The functional activities of antibodies have been assessed in several different in vitro, cell-based assays. Antibodies to E2 can block the binding of soluble recombinant E2 glycoproteins to CD81, which is widely accepted to be a co-receptor for the virus (Allander et al., 2000; Ishii et al., 1998; Bartosch et al., 2003c; Pileri et al., 1998). More recently, retrovirus particles have been pseudotyped with the E1 and E2 proteins (Bartosch et al., 2003b; Hsu et al., 2003) to produce HCV pseudoparticles ("HCVpp"), which have been used as surrogates for assessing the functional activities of antibodies. Antibodies that limit the ability of HCVpp to attach to and enter cells are present in very low abundance and are very strain-specific early in the course of infection, when antibodies first appear (Lavillette et al., 2005; Meunier et al., 2005; Logvinoff et al., 2004; Netski et al., 2005). However, their titer increases and functional activity broadens after several months of infection so as to include the ability to neutralize heterologous HCV genotypes (Lavillette et al., 2005; Meunier et al., 2005; Logvinoff et al., 2004; Netski et al., 2005). An inverse correlation has been demonstrated between the magnitude of viremia and serum HCVpp neutralizing antibody titers in

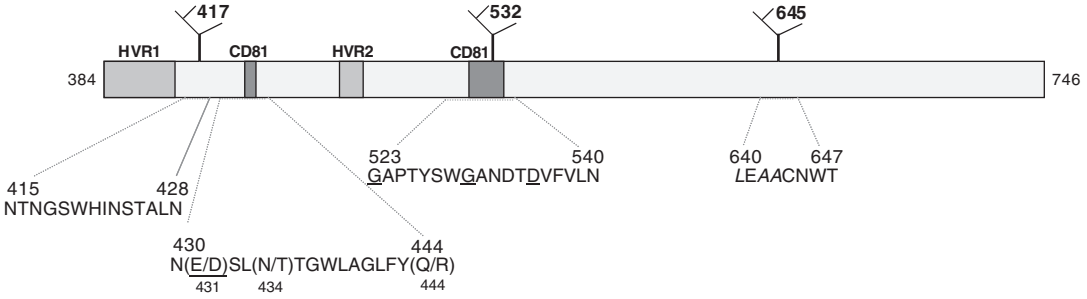

FIGURE 24.5 Mapping of neutralization epitopes on the HCV E2 protein sequence. Regions that are associated with CD81 binding hypervariable regions, and glycosylation sites that affect neutralization by domain B-reactive monoclonal human antibodies are labeled. The underlined residues are in the epitope recognized by CBH-2, a domain B-reactive human monoclonal antibody. Leu640, Ala642, and Ala643 (shown in italics) are necessary for overall E2 structure. Substitution of Ala431 with Glu results in escape from CBH-2 neutralization (Keck et al., submitted).

one study of chronically infected subjects (Lavillette et al., 2005).

Infectious virus produced in cell culture (HCVcc) has also been used to document the neutralizing activity of antibodies (Lindenbach et al., 2005; Yi et al., 2006). Although such data remain limited, they are largely consistent with earlier studies using pseudotyped retrovirus particles, including the limited genotype specificity of early antibody. In one study, sera collected from two of three patients about 1 year after acute infection with genotype 1a virus neutralized only genotype 1a virus, and not genotype 2a virus, while the third patient had a much greater titer of neutralizing antibody against the genotype 1a virus (Yi et al., 2007).

All in vitro neutralization studies should be viewed with some caution, however, given present uncertainties concerning the structure of HCV described above, and significant differences in the buoyant densities of HCVcc and HCV found in serum or plasma (Lindenbach et al., 2006).

VIRAL NEUTRALIZATION EPITOPES

As indicated above, there are no detailed crystallographic or cryoelectron microscopic reconstructions of the HCV envelope, and thus current understanding of structure–function relationships within the envelope are rudimentary and based largely on mutational analyses. Moreover, the envelope glycoproteins display some of the highest levels of genetic diversity among the HCV proteins, with E2 displaying greater variability than E1. The hypervariable HVR1 region found at the amino terminus of E2 (Fig. 24.5) is highly immunogenic, and is a major determinant for isolate-specific neutralizing antibody responses (Farci et al., 1996; Shimizu et al., 1994). However, such antibody provides little protection against the virus, as the HVR1 sequence continuously evolves during the course of infection, apparently in response to selective forces exerted by HVR1-specific neutralizing antibodies on the viral quasispecies population. This was clearly demonstrated in a study of sequential HCV sequences isolated from one patient over a 26-year period, in which serum antibodies failed to neutralize the concurrent dominant E1E2 species present in the blood (von Hahn et al., 2007). Escape was associated with mutations within the HVR1 that led to decreased binding and neutralization by MAbs that were produced to the HVR1 sequence present in the earliest isolate obtained from the patient.

More broadly neutralizing antibodies are usually directed against conformational epitopes within E2 (Allander et al., 2000; Hadlock et al., 2000; Bugli et al., 2001; Habersetzer et al., 1998; Ishii et al., 1998). Cross-competition analyses with HMAbs recognizing conformational epitopes on the HCV E2 molecules have delineated at least three immunogenic clusters of overlapping epitopes with distinct functions and properties (Keck et al., 2004, 2005). Non-neutralizing antibodies recognize one cluster, which has been designated as domain A, while neutralizing HMAbs can be segregated into two distinct groups recognizing two different clusters of epitopes, designated domains B and C respectively (Keck et al., 2007).

