol Mtb challenge (Scott-Browne et al., 2007). These findings underline the need to improve the Th1, effector T cell bias of TB vaccines and suggest that LTBI vaccine candidates will need to overcome a Th2 and regulatory T cell bias that may occur by coinfection with other pathogenic organisms, such as roundworms (Rook and Zumla, 2001), which are factors common in areas where a TB vaccine is most needed. Complicating the situation, however, is the role that Tregs play in limiting immunopathological damage. Host suppressor mechanisms that maintain immune homeostasis may qualify Tregs as friend, not only foe (Mills, 2004). For example, in early stages of Mtb infection, IL-10 also enhances the function of NK cells, leading to increased antigen availability through pathogen destruction (Mocellin et al., 2003).

EPIDEMIOLOGY

Significance as Public Health Problem

During the 1980s and the 1990s, TB reemerged in the developed world as a result of TB/HIV coinfection (Daley et al., 1992), but recent efforts to address this problem have decreased the level of TB transmission in the Americas and Europe (WHO, 2007). Despite the decline in TB case rates in the United States, recommendations to test all TB patients for HIV infection are followed in less than 30% of cases (CDC, 2007a, 2007b, 2007c). For similar reasons, TB remains a significant burden and major contributor to morbidity in developing countries located in sub-Saharan Africa and the former Soviet Union.

TB is the 10th leading contributor to the global burden of disease, measured as a function of disability-adjusted life years (DALYs) (Lopez et al., 2006). TB accounts for the loss of 34.5 million DALYs, or 2.5% of total losses in low- and middle-income countries. In sub-Saharan Africa, which is highly dependent on manual labor, the impact is even greater—it is the eighth leading cause of DALY losses, representing 10 million or 2.7% of its total. As a result of the structural inequalities between developed and developing nations, TB remains one of the leading causes of preventable death throughout the underdeveloped world.

Directly observed treatment, short-course (DOTS) was invented to address the problem of adherence to therapy. Due to delayed diagnosis of active TB cases, relapse rates as high as 5% after DOTS, and the inherent difficulty in compliance with the long DOTS regimen, DOTS alone is not expected to eradicate TB (Dye et al., 1999; WHO, 2000).

The task of TB control is further complicated by the HIV epidemic and the emergence of drug-resistant TB strains (Wells et al., 2007). HIV coinfection accelerates the rate of conversion to active TB: LTBI individuals who are also HIV-infected have an estimated 7–10% chance of developing TB within 1 year (Selwyn et al., 1989), compared to within a lifetime for counterparts not infected with HIV. Thus TB is currently the leading cause of death from AIDS (Raviglione et al., 1997; Alban and Andersen, 2007). As the global epidemic of HIV continues to expand into countries with high rates of TB, more active TB cases can be expected (Sepkowitz, 2001).

Both suboptimal TB care and poor patient compliance with the treatment regimen can result in the emergence of MDR TB. The WHO is now reporting that resistance to first-line anti-TB medications (including those in the DOTS regimen) was already as high as 40% in some countries in the late 1990s (Pablos-Mendez et al., 1998). In fact, resistance to isoniazid (INH), the first-line drug against Mtb, is nearly 100% in parts of Russia and Eastern Europe (Andersen, 2001). Unfortunately, due to the emergence of MDR TB, it is likely that many of the individuals who have latent Mtb infection in those regions of the world have MDR LTBI. As a consequence of the continuing expansion of the MDR TB and the HIV pandemics, the development of an effective TB vaccine has become a matter of increasing urgency.

XDR TB

The worldwide emergence of XDR TB and a provisional definition for this form of TB were first reported in 2005. In October 2006, the WHO convened an Emergency Global Task Force on XDR TB, which revised the case definition to specify resistance to at least INH and rifampin among first-line anti-TB drugs, any fluoroquinolone, and at least a second-line injectable drug (amikacin, capreomycin, or kanamycin). During 1993–2006, a total of 49 cases in the United States (3% of evaluative MDR TB cases) met the revised case definition for XDR TB. Seventeen (35%) were reported during 2000–2006, and a trend toward more frequent reporting of XDR TB in foreign-born individuals was also noted (CDC, 2007b). XDR TB presents a challenge to TB control activities worldwide. To prevent the spread of XDR TB, renewed vigilance is needed in drug-susceptibility testing, case reporting, specialized care, infection control, and expanded capacity for outbreak detection and response.

Potential as Biothreat Agent

MDR TB is classified by the National Institute of Allergy and Infectious Diseases as a Category C priority pathogen (NIH, 2007). As a third-tier biothreat, it is recognized as an emerging pathogen that may be widely disseminated because of its accessibility, ease of production, and dispersal and likelihood of high morbidity and mortality rates (CDC, 2007). Fortunately, the bacillus is sensitive to radiation (such as that contained in sunlight) and thus not likely to survive a dissemination attempt by large-scale aerosolization. Nonetheless, XDR TB and MDR TB both have greater potential to have a negative impact on the populations of developing and Eastern European countries; therefore, TB detection, treatment, and vaccine development should remain high priorities for the defense of public health.

CLINICAL DISEASE

Diagnosis

Active TB

Chronic cough, hemoptysis, and wasting are all symptoms of active pulmonary TB. A positive diagnosis is made using sputum smear and culture for AFB. Extrapulmonary TB is rare (less than 10% of TB cases) but most common in children and immunocompromised individuals. The presence of AFB can also be detected in urine, pleural fluid, and cerebrospinal fluid.