HMAbs recognizing E2 domain B epitopes demonstrate varying abilities to neutralize HCVpp containing glycoproteins derived from the six different HCV genotypes (Owsianka et al., 2008). One such antibody, CBH-5, reduced the infectivity of HCVpp derived from all genotypes by more than 60%. Importantly, CBH-5 and other domain B antibodies block the binding of E2 to CD81. Alanine scanning mutagenesis has shown that four highly conserved E2 residues (Gly523, Pro525, Gly530, and Asp535) are required for CBH-5 binding (Owsianka et al., 2008). Two of these residues (Gly530 and Asp535) have been shown to be essential for the interaction of E2 with CD81. Another residue (Gly523) also appears to have involved in the interaction with CD81, since an alanine substitution at this position lessens CD81 binding by 80% and HCVpp infectivity by 90% (Owsianka et al., 2006). The data thus suggest that CBH-5 exerts its potent and broad neutralizing effect on HCV by competing with CD81 for binding to conserved residues on E2 that are important for viral entry. Consistent with this, broadly neutralizing human antibodies derived from combinatorial libraries isolated from individuals with chronic hepatitis C also recognize epitopes containing Gly523, Trp529, Gly530, and Asp535 (Johansson et al., 2007; Law et al., 2008; Perotti et al., 2008). In addition, HCVpp bearing an alanine substitution at Asn532 demonstrate enhanced neutralization by sera from individuals infected with genotype 1a, 1b, 2b, 3, 4, and 5 viruses, suggesting that all of these sera contain antibodies directed at this region (Falkowska et al., 2007). Taken together, these data suggest that domain B represents a conserved, immunodominant site recognized by broadly reactive, neutralizing antibodies.

Of particular concern from a vaccine perspective, single amino acid substitutions within domain B antibodies can lead to virus escape from some domain B-reactive antibodies, thus recapitulating the escape observed with antibodies directed against the HVR1 domain. CBH-2 is a HMAb that recognizes a broadly conserved epitope in domain B that contains residues Gly523, Gly530, and Asp535 (similar to CBH-5).

These are also contact residues for E2 binding to CD81, as described above. However, a single amino acid substitution at residue 431, which is located at a considerable distance within the linear sequence of E2 from other domain B residues (Fig. 24.5), results in complete escape from CBH-2-mediated neutralization in a genotype 1a virus (Keck et al., 2008, submitted). These recent results highlight the substantial challenges inherent in developing HCV vaccines, and show that an effective vaccine will need to induce antibodies to both conserved as well as invariant epitopes to lessen the probabilities of virus escape.

APPROACHES TO VACCINE DEVELOPMENT

Sterilizing immunity is not essential to the success of a hepatitis C vaccine. The public health consequences of HCV arise from its ability to cause liver disease in the context of persistent infection, and thus the ability to prevent persistent infection should be the goal in vaccine development. As described in greater detail below, the pre-clinical development of a recombinant envelope protein vaccine was pursued for more than a decade by Chiron prior to its acquisition by Novartis, reaching phase I/II safety and immunogenicity trials in humans (Houghton and Abrignani, 2005). Vaccines comprised on recombinant envelope proteins appear generally safe and capable of eliciting both cellular and humoral immune responses that may be at least partially protective (Leroux-Roels et al., 2004; Houghton and Abrignani, 2005; Stamataki et al., 2007). Immunization with both recombinant envelope glycoproteins may prevent or delay the onset of viremia following infectious virus challenge (Puig et al., 2004; Choo et al., 1994; Houghton and Abrignani, 2005). However, it is far from certain that recombinant envelope protein vaccines, which are designed primarily to elicit neutralizing antibodies and CD4+ T cells, will prove to be sufficiently immunogenic for prevention of persistent human infections.

As indicated above, there are no well defined in vitro correlates of immunity, either for protection against acute infection or for prevention of progression of acute infections to long-term persistence of the virus. Moreover, vaccine developers are severely handicapped in not having adequate tools available to study the potential protection afforded by immunization. A number of pre-clinical studies have been carried out in chimpanzees, but the availability of this animal model is severely limited and the numbers of animals included in individual studies typically very small. In most cases, these studies have involved challenge with relatively low-titer infectious inocula that were closely related to the virus from which the vaccine antigens were taken. The extreme genetic heterogeneity of the envelope glycoproteins of HCV, described above, is a major challenge to be overcome. Moreover, chimpanzees appear to have a remarkably high rate of spontaneous resolution of HCV infection (Bassett et al., 1998), making determination of the effects of a vaccine on virus persistence very difficult.