LTBI

In the absence of active, ongoing disease, the diagnosis of LTBI is usually based on a positive skin test and the absence of ongoing TB disease. The tuberculin skin test (TST) remains the cornerstone of LTBI diagnosis—especially in countries where the test result is not complicated by prior BCG vaccination. New laboratory diagnostics, such as the enzyme-linked immunosorbent spot (ELISpot), have been developed and may be better at discriminating between prior BCG vaccination and TB infection

as they include antigens that are present in Mtb but not BCG (Johnson et al., 1999). Individuals who have received BCG vaccine are still considered to have LTBI if their TST is positive (>10 mm). If the TST or ELISpot is positive, a chest radiograph is performed to evaluate the presence of pulmonary lesions. If lesions or other suspicious aspects are detected, the clinician should perform a sputum examination for AFB and culture the sputum for Mtb.

Treatment of TB Disease

The American Thoracic Society, Infectious Diseases Society of America, and Centers for Disease Control and Prevention issued updated guidelines for the treatment of TB (CDC, 2003). The most recent TB treatment guidelines provide a complete discussion of the drugs currently available to treat TB, including dosing, dose adjustments needed for renal or hepatic dysfunction, toxicities, management of common adverse effects, and information about interactions between anti-TB drugs and other drugs. Since one of the key anti-TB agents, rifamycin (rifampin, rifampicin (RIF), has the potential for drug–drug interactions, including some antiretroviral medications, special attention must be given to the treatment of the patient who has coinfection with HIV and Mtb.

DOTS

DOTS programs focus on increasing patient adherence, the primary determinant in treatment success rates. DOTS is currently the WHO-recommended strategy for TB control. DOTS involves treatment with a four-drug regimen [INH, RIF, pyrazinamide (PZA), and ethambutol (EMB)] for 6–9 months. DOTS must be used throughout the entire course of therapy for best cure rates. The core intervention involves a health worker who observes the patient when s/he is swallowing each dose of anti-TB medication. DOTS also involves the regular collection of sputum specimens until two consecutive samples test negative for AFB. Although DOTS is labor intensive, the standardized first-line regimen costs only around $10 per patient and is associated with a 90% cure rate in the absence of drug-resistant strains. Up to 89% of countries, both developed and developing, had implemented DOTS by the end of 2006. However, since case detection rate is as low as 50% in some countries, and completion rates for those cases of TB that are detected also remain low, at a rate of approximately 75% (2004), the implementation of DOTS remains at best in progress in most developing countries.

Treatment of LTBI

The preferred treatment for LTBI is 9 months of INH taken either daily or biweekly. Without DOTS, the cure rate of the biweekly regimen is worse than that of the daily regimen since a missed dose in intermittent treatment constitutes a greater percentage of total doses. Because the levels of primary INH resistance are on the rise, and because of a 0.3% rate of INH side effects, not all countries recommend treating LTBI in this way, if at all. In the United States, LTBI affects 10–15 million individuals, each with a 10% chance of progressing to TB disease without treatment; thus, in the 1950s, the U.S. Public Health Service (USPHS) Commissioned Corps began to recommend and financially support the treatment of LTBI with INH. Whether for TB disease or LTBI, cure rates are highest when treatment is administered by those experienced in the management of TB, or in consultation with someone with such experience. This is especially true for drug-resistant cases.

PATHOGENESIS

TB Disease Process

TB vaccine development has been hampered by our lack of understanding of the details of TB pathogenesis. Protective immunity against Mtb occurs since only 8–10% of Mtb-infected individuals go on to develop TB, following exposure. However, the set of host immune responses that determine effective protection against TB disease remain an enigma.

Mtb is spread in tiny aerosol droplets expelled by one person and taken up into the lung of another. Mtb finds its home in alveolar macrophages, where it prevents endosome maturation by inhibiting acidification through expression of UreC. Infected macrophages participate with other cells (see next section) in the formation of a granulomatous lesion that contains the bacteria together with host immune cells (Fig. 60.3). Surrounded by a fibrotic wall, the granuloma is a low-oxygen environment that forces Mtb to enter a reversible state of dormancy (Boshoff and Barry, 2005). Mtb respiration and metabolism are significantly diminished and growth stops. This state of dormancy, or latency from the perspective of the host, is the basis of a truce between host and pathogen where infection ensues without manifestation of clinical disease. Upon disruption of this fine balance, oxygen enters the lesion, leading to resuscitation, a molecular process of increasing metabolic and replicative activity and production of resuscitation