However, as noted above, chimpanzees and possibly also humans who have successfully resolved previous infections with HCV may have a level of protective immunity that, while not capable of preventing acute re-infection, may prevent subsequent progression to persistent infection when rechallenged with the virus. Substantial data suggest that such immunity is mediated by CD4+ and CD8+ T cells (Bassett et al., 2001; Grakoui et al., 2003; Major et al., 2002; Shoukry et al., 2003). Thus, the most successful vaccine strategies may be those designed to stimulate the T-cell responses elicited during naturally resolving HCV infections. A number of approaches have been developed for priming class I and II restricted T cells against HCV (Houghton and Abrignani, 2005; Inchauspe and Feinstone, 2003). Examples include the use of virus-like particles (VLP) comprised of the HCV nucleocapsid and envelope proteins (Lechmann et al., 2001), recombinant viral vectors (Wuest et al., 2004; Vidalin et al., 2000; Abraham et al., 2004), and bacterial vectors (Simon et al., 2003; Wedemeyer et al., 2001; Abraham et al., 2004), as well as genetic immunization with plasmid sequences encoding segments of both structural and nonstructural proteins of the virus (Satoi et al., 2001; Pancholi et al., 2003; Encke et al., 1998). Some studies have also combined two of these modalities, such as priming with DNA immunization followed by boosting with a recombinant poxvirus vector (Pancholi et al., 2000), or priming with recombinant adenovirus, then boosting with DNA (Folgori et al., 2006). Although relatively few of these candidate approaches to immunization have been tested in the chimpanzee model, many have proven capable of priming specific CD4+ and CD8+ T-cell responses against HCV in mice. Several of these vaccine candidates have also been shown to be capable of stimulating HCV-specific T cells in nonhuman primates such as baboons (Jeong et al., 2004) and rhesus macaques (Rollier et al., 2005; Polakos et al., 2001; Capone et al., 2006), which may be more reliable models of the immunogenic response in humans.

In general, vaccines that are capable of priming virus-specific T-cell responses have been found to delay or diminish the magnitude of viremia in immunized chimpanzees following virus challenge, compared

to unimmunized control animals (Folgori et al., 2006; Youn et al., 2005; Rollier et al., 2004; Forns et al., 2000a). Suppression of viremia was particularly profound with one vaccine that expressed only nonstructural proteins of the virus and thus was incapable of inducing virus-neutralizing activities (Folgori et al., 2006). Protection in this case was almost certainly mediated exclusively by T cells. However, despite evidence of exerting some control over the acute infection, in many studies there has been no evidence of a reduction in rates of progression to long-term, persistent infection (Forns et al., 2000a; Rollier et al., 2004). All of these studies have been limited by the small numbers of animals available, but this is nonetheless a critical distinction in that the significance of HCV as a human pathogen relates to its ability to establish persistent infection and cause chronic liver disease. There is no good explanation for the failure of such T-cell vaccines to protect against persistent infection, but it may reflect deficiencies in the frequency and perhaps breadth of the memory T-cell populations they elicit.

In summary, while there are no clearly established in vitro correlates of protective immunity against infection with HCV, strong indications from multiple sources suggest that CD4+ and CD8+ T-cell responses, while critical for control of acute infection, are insufficient for prevention of long-term persistent infection, at least in chimpanzees. At the same time, some evidence exists to support the importance of neutralizing antibody to the virus, and the ability of B-cell responses to modify the course of infection. Thus, an ideal vaccine should elicit both robust T-cell as well as B-cell responses. However, despite intensive efforts on the part of many, and despite continued progress in the field, no candidate vaccine has yet been shown to produce the level and/or type of immunity required for prevention of HCV-associated liver disease (Table 24.1).

RECOMBINANT PROTEIN VACCINES

Chiron Recombinant gpE1/gpE2 Vaccine

Early work at Chiron, the company that first identified the virus responsible for hepatitis C, focused on the development of recombinant HCV envelope glycoproteins as vaccine candidates (Choo et al., 1994). The E1 and E2 glycoproteins were expressed in mammalian cells with a recombinant vaccinia vector and found to associate with each other as a noncovalent heterodimer that bound antibody present in many serum samples from patients with chronic hepatitis C (Ralston et al., 1993). Immunization with this "gpE1/gpE2" preparation induced virus-specific antibodies and Th-cell responses in naïve chimpanzees (Houghton and Abrignani, 2005; Choo et al., 1994). In a landmark series of experiments, chimpanzees were immunized over a period of 6 months with three doses of the gpE1/gpE2 vaccine (generally 30–80 μg each) in an oil/water adjuvant, then challenged intravenously with 10–100 chimpanzee-infectious doses (CID_{50}) of virus 2 months later. Remarkably, 5 out of 12 immunized animals were completely protected against homologous challenge with the strain of virus from which the vaccine antigen was derived (HCV-1), and only two of the infected animals progressed to chronic infection (Houghton and Abrignani, 2005). In contrast, ten of ten unimmunized control animals (including nonconcurrently studied historic controls) became infected, seven of them persistently (Houghton and Abrignani, 2005). This difference in the proportion of animals sustaining a chronic infection was statistically significant ($p < 0.03$), but then the rate of persistent infections in the unimmunized animals was higher than that reported in other studies (Bassett et al., 1998). Similar protection against persistent infection was observed following challenge of immunized chimpanzees with a different strain of genotype 1a virus (HCV-H): nine of nine immunized animals became infected, but only one of the nine animals progressed to chronicity. In contrast, 8 of 14 nonimmunized animals developed chronic infection (all 14 were infected). It is not possible to predict how protective this genotype 1a vaccine might be against genotype 1b or genotype 2 or 3 infections.