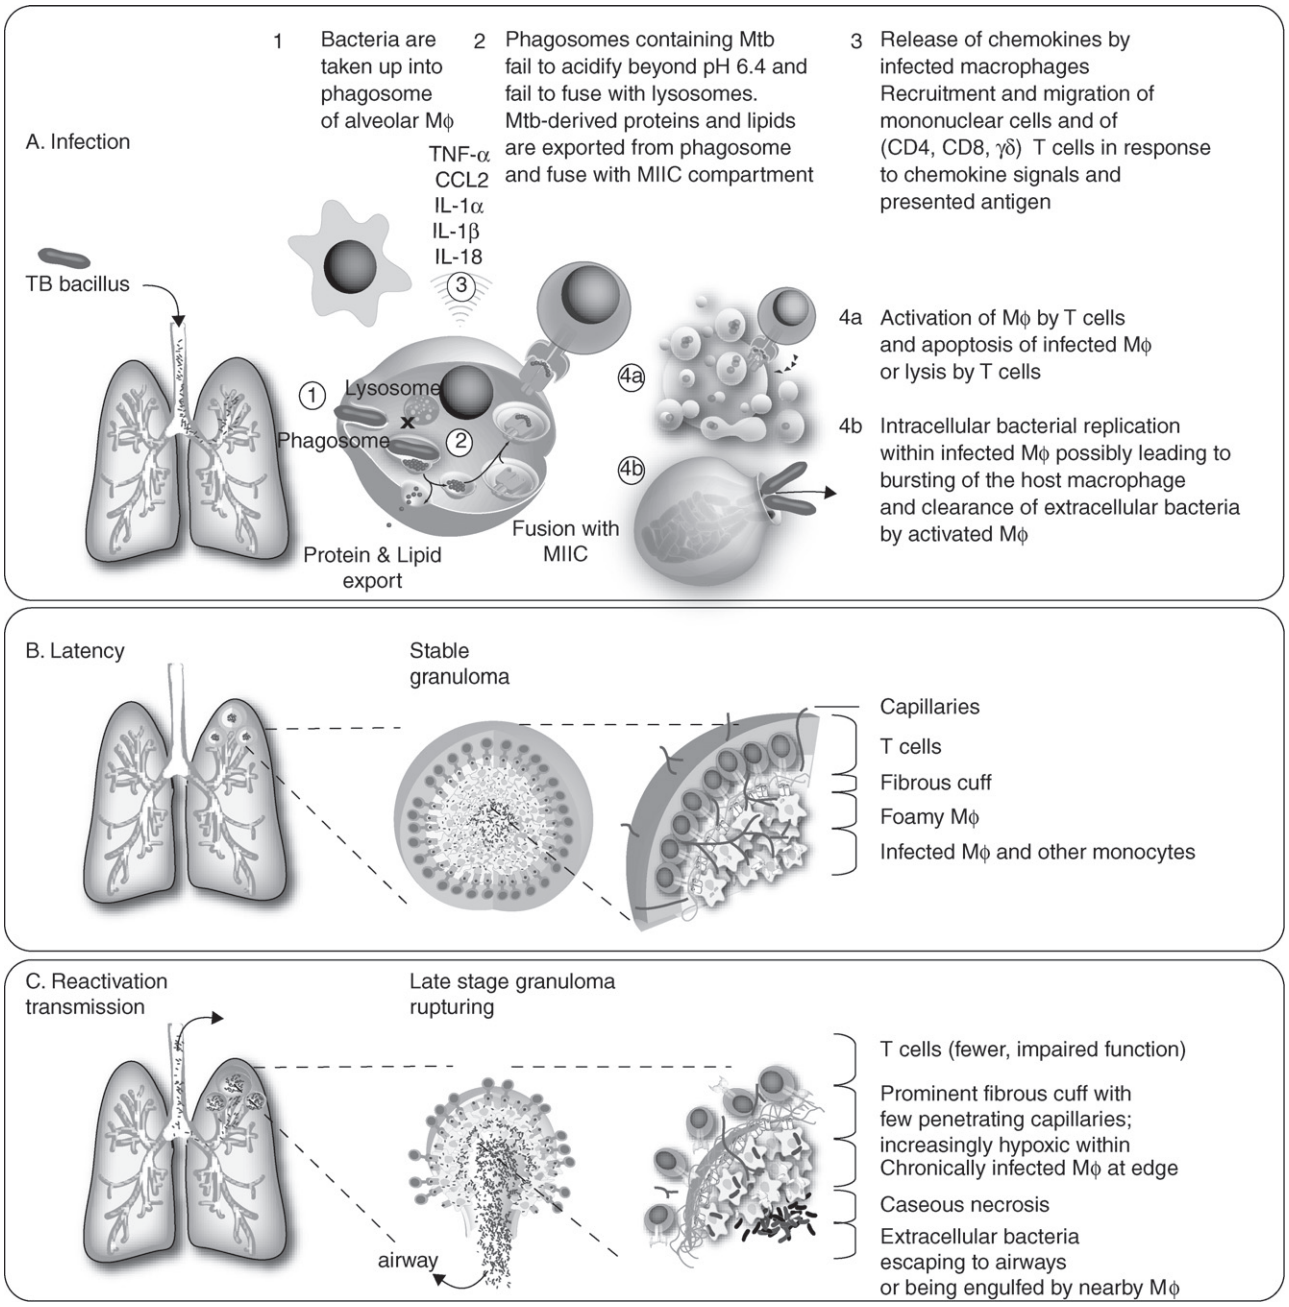

FIGURE 60.3 Pathogenesis of pulmonary tuberculosis. Infectious Mtb bacilli are inhaled into the lung where they are phagocytosed by alveolar macrophages. Mtb-containing phagosome fails to acidify beyond 6.4. Infected macrophages produce a localized proinflammatory response that leads to the recruitment of macrophages and other mononuclear phagocytes and T cells. The recruited T cells can cause infected macrophages to apoptose or lyse. Alternatively, bacterial replication inside the macrophage can lead to its bursting open. Extracellular bacteria are then engulfed by surrounding macrophages; together the recruited cells form a granuloma at the center of which are infected macrophages and foamy macrophages surrounded by a fibrous cuff and a layer of T cells. The stable granuloma walls off the bacteria, preventing them from causing outward manifestations of disease and from being transmitted to other hosts. In later stages, the granuloma develops a collagenous fibrous sheath through which few capillaries penetrate and consequently the outer boundary of these granulomas hypoxic. When the immune status of the host is impaired due to age, malnutrition or coinfection with HIV, the number or function of the patrolling T cells is compromised, resulting in the structural decay of the granuloma center into a caseous mass of cell debris. The failure of the granuloma leads to the development of a cough that propels the bacteria out through the airways.

promoting factors (Rpfs) (Downing et al., 2004, 2005). Rpfs send signals to neighboring dormant bacteria, enabling them to recover. It is thought that resuscitation may lead to reactivation where high bacterial burden can develop in lesions causing caseation and cavitation of the lung. Active disease ensues with lung tissue deterioration leading to weakened lung function and bacterial dissemination to other organs.

Immune Response to Infection

Mtb-infected cells migrate to nearby draining lymph nodes, where the host immune response is initiated. TB bacilli residing in the arrested phagosome shed antigens that are processed via the major histocompatibility complex (MHC) Class II antigen presentation pathway (Russell, 2007), leading to a predominantly CD4+ Th1-type response. IFN-gamma and TNF-alpha are cytokines associated with this response that leads to formation of the granuloma to contain Mtb. Granuloma formation is a complex process involving recruitment of CD4+ T cells, CD8+ T cells, and CD1-restricted $\alpha\beta$ T cells. The CD8+ T cell response arises from cross-priming on MHC Class I molecules via Mtb antigens that are released from apoptosed infected macrophages and taken up by dendritic cells.

As described above, both effector and memory Th1 cells develop in response to antigens expressed early in infection. Memory cells against early antigens may persist during latency and prevent reactivation but may not be able to contain dormant Mtb, which expresses a differential set of antigens that are controlled by *DosR* genes (Voskuil et al., 2003; Sherman et al., 2001; Schnappinger et al., 2003). Indeed, non-Th1 (Th2 and regulatory) cytokine levels are elevated in patients in advanced stages of disease (van Rie et al., 1999; Rook et al., 2004,), which suggests that the T cell response may be refocused from Th1 to Th2 or suppressed by Tregs in the course of reactivation. This idea is supported by the finding that IL-10-overexpressing mice have a higher bacterial burden in later stages of infection (Turner et al., 2002). Much remains to be learned about the host immune response to Mtb infection.

VACCINES

History

Prophylactic Vaccines

BCG, the live attenuated vaccine for TB developed by Albert Calmette and Camille Guérin between 1908 and 1921 remains the most widely distributed vaccine in use in the world today. It is estimated that 76% of children born in 2002 received (BCG) vaccination, recommended by the WHO because it confers protection against childhood TB (Trunz et al., 2006) and leprosy (Sterne et al., 1996). Despite this wide coverage, BCG's efficacy is highly variable, ranging from 0% to 80% against adult pulmonary TB (Colditz et al., 1994). The suboptimal efficacy of BCG occurs for a number of possible reasons, including waning efficacy over time, differences between BCG sub-strains (Wu et al., 2007), deletion of protective antigens found in Mtb, and failure of BCG to stimulate adequate balanced CD4+ and CD8+ T cell responses.

A number of different approaches to developing novel TB vaccines are being actively pursued. In the next section, we will review prophylactic vaccination (live vaccines such as augmented BCG, live attenuated Mtb, and subunit) and then focus on "therapeutic vaccination" approaches.

Currently Licensed Vaccines

The only currently licensed TB vaccine is BCG. There are a number of BCG strains (BCG "Pasteur," BCG "Copenhagen," etc.), each of which was attenuated from an original BCG strain through serial passage. The strains used in BCG are well known to be divergent from the original strain developed at the Pasteur Institute. As a result of years of passage in geographically distant laboratories, the following vaccine strains are now recognized: BCG Russia/Moreau/Japan; BCG Sweden/Birkhaug; BCG Glaxo/Danish (passage 1331)/Merieux (passage 1077)/Prague; BCG Pasteur (passage 1173)/Tice/Frappier/Connaught/Phipps (Brosch et al., 2007) (Fig. 60.4).

Vaccine Recommendations, Including Potential to Administer with Other Vaccines

BCG is given as a single intradermal injection in the deltoid. It is rarely given to adults, and in fact, BCG is not used in the United States, except for therapy of certain cancers (bladder cancer, for example). In the developing world, BCG is given to newborns; vaccination coverage is approximately 80%. In Europe, 10 countries recommend BCG for children under 12 months, five countries give the vaccine to older children, and 10 countries give the vaccine to children considered to be at increased risk (due to the country of origin, close contact, or travel). Seven countries do not recommend the use of BCG as a routine vaccination. Revaccination is given to children in four