A significant limitation to the chimpanzee studies of the gpE1/gpE2 vaccine is the lack of understanding of the significance of protection against an intravenous challenge with 10–100 CID_{50} of virus. Although this has become a standard in the field, it is not clear how it relates to the real-world situation. While a contaminated blood transfusion would provide a challenge many orders of magnitude greater than this, such an event would be very unlikely today because of screening procedures in place to protect the blood supply. The typical inoculum size in the setting of community-acquired infections is not known and can only be guessed at. Nonetheless, the data obtained in these chimpanzee challenge experiments suggest that the gpE1/gpE2 vaccine may be capable of protecting against persistent infection with at least genotype 1a viruses (Houghton and Abrignani, 2005). This is likely to be accomplished this via the induction of neutralizing antibodies, since the existence of sterilizing immunity in some animals correlated at least roughly with the magnitude of the antibody response

TABLE 24.1 HCV vaccine candidates that have entered clinical trials

Type	Primary clinical goal	Immunogen	Developer	Significant findings	Stage
Recombinant protein	Prevention	gpE1/gpE2 in oil/water adjuvant	Chiron/Novartis	Induces humoral and cellular immune responses and may protect against persistent infection with closely related virus in chimpanzees	Phase 1b
	Therapy	gpE1 in alum adjuvant (INO-101)	Innogenetics	Primes humoral and cellular immune responses in humans, but did not reduce liver injury in patients with chronic hepatitis C	Discontinued after Phase 2
	Therapy	Core protein in ISCOMATRIX® adjuvant	Chiron/Novartis and CSL	Primes T-cell responses in macaques	? Phase 1
	Therapy	NS3–NS4–NS5–Core polyprotein in ISCOMATRIX® adjuvant	Chiron/Novartis and CSL	Primes T-cell responses in chimpanzees	? Phase 1
Synthetic peptide	Therapy	Core, NS3, and NS4 peptides with poly-arginine adjuvant (IC41)	Intercell	Induced CD4+ and CD8+ T-cell responses in HLA-A2+ HCV-infected persons	Phase 2
	Therapy	HCV peptides formulated with influenza virosomes	Pevion Biotech	Induces virus-specific CTL and Th response in mice	Phase 1
	Therapy	"Personalized" peptide cocktail derived from E1, E2, NS3, and NS5A	Kurume University	Induced humoral and cellular immune responses in HCV-infected patients	Phase 1
DNA	Therapy	ChronVac-C®	Tripep and Inovio	Not available	Phase 1
Recombinant vectors	Prevention	MVA expressing NS3, NS4, and NS5B (TG 4040)	Transgene	Induces T-cell response in mice	Phase 1
	Therapy	Heat-killed yeast expressing Core and NS3 (GI-5005 Tarmogen)	GlobeImmune	Primes T-cell response in mice	Phase 1/2
Antibody	Therapy	HCIG human polyclonal antibody (Civacir®)	NABI/Biotest	Delayed infection in chimpanzees, but no impact on HCV viremia in liver transplant recipients	Phase 2
	Therapy	Ab68 + Ab65 monoclonal antibodies (XTL-6865)	XTL Bio-pharmaceuticals	No statistically significant changes in HCV viremia in patients with chronic hepatitis C	Discontinued after Phase 1

to E2 as assessed by inhibition of E2 binding to CD81 and neutralization of HCVpp entry (Houghton and Abrignani, 2005).

Encouraged by these results, a randomized phase I clinical study has been carried out to evaluate the safety, tolerability, and immunogenicity of the Chiron gpE1/gpE2 vaccine given at doses of 4, 20, or 100 μg with MF59 adjuvant versus a placebo in a total of 60 HCV-naïve subjects. The study was completed in August, 2005. Results have not been published as of February 2008, but accounts indicate that all 45 vaccine recipients developed neutralizing antibodies. Potentially important to the future of the gpE1/gpE2 vaccine, Chiron was acquired by Novartis in 2006, leading to significant changes in the management of the development program.

Innogenetics Recombinant E1 Vaccine

Recombinant E1 (in the absence of E2) has also been evaluated as an immunogen for therapeutic vaccination. The vaccine, developed by Innogenetics, consisted of a 135 amino acid polypeptide representing carboxy-terminally truncated E1 from a genotype 1b virus, adjuvanted with alum (Nevens et al., 2003). The underlying rationale behind the selection of E1 as a vaccine immunogen appears to have been based on correlations observed between high anti-E1 antibody levels and response to IFN therapy, as well as the absence of high titer anti-E1 antibodies in many persons with chronic HCV infection (Leroux-Roels et al., 2004; Nevens et al., 2003). Preliminary studies in chronically infected chimpanzees immunized with E1 protein reportedly resulted in improvements in disease (Maertens et al., 2000). In a phase I immunogenicity and tolerability study involving 20 healthy, HCV-negative volunteers, a series of three doses of this vaccine, 20 μg each, given at 3-week intervals, was well tolerated, and resulted in strong Th1 and anti-E1 antibody responses that were increased following a fourth dose given at 26 weeks (Leroux-Roels et al., 2004). In a subsequent pilot study, 35 patients with chronic hepatitis C were randomized to receive either five doses of this vaccine (at weeks 0, 4, 8, 12, and 24, $n = 26$) or placebo ($n = 9$) (Nevens et al., 2003). By week 48–50, serum ALT levels had declined significantly in the immunized group, but they were not different statistically at this point in time from the ALT values observed in the smaller number of control patients. Beyond 50 weeks, all of the patients enrolled in the study were offered an additional series of five doses of open-label vaccine. Follow-up liver biopsies suggested improvements in histopathology in 9 of 24 patients, but it is difficult to interpret these data in the absence of a bone fide control group. There were no significant changes noted in the level of viremia (Nevens et al., 2003). The only conclusion to be drawn from this study was that further analysis of the vaccine might be warranted.