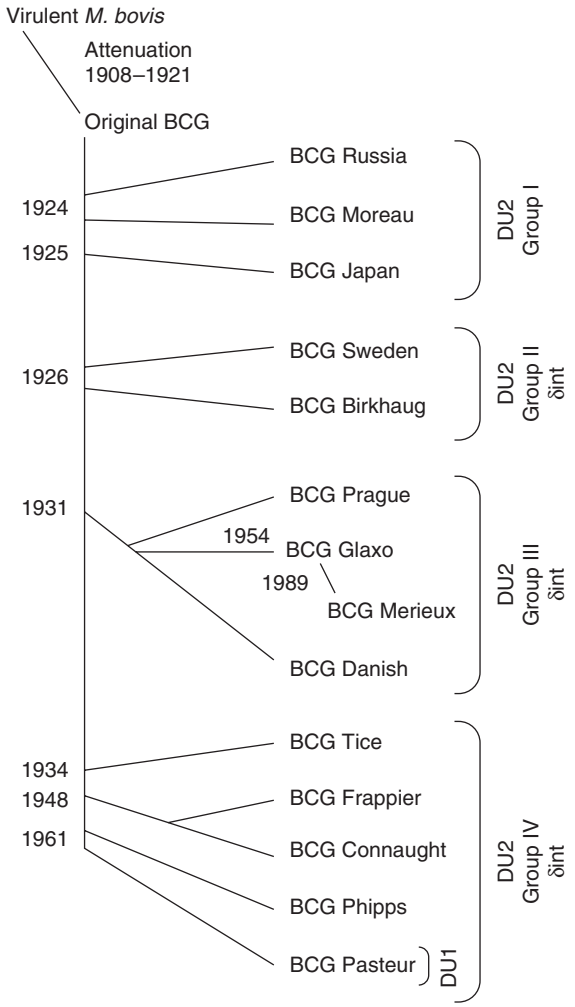

FIGURE 60.4 Genealogy of BCG vaccines. Repeated passages of virulent *M. bovis* gave rise to the live attenuated BCG vaccine in the early 1920s. BCG was circulated to multiple laboratories where daughter strains with differing genomes were produced by further passage over the years. BCG vaccines are distributed into four major groups according to their major genomic polymorphisms, tandem duplications (DU), and internal deletions (Dint). Adapted from Brosch et al. (2007).

countries. Where BCG is provided as part of universal vaccination, BCG coverage is very high (83–99.8%). Despite vaccination, TB has been observed in vaccinated children, and due to the lack of efficacy and the potential for side effects (see below), nearly half the countries in Europe were considering revisions of their vaccine policies in 2005 (Infuso and Falzon, 2006).

Countries where Vaccine is Licensed, Including Manufacturers

BCG has near universal licensure and is produced by 40 or more manufacturers around the world. The major commercial producers include Pasteur Merieux Connaught, Evans-Medeva, and Japan BCG Laboratory (WHO, 1999). As noted above, not all BCG vaccine strains are identical.

Indications for Vaccination/Target Populations

Despite the fact that BCG is one the most widely implemented vaccines, the mechanism of action of this vaccine is not well understood, and different strains of BCG have demonstrated wide-ranging degrees of efficacy in studies carried out in different regions of the world (from 0% protective efficacy to greater than 80%). Some of the countries in which protective efficacy is low or lacking choose not to administer BCG at all. Where BCG is administered, age at vaccination varies from at birth to 15 years of age, depending on the country.

Duration of Immunity

Duration of immunity afforded by BCG is not well characterized. Studies that show a protective effect of BCG indicate that immunity lasts 10–20 years (Sterne et al., 1998). Interestingly, a retrospective study of BCG vaccines found a sex difference in waning vaccine efficacy with a decline for men but not women (Aronson et al., 2004). While this finding corroborates data from a herpes simplex virus type 2 vaccine study (Stanberry et al., 2002), it remains to be confirmed in a future, prospective BCG study that is designed to address this hypothesis.

Contraindications of Vaccination, Including Special Risk Groups

BCG is contraindicated for immunocompromised individuals since the vaccine can cause disseminated infection in these individuals (WHO, 2007b). Despite widespread knowledge about the potential effects of BCG in immunocompromised individuals, this recommendation was only recently extended to HIV-infected children who have received the bulk of BCG vaccination since the beginning of the HIV epidemic. The prevalence of BCG disease that develops in HIV-infected infants who have received BCG is yet to be determined, although recent reports are alarming: One study concluded that the risk of disseminated BCG disease is increased several hundred-fold in HIV-infected infants compared to the documented risk in HIV-uninfected infants (Hesseling et al., 2007). Population- and hospital-based surveillance will be

required to accurately estimate morbidity and mortality associated with BCG vaccination in HIV-exposed and infected infants.

Adverse Events

BCG has an excellent safety record when properly administered to healthy persons, although BCG can cause pain and scarring at the site of injection in healthy individuals. If BCG is delivered subcutaneously, it can cause skin infection that can spread to lymph nodes. It should also be noted that BCG should not be given to purified protein derivative (PPD) skin test-positive (LTBI) individuals. Skin testing is recommended prior to BCG vaccination because BCG can cause significant local inflammation that contraindicates its use for persons who are already skin test positive.

The Case for Further TB Vaccine Research and Development

INH treatment for LTBI provides an excellent yardstick against which the potential commercial success of an effective TB vaccine can be measured. In the United States alone, between 1954 and 1997, the use of anti-TB treatment reduced the number of newly diagnosed cases of active TB by 32%, the number of mortalities by 81%, the number of life years lost by 87%, and the cost of medical treatment by 76%. The total financial burden of illness over this time period (including the value of lost life years) was reduced from $894 billion to $128 billion in 1997 (Javitz and Ward, 2002). Thus, a TB vaccine that would prevent the progression of LTBI to active disease would reduce medical expenditures in the United States by approximately $250 million per year.

As already described, vaccines against TB can be divided into two types: vaccines to prevent primary TB infection and vaccines to prevent reactivation of latent TB disease. Vaccination to prevent primary TB infection would eliminate mycobacteria before they are able to take up residence in host macrophages, thereby eliminating the potential for the development of latency and eliminating the potential for later development of full-blown TB disease. Vaccination during LTBI would contain infection, preventing the multiplication of Mtb bacilli and the development of full-blown TB disease.

The ideal vaccine would be an effective vaccine to *prevent* TB infection. Such a vaccine would help reduce the global burden of TB. However, replacing BCG with a new TB vaccine is likely to be very difficult, for many of the reasons already stated—it has been shown to be protective in infants. Demonstrating superiority of a new vaccine over BCG will also be difficult since a Phase III prevention study comparing BCG to a new vaccine requires a time frame of 10–20 years.

On the other hand, an effective vaccine targeting LTBI would significantly reduce the global burden of TB and is predicted to be cost-effective (Dye, 2003; Aeras, 2007). Furthermore, it could also be used in the context of BCG pre-immunization since the goal of such a vaccine would be to "boost" preexisting immune responses. Performing Phase III trials with a dual-purpose vaccine in LTBI- or BCG-immunized adults would be simpler and pose less risk than performing large, prospective Phase III comparisons of BCG with a new preventative TB vaccine in children.

Which approach should be used when building a vaccine for TB? Clearly, the most relevant approach would be to stimulate immune responses that correlate with protective immune response in natural TB infection. Fortunately, a protective immune response to TB can indeed be generated (unlike the situation with HIV) since only 8–10% of Mtb-infected individuals go on to develop TB. Unfortunately, it is not perfectly clear what the critical components, or correlates, of immunity to TB might be.

Discovery/Basic Science

A variety of vaccine approaches are currently under exploration. These include attenuated live vaccines, subunit vaccines, vectored vaccines, and epitope-driven vaccines; each will be described in the following sections.

Attenuated Live Mtb Vaccines Attenuated live Mtb vaccines, produced by targeted inactivation of regulatory proteins, contain antigens that are otherwise missing in BCG without being virulent themselves. For example, inactivation of PhoP diminished Mtb virulence and elicited immune responses similar to parental Mtb (Soto et al., 2004). Auxotrophic Mtb mutants, such as the one produced by targeted deletion of the *panC*, *panD*, and *lysA* genes, are similarly live vaccines that are infective but replication deficient. The *panCpanDlysA* vaccine produced similar responses to the BCG vaccine (Sambandamurthy et al., 2005). A similar *panCpanD* mutant with deletion of the RD1 region, which is thought to be partly responsible for attenuation of BCG, also produced responses comparable to BCG (Sambandamurthy et al., 2006). A major drawback of the live TB vaccine approach is safety concerns about reverting mutations that may restore virulence.

Moreover, the delicate balance between sufficient attenuation and protective efficacy is difficult to strike.

Recombinant BCG Vaccines rBCGΔureC:Hly is a recombinant BCG that expresses listeriolysin and carries a urease deletion mutation. It is being developed by Vakzine Projekt Management GmbH under license from the Max Planck Society. This vaccine secretes listeriolysin to form pores in the endosome and enable escape of BCG into the cytoplasm of infected cells to induce CD4+ and CD8+ T cell responses. Urease is deleted to provide the optimal pH conditions for listeriolysin function. In preclinical studies, this vaccine induced increased efficacy compared with the parental BCG strain (Grode et al., 2005). The vaccine is currently under good manufacturing practice (GMP) production, and Phase I clinical trials are expected to begin in early 2008. A similar recombinant BCG vaccine that combines antigen overexpression and endosome escape approaches is under development by the Aeras Global TB Vaccine Foundation. Aeras-X03 overexpresses Mtb antigens Ag85A, Ag85B, Rv3407, and TB10.4. To enable endosomal escape of Mtb antigens for induction of CD4+ and CD8+ T cells, this modified BCG expresses perfringolysin (similar to listeriolysin) and bears a urease deletion mutation (Skeiky and Sadoff, 2006). It is in late-stage preclinical development and expected to enter Phase I clinical trials in 2008.

Bacterial Vectors Aeras-X05 is a bacteria-vectored oral vaccine under development by Aeras. Mtb antigens Ag85A, Ag85B, and Rv3407, encoded in *Shigella*-delivered double-stranded RNA nucleocapsids, induce high levels of CD8+ T cells. It is in late-stage preclinical development and scheduled for Phase I clinical trials in 2008.

Clinical Trials

Some newer approaches are currently in clinical trials. These include modified BCG vaccines, vectored vaccines, and subunit vaccines; they are described according to the phase of clinical trail in the next section.

Phase I

Viral-Vectored Vaccines Aeras and Crucell Holland B.V. developed Aeras-402, a viral-vectored TB vaccine that entered Phase I safety trials in the United States in 2006. The replication-incompetent adenovirus 35 vector carries genes for the expression of Mtb antigens Ag85A, Ag85B, and TB10.4 to induce IFN-gamma-producing CD4+ and CD8+ T cells. In preclinical studies, the vaccine exhibited protective T cell responses in two mouse strains with distinct MHC backgrounds. This result suggests that the Mtb antigens may encode sufficient numbers of protective T cell epitopes to provide broad coverage of heterogeneous MHC haplotypes in humans (Havenga et al., 2006; Radosevic et al., 2007).