Results of a follow-up phase IIb trial of the E1 therapeutic vaccine candidate were reported by Innogenetics in June, 2005, and demonstrated no differences in disease progression in groups of patients with chronic hepatitis C who were treated with vaccine versus placebo. In September of 2007, Innogenetics announced the results of a longer, 3 year, prospective, multicenter, randomized, double-blind, placebo-controlled phase IIb trial involving 122 patients. Those in the vaccine group had received four courses of vaccine consisting of recombinant E1 produced in yeast at doses of 50 μg each. Liver biopsies taken at the beginning and end of the study were examined for the primary clinical end-point which was a reduction in liver tissue damage. Patients treated with the vaccine were reported to show strong immune responses against the E1 protein, but failed to demonstrate a significant reduction in liver tissue damage assessed by histopathologic examination. Following this study, the E1 therapeutic vaccine program was discontinued.

Other Recombinant Protein Vaccine Candidates

In studies distinct from the Chiron program, E1E2, expressed from a recombinant Sindbis virus, has also been evaluated for its ability to elicit protective immunity in a small number of chimpanzees. Two animals were immunized: one who had recovered from a prior infection with HCV, and another who received priming doses of a DNA plasmid and a peptide immunogen prior to the recombinant E1E2 (Puig et al., 2004). The very small number of animals studied, compounded by differences in the pre-immunization history of the animals as well as the adjuvants and challenge inocula used, preclude any specific conclusions about the efficacy of the immunization. However, viremia appeared to have been delayed by several weeks in the two immunized animals following challenge with 100 CID_{50} of homologous virus, when compared with an unimmunized control animal who was challenged with only 3.5 CID_{50} (Puig et al., 2004). The naïve immunized animal that received the priming dose of the peptide immunogen progressed to persistent infection, while the other two animals resolved the infection. Importantly, both immunized animals became infected despite having developed robust antibody responses (including to the HVR1 domain of E2) and proliferative T-cell responses.

Other HCV proteins and several different adjuvants have also been evaluated as potential vaccine immunogens. Investigators at Chiron and CSL collaborated on evaluation of a prototype core protein-ISCOMATRIX vaccine that elicited high titers of antibody to core and primed strong CD4+ and CD8+ T-cell responses in rhesus macaques (Polakos et al., 2001). As many as 0.30–0.71 and 0.32–2.21% of the circulating CD8+ and CD4+ T cells, respectively, recognized core peptides by intracellular cytokine staining. An ISCOMATRIX-adjuvanted NS3-4-5–Core polyprotein is also reported to have elicited broad Th1-like CD4+ and CD8+ T-cell responses in chimpanzees; it may have ameliorated disease but did not prevent persistent infection following heterologous virus challenge (Houghton and Abrignani, 2005).

SYNTHETIC PEPTIDE VACCINES

Several different candidate vaccines under development incorporate synthetic peptides that represent conserved epitopes that have been shown to be recognized by HCV-specific T cells. These vaccines are for the most part being developed for therapeutic rather than preventive purposes, and are either cocktails of multiple peptides, or synthetic multi-epitope polypeptides. Several have entered clinical trials. All are potentially limited by the HLA-restricted nature of epitopes recognized by CD8+ T cells, as well as the sequence diversity existing among different HCV strains.

Intercell IC41 Peptide Vaccine

This therapeutic HCV vaccine candidate contains peptides representing three Th epitopes and five conserved HLA-A2 restricted cytotoxic T-cell epitopes derived from the core, NS3, and NS4 sequences, complexed with a proprietary poly-arginine adjuvant (Schlaphoff et al., 2007; Firbas et al., 2006). Clinical trials have been confined to HLA-A2+ individuals, who comprise about 40–50% of all Caucasians. In a phase I clinical trial involving ascending doses of the vaccine, 50% and 40% of healthy HCV-naïve adults who were immunized with 5.0 μg doses of the peptide vaccine developed positive IFN-γ Eli-spot tests for HCV-reactive CD4+ and CD8+ T cells, respectively (Firbas et al., 2006). Similar responses were not seen in placebo recipients. Comparable results were obtained in tetramer and proliferation assays, supporting the immunogenicity of the vaccine. In a second clinical study, HLA-A2 patients with chronic hepatitis C received a total of six doses of the vaccine at 4-week intervals. Modest increases in the frequency of HCV tetramer-positive CD8+ cells were observed in about one quarter of these patients, but there were no changes noted in circulating HCV RNA levels (Schlaphoff et al., 2007). This vaccine remains in development. In February, 2008, Intercell AG released the results of a study involving 50 patients with chronic genotype 1 infection. Study subjects who received eight intradermal injections of the IC41 vaccine at bi-weekly intervals were said to have demonstrated a minimal (40%) but statistically significant reduction in the abundance of circulating virus.

Pevion Biotech Virosome-Formulated Peptide Vaccine

Pevion is currently enrolling patients in a phase I clinical trial of virosome-formulated HCV peptides as a candidate therapeutic immunogen. The concept underlying this vaccine is that reconstituted influenza virosomes (IRIVs), composed of phospholipids and influenza surface glycoproteins, are capable of efficiently delivering peptide epitopes to the MHC class I antigen presentation pathway due to their fusogenic activity. Virosomes containing a 132-amino acid long peptide fragment of the HCV core protein were capable of inducing virus-specific cytotoxic and IFN-γ-producing T cells in HLA-A2.1 transgenic mice (Amacker et al., 2005).