Subunit Vaccines Two protein subunit vaccines are currently in Phase I clinical trials in the United States and Europe. In 2006, GlaxoSmithKline (GSK) and Aeras joined forces to begin a clinical trial of M72, a recombinant fusion of Mtb antigens Rv1196 and Rv0125. The vaccine is delivered with GSK proprietary adjuvant AS02. Like M72, HyVac4 is an adjuvant subunit vaccine. It was developed on the heels of Hybrid-1, a fusion molecule of the Ag85B and ESAT-6 antigens (Agger et al., 2006), which was abandoned because ESAT-6 had shown utility in diagnostic tests. HyVac4 is a recombinantly expressed fusion of Mtb antigens Ag85B and TB10.4 that is delivered in IC31, an Intercell proprietary adjuvant based on a cationic peptide $KLKL_5KLK$ and immunostimulatory oligodeoxynucleotide ODN1a. It was developed by the Statens Serum Institute, Intercell, and Aeras (Aeras-404) and entered Phase I clinical trials in 2007.

Phase II

The most advanced new TB vaccine in clinical trials is MVA85A, a viral-vectored vaccine developed by Adrian Hill and Helen McShane at the University of Oxford with funding from the Wellcome Trust and the European Commission. MVA85A, which is intended to be used as a BCG booster, is a modified vaccinia Ankara (MVA) virus that expresses Mtb antigen Ag85A (Chambers et al., 2004). MVA is an attenuated strain of vaccinia virus with a safety record established in humans during the smallpox eradication campaign. MVA85A completed Phase I in Gambia, South Africa, and the United Kingdom in BCG-naive and -vaccinated healthy adults. The vaccine was safe and generated high levels of antigen-specific IFN-gamma-secreting T cells in both patient groups (Dunlap and Briles, 1993). In Phase II, which began in July 2007 in Gambia, 471 HIV-negative 4-month-old babies will be evaluated for MVA85A-induced immune responses at various dosing levels as well as for interactions with other vaccinations, including those for diphtheria, pertussis, tetanus, and *Haemophilus influenzae* type b. In South Africa, the vaccine is being tested in HIV-infected adults.

Phase III

Although there are currently no new TB vaccines in Phase III clinical trials, the Working Group on New TB Vaccines under the Stop TB Partnership has set the target for licensure of a safe, effective vaccine available at reasonable cost by 2015.

New TB Vaccines in Development

A number of vaccines to prevent TB are under development although few of these vaccines are directed at the problem of LTBI. As no adequate animal model of TB exists, most TB vaccine research is performed in mice (who, unlike humans, do not develop cavitary TB lesions in their lungs) and in guinea pigs (who develop TB lesions that resemble human disease). Since animal models are poor predictors of TB vaccine efficacy, trial sites are being prepared in locations where TB is highly prevalent around the world.

Vaccines to Prevent Mtb Disease in the LTBI Host

Revaccinating subjects who have LTBI with BCG has never been considered to be a very effective means for preventing TB disease—indeed, the first trial of BCG for this indication failed more than 80 years ago. One reason that this approach may have failed is that exposure to Mtb antigens could exacerbate latent disease. This effect was recently demonstrated in the context of live or heat-treated BCG, with or without lipid adjuvants, on the recurrence of Mtb in latently infected mice (Moreira et al., 2002). In these experiments, increased antigen-specific T cell proliferation was observed, but there was no reduction in bacterial load in the lungs of BCG-vaccinated mice rechallenged with Mtb and, perhaps more worrisome, larger lung granulomas were discovered. This effect seemed to be due to increased expression of TNF-alpha and IL-6. The studies appeared to demonstrate that providing Mtb antigens in the context of prior Mtb infection leads to immune activation, exacerbating lung pathology. The exacerbation may be due to TNF-alpha-induced inflammation. It is however possible that the effect of immunization with whole BCG, including bacterial cell membranes, lipids, and other components, shifted the immune response to Th2-type responses, which would be associated with TNF secretion.

In contrast, immunization of mice with pure (recombinant) antigens, as in the experiments performed with DNA by Repique et al. (2002), did not appear to exacerbate LTBI or increase disease pathology following rechallenge. A number of other researchers have also failed to demonstrate that postexposure vaccination prevents relapse in mice with latent TB. For example, Turner et al. (2000) showed that a DNA vaccine that was effective against a primary infection did not protect when administered immunotherapeutically in a postexposure model. In addition, immunization with either BCG or a heat-killed *Mycobacterium vaccae* vaccine did not alter the relapse rate in a murine model of dormant TB (Collins and Mackaness, 1970).

A DNA vaccine expressing the heat shock protein 65 (hsp 65) vaccine has been the subject of a great deal of controversy. This vaccine was first shown to be successful in the prevention of TB recurrence in the Cornell model of MDR TB by Lowrie and associates (Tascon et al., 1996). Only a few years later, another group of researchers claimed that the hsp 65 vaccine might exacerbate TB in mice (Orme et al., 2001). In latter studies, mice appeared to develop discrete regions of cellular necrosis throughout the lung. Similar reactions were seen in mice given a vaccine with DNA coding for the Ag85 antigen of Mtb (Taylor et al., 2003). The relevance of this study to DNA immunization in humans is yet to be determined.

Thus, at least four recent attempts at developing LTBI vaccines have failed in murine models or had equivocal results. Morris and others have postulated that this failure may be due to the effect of LTBI itself on immune cells. While competent immune response against latent TB appears to be maintained in most hosts because the bacteria are contained inside the granulomas, the type of response that is required to clear infection may be qualitatively different. To reduce or eliminate LTBI, a vaccine may need to promote greater macrophage (or dendritic cell) activation. For example, Britton and coworkers have shown that DNA immunization in conjunction with plasmids expressing IL-12 are effective means of inducing TB immunity (Palendira et al., 2002). IL-12 can also be given as a recombinant protein, which avoids the problem of prolonged IL-12 exposure due to DNA delivery. Alternatively, coadministration with adjuvants that increase Th1 response, such as CpG motif-containing plasmids, may overcome the refractory nature of local immune response.

New Approach to TB Vaccine Development: Epitope-Driven Vaccines

Taking the Lowrie, Morris, and Kaplan studies in context, "whole" TB vaccines (based on BCG, or

attenuated Mtb) for LTBI may have an adverse effect on the immune response due to the priming of the immune system for Th2-type responses. As neither Lowrie nor Morris observed exacerbation in LTBI mice vaccinated with DNA vaccines, removing the protein antigens from the context of the whole or killed bacteria appears to reduce the Th2 effect associated with mycobacterial cell wall components, which may in turn be responsible for the increased pathology. This suggests that it is worth pursuing a vaccine based on the delivery of multiple antigens—or epitopes derived from these antigens—in an immunostimulatory adjuvant or perhaps in conjunction with the TB vaccine developed by Lowrie. Thus, as an alternative to replacing BCG, it may be possible to develop such a genome-derived multi-epitope/antigen vaccine as would afford additional protection from TB disease in individuals already either vaccinated with BCG or latently infected with TB.

A new paradigm of TB vaccine development is therefore emerging, based on the concept that an *ensemble of epitopes* could stimulate protective Th1 immune responses, while the whole antigen and/or the whole organism might suppress immune responses. This new paradigm is based on the following observations. Following exposure to a pathogen, epitope-specific memory T cell clones are established. These clones respond rapidly and efficiently upon any subsequent infection, elaborating cytokines, killing infected host cells, and marshaling other cellular defenses against the pathogen. Broad T cell response may resemble multidrug TB therapy in that multiple T cell clones may be able to contain the bacteria or significantly impair bacterial replication, leading to clearance of the bacilli.

PROSPECTS FOR THE FUTURE

An effective TB vaccine will have a significant economic benefit in terms of global health. Experts estimate that such a vaccine would be worth at least $25 billion in terms of avoided medical spending worldwide. More specifically, the 1 billion people who are currently at risk of developing TB following exposure could expect to save $25 in medical costs if they had received a 75%-effective vaccine for 10 years (Weis et al., 1999; Bishai and Mercer, 2001). An effective LTBI vaccine could easily be priced in the same range as the hepatitis vaccine ($50 per dose or $150 per three-dose regimen) in the developed world. Pricing in that range would generate more than $500 million in revenue in the U.S. market and as much or more in other developed countries where the LTBI rate is as high as 50 times the rate in the United States. In the developing world, the current intervention for active TB costs $5 per DALY. An effective vaccine priced at $1 per dose would be equivalent to the cost per DALY of a directly observed short-course therapy for LTBI. According to the WHO, an acceptable price for an effective TB vaccine might be as high as $10 per dose in developing countries, given the urgency of the TB epidemic.

Significant progress is being made in terms of new vaccines in the pipeline, due to the infusion of funding from philanthropic organizations in the past decade. The expansion of the number of vaccines should not diminish the sense of urgency for a new TB vaccine but, rather, should serve to stimulate additional funding to support the development of vaccines from bench to clinic, so that we do not fall short of this important goal.

KEY ISSUES

- Mtb transmission is a worldwide public health threat.
- Upon infection, the host mounts an immune response that contains but does not eradicate Mtb.
- Infected individuals have a 10% lifetime risk of Mtb reactivation that leads to lung disease and dissemination to other organs.
- HIV-co-infected individuals have a 7–10% risk of reactivation in 1 year. TB has emerged as the leading cause of death from AIDS.
- The TB pandemic has continued unabated despite the use of directly observed chemotherapy programs. Moreover, multidrug-resistant and extensively drug-resistant TB have emerged and require control to prevent spread.
- Vaccination is a means to bring TB under control by preventing transmission or providing therapy.
- BCG, the only licensed TB vaccine available today, is administered to millions of people every year. While BCG reduces the incidence of TB in children, meningeal TB, and leprosy, it does not reliably prevent adult pulmonary TB, the most common form of the disease.
- New vaccines to replace or boost BCG are under development from the discovery stages to preclinical development to Phase II clinical trials today.
- Vaccine development approaches include live attenuated Mtb, recombinant BCG, viral- and bacterial-vectored, and subunit- and epitope-driven vaccines.

- TB research and development underfunding threatens to prevent achievement of the goals for new diagnostics, drugs, and vaccines by 2015 as set out by the Stop TB Partnership.