Other Peptide-Based Vaccine Candidates

An academic group has reported the development of humoral and cellular immune responses to HCV peptides that were used to immunize HCV-infected HLA-A24+ patients who had failed IFN therapy (Yutani et al., 2007). Specific peptide sequences were selected to immunize each study subject based on pre-immunization stimulation of CD8+ cytotoxic T cells, making this a "personalized" vaccine. Reductions in viral load and improvements in serum ALT levels were noted in some of these vaccine recipients in this uncontrolled clinical study.

Several other studies have evaluated different strategies for presenting peptide epitopes to the immune system in mouse models. A library containing HVR1 peptide variants and a multi-epitope polypeptide immunogen containing HVR1 sequences both induced strong and specific antibody responses (Roccasecca et al., 2001; Torresi et al., 2007). A conceptually different approach, involving a synthetic multi-epitope polypeptide containing triple tandem repeats of five conserved epitopes from HCV was capable of inducing antibody as well as cytotoxic lymphocytes in BALB/c mice (Chen et al., 2007). The antibody elicited by this peptide

immunogen was reported to have antiviral activity in infected transgenic mice harboring chimeric human livers. In a separate study, multi-epitope peptides containing sequences from NS3, NS4, and NS5B were capable of eliciting both primary and memory T-cell responses (Fournillier et al., 2006). Whether such immunogens will eventually make it to clinical trials remains to be seen.

GENETIC IMMUNIZATION

A number of studies have evaluated different approaches for DNA immunization against HCV in mice, including the use of DNA encoding a multigenotype E1 library (Encke et al., 2007), envelope proteins (Nakano et al., 1997; Fournillier et al., 1998; Tedeschi et al., 1997), a combination of E1 and core epitopes (Shi et al., 2006), and NS3 (Gao et al., 2006). In general, the immunization of mice with DNA results in robust induction of mostly Th1- and CD8+ T-cell responses. Efforts to enhance DNA delivery have involved use of a gene gun (Nakano et al., 1997; Fournillier et al., 1998; Tedeschi et al., 1997), as well as in vivo electroporation (Zucchelli et al., 2000; Ahlen et al., 2007).

In general, naked DNA is less immunogenic in larger animals than in mice. However, in a small trial involving two chimpanzees, immunization with DNA encoding a truncated E2 protein resulted in an anti-E2 antibody response (including to the HVR1 domain). However, there was little evidence of protective immunity as both chimpanzees became infected following challenge with 100 CID_{50} of homologous virus (Forns et al., 2000a). The immunized chimpanzees resolved the infection, while a control animal challenged with 3 CID_{50} of virus did not. Unfortunately, it is not possible to draw any conclusions from this study concerning the potential efficacy of DNA immunization given the small number of animals, as well as differences in the magnitude of the inocula used to challenge the control versus the immunized animals. In another study, DNA encoding the E1E2 envelope proteins was adsorbed onto cationic poly (lactide co-glycolide) (PLG) microparticles (O'Hagan et al., 2004). Administered as a series of 3–4 doses, this DNA vaccine generated antibody responses comparable to MF59-adjuvanted gpE1/gpE2 protein in rhesus macaques, and also was capable of priming for a response to a protein booster (O'Hagan et al., 2004).

Replication-defective adenoviruses are very effective for delivery of genetic vaccines (Fattori et al., 2006), and strong immune responses have been observed following delivery of DNA to chimpanzees by this method (Folgori et al., 2006). Recombinant replication-deficient adenovirus vectors derived from two different adenovirus subtypes were used to deliver the first three genetic immunizations against genotype 1b NS3–NS5B proteins, at 0, 4, and 24 weeks, and were then followed by three doses of DNA given between weeks 35 and 39. The animals were challenged at week 49 with 100 CID_{50} of a heterologous, genotype 1a inoculum (Folgori et al., 2006). Since there are no neutralization determinants within the NS3–NS5B segment of the polyprotein, this vaccination approach was designed to elicit T-cell immunity. Proliferative CD4+ and CD8+ cell responses were observed in five of five immunized chimpanzees, while potent cytotoxic activity was induced in four animals. Importantly, cross-reactive T cells recognizing heterologous genotype 1a epitopes were detected in four of the five immunized animals, while intrahepatic HCV-specific CD8+ T cells were detected in all (Folgori et al., 2006). On challenge with a heterologous genotype 1a virus, viremia was delayed by at least a week and reduced 100-fold in magnitude, compared to five control, nonimmunized chimpanzees. The infection resolved spontaneously in four of the five immunized chimpanzees, but this also occurred in three of the five control animals. Strikingly, none of the immunized animals demonstrated biochemical evidence of acute hepatitis in association with HCV infection, while ALT elevations were noted in all of the controls (Folgori et al., 2006).

Although the immunization regimen used in this study is not one that would be amenable to incorporation into clinical practice, this study is important because it demonstrated that T-cell immunity, elicited by genetic immunization, can provide protection against acute liver disease and also limit virus replication following challenge with a heterologous strain of HCV (Folgori et al., 2006). This latter finding is particularly worthy of emphasis, because the genotype 1b and 1a viruses used as the basis for immunization and challenge in this study, respectively, differed from each other close to the limits of genetic diversity observed among genotype 1 viruses of both subtypes (Fig. 24.2) (Folgori et al., 2006). Although the study involved a relatively large number of animals, including five nonimmunized animals studied as contemporary controls, no conclusions can be drawn from it regarding the ability of such immunization to prevent viral persistence.

Similar results were obtained in another study, in which uninfected chimpanzees received three priming doses of DNA encoding genotype 1b core, E1E2, and NS3-5 proteins, followed by a recombinant adenovirus booster expressing the same proteins. This immunization regimen induced HCV-specific antibody and T-cell proliferation and IFN-γ Eli-spot responses, and resulted

in a 100-fold reduction in the peak viremia following challenge with a different genotype 1b virus (Youn et al., 2005). A prime-boost strategy was also tested in a study in which two chimpanzees were primed with plasmid DNA encoding four HCV proteins (core, NS3, and truncated forms of E1 and E2), followed by a protein boost with the same recombinant proteins. Both of the immunized animals were infected on heterologous virus challenge, although the magnitude of viremia was reduced in comparison to an unimmunized control animal (Rollier et al., 2004). One of the immunized animals rapidly resolved the infection. Interestingly, immunization in this animal resulted in a bias towards Th1-type cytokine responses for E1 and NS3. In yet another study, immunization of naïve chimpanzees with DNA encoding core–E1E2 and NS3 followed by a poxvirus booster immunization using the modified vaccinia Ankara (MVA) vector resulted in robust HCV-specific immune responses as well as marked reduction in the magnitude of acute viremia on challenge with a heterologous virus (Rollier et al., 2007). However, despite good evidence for partial control of the acute infection, three of the four immunized animals in this study progressed to persistent infection.

Taken together, these studies show that genetic immunization, used either for priming or boosting immune responses to HCV, can result in robust virus-specific CD4+ and CD8+ T-cell responses that are capable of limiting the extent of virus replication upon challenge with even distantly related heterologous viruses of the same genotype. However, the bulk of the evidence would suggest that such immunization approaches do not provide a level or type of immunity that is sufficient for protection against persistent infection. This is in contrast with other evidence summarized above that suggests that immunization with recombinant gpE1/gpE2, while also failing to provide sterilizing immunity, might provide some protection against the development of subsequent persistent infection with closely related virus. Unfortunately, however, spontaneous resolution of acute HCV infections is a frequent occurrence in nonimmunized, HCV-naïve chimpanzees (Bassett et al., 1998). It is likely that compelling evidence for vaccine-induced protection against persistent infections will come only from clinical trials carried out in human subjects.

Genetic immunization is also being considered as an approach to therapy for persons with established, chronic HCV infection. A candidate therapeutic DNA vaccine, ChronVac-C (TriPep), is currently being evaluated in a nonrandomized, open-label phase I study of safety and immunogenicity. Based on pre-clinical results obtained in mice (Ahlen et al., 2007), this study will evaluate the use of electroporation to enhance delivery of the ChronVac-C vaccine in treatment-naïve patients with low virus loads.

RECOMBINANT VECTORED VACCINES

A variety of strategies for expression of HCV proteins by viral vectors have been explored extensively in mice. Viral vectors that have been utilized for the expression of both structural and nonstructural proteins of HCV include adenovirus (Arribillaga et al., 2002; Frelin et al., 2004), poxviruses, including canarypox virus and the MVA strain of vaccinia (Pancholi et al., 2003; Abraham et al., 2004), vesicular stomatitis virus (Majid et al., 2006), alphaviruses (Perri et al., 2003; Vidalin et al., 2000; Brinster et al., 2002), and ovine atadenovirus (Wuest et al., 2004). While of interest, however, such studies are generally not predictive of the immune responses to such immunization in larger animals, including humans. Nonetheless, a candidate virus-vectored vaccine, TG4040, is being developed by Transgene for use in humans using the MVA strain of vaccinia virus as an expression platform. MVA is highly attenuated, and not capable of replication in mammalian cells. The TG4040 vaccine is designed to express the nonstructural NS3, NS4, and NS5B proteins, and is intended to stimulate a therapeutic T-cell response. In transgenic HLA class I mice, an accelerated schedule of immunization with the vaccine was capable of inducing virus-specific cytolytic CD8+ T cells as well as specific CD4+ T responses (Fournillier et al., 2007). The TG4040 vaccine advanced to early phase I clinical trials to assess its safety and immunogenicity in 2007.

Bacterial and yeast-derived vectors have also been evaluated for expression of HCV proteins. The use of transformed attenuated *Salmonella typhimurium* AroA$^-$ strains expressing core or NS3 has been shown to efficiently prime cytotoxic T cells in mice, and to provide the ability to immunize mice orally (Liao et al., 2007; Wedemeyer et al., 2001). Yet another approach is the GlobeImmune GI-5005 Tarmogen, which is composed of whole, heat-inactivated recombinant *Saccharomyces cerevisiae* expressing a NS3–core fusion protein. In mice, GI-5005 induced antigen-specific proliferative and cytotoxic T-cell responses associated with Th1-type cytokine secretion, and led to eradication of tumor cells that expressed the NS3 protein (Haller et al., 2007). GI-5005 is being developed as a potential therapeutic vaccine. In November, 2007, GlobeImmune announced plans to advance GI-2005 to a phase II clinical trial after reporting results of a phase Ib trial in which six patients were said to have achieved reductions in circulating viral load of 0.75–1.25 $\log_{10}$.

INACTIVATED HCV AND VIRUS-LIKE PARTICLE VACCINES

The development of a conventional cell culture-propagated, whole virus vaccine became feasible with discovery of the genotype 2a JFH-1 virus that is capable of replication in cultured Huh7 human hepatoma cells (Lindenbach et al., 2006; Wakita et al., 2005). Inter-genotypic virus chimeras, constructed in the JFH-1 background but in which the structural proteins are derived from more prevalent genotype 1 viruses, are also replication competent and produce as many if not more virus particles (Pietschmann et al., 2006; Yi et al., 2007). Based on reported proprietary enhancements in the growth of virus and the ability of inactivated cell culture-produced virus to elicit HCVcc-neutralizing antibodies in mice, Toray Industries, Inc. announced plans in August, 2007, to develop an inactivated whole virus hepatitis C vaccine in collaboration with the National Institute for Infectious Diseases in Tokyo. So far, this work has not been published in the scientific literature, and numerous regulatory obstacles will need to be overcome to produce an acceptable product. Whether inactivated, cell culture-produced virus would have advantages over the use of recombinant proteins as immunogens is unknown, as is the ability of inactivated virus to induce protective immunity in animals.

HCV-like particles (HCV-LPs), composed of HCV structural proteins expressed in insect cells and assembled into particulate structures (Baumert et al., 1998), represent an interesting alternative to HCV vaccine development. These particles have a virus-like structure, and so could express conformational determinants that exist naturally but are not present in soluble recombinant proteins. HCV-LPs have been produced in insect cells with a recombinant baculovirus expressing cDNA encoding the structural proteins of HCV (core, E1, and E2, with or without p7) (Baumert et al., 1998). Morphologic and biophysical studies suggest that such particles may resemble virions present in infected humans (Baumert et al., 1998). In mice, HCV-LPs induced both humoral and cytotoxic and Th-cell responses directed against the core, E1, and E2 proteins (Baumert et al., 1999; Lechmann et al., 2001; Murata et al., 2003). Furthermore, immunization with HCV-LPs was able to protect mice against challenge with a recombinant vaccinia virus expressing the structural proteins of HCV (Murata et al., 2003). In another series of studies, HCV-LPs were combined with a novel adjuvant (AS01B, monophosphoryl lipid A [MPL], and QS21) to induce increased titers of antibodies directed against E1 and E2 (Qiao et al., 2003). However, HCV-specific humoral and cellular immune responses induced by HCV-LPs in baboons were only marginally enhanced by the use of adjuvants (Jeong et al., 2004). In a recent study, chimpanzees immunized with HCV-LPs or HCV-LPs adjuvanted with AS01B (two animals each) developed IFN-γ^+, IL-2+, CD4+, and CD8+ T-cell proliferative responses specific for core, E1, and E2. Surprisingly, however, there was little if any antibody response detected. The immunized chimpanzees were challenged with 100 CID_{50} of homologous infectious virus. Each of the immunized animals became infected, but the magnitude and duration of viremia was less than in historic control animals that had been similarly challenged in the past (Elmowalid et al., 2007). These early pre-clinical results are promising with regard to the cellular and humoral immune responses induced by HCV-LPs. Chimeric hepatitis B particles have also been studied as a potential expression platform for HCV antigens (Vietheer et al., 2007).

DENDRITIC CELL IMMUNIZATION

Ex vivo stimulation of dendritic cells (DC) has been considered based on the ability of DCs to potently present antigen and stimulate T-cell responses, and a large but conflicting body of evidence suggesting that DC function may be impaired in patients with chronic HCV infection (Decalf et al., 2007; Kanto and Hayashi, 2007; Kanto et al., 2004; Auffermann-Gretzinger et al., 2001). To date, this strategy has been studied only in vitro and in mouse models. In one study, considerably stronger cytotoxic T-lymphocyte responses were primed by injecting mice with DCs transduced with a recombinant adenovirus expressing the core protein, resulting in partial protection against challenge with a recombinant core protein-expressing vaccinia virus (Matsui et al., 2002). A second research group has also demonstrated the induction of humoral and cellular immune responses, and similar partial protection in a mouse challenge model, after adoptive immunization with DCs pulsed with the core protein in vitro (Encke et al., 2005). Immunization with DCs transduced to express nonstructural proteins has also been shown to generate strong virus-specific cytotoxic CD8+ and CD4+ Th1 responses (Racanelli et al., 2004; Zabaleta et al., 2008). Moreover, in recently published work, adoptive immunization with DCs transduced with adenoviral vectors encoding NS3 protein resulted in protection against the growth of NS3-expressing tumor cells, and also down-regulated intrahepatic expression of HCV RNA following transfection by

hydrodynamic injection (Zabaleta et al., 2008). In other studies, DCs from healthy, HCV-naive human subjects which were transduced to express nonstructural proteins with recombinant adenovirus were able to prime for antigen-specific autologous T-cell responses in vitro (Li et al., 2008). Taken together, these studies show that adoptive immunization with DCs transduced ex vivo to express HCV proteins has considerable potential to stimulate virus-specific immune responses. These studies need to be expanded to include the chimpanzee model in order to determine whether DC immunization has significant advantages over other immunization strategies for control of hepatitis C. In the long run, if it proves to be of practical value, DC immunization is likely be more useful for therapy than for prevention.

PASSIVE IMMUNIZATION

Early support for the potential efficacy of passive immunization against HCV came from a clinical trial, carried out prior to the discovery of HCV, in which the administration of pooled human γ-globulin protected against the development of chronic hepatitis following acute, transfusion-acquired non-A, non-B hepatitis acquired by blood transfusion (Knodell et al., 1976). However, since this study was carried out, screening for HCV has been introduced into transfusion medicine, and all donor units that test positive for HCV (and might contain significant levels of neutralizing antibodies to HCV) are discarded and no longer included in the manufacture of pooled human immune globulin (IG). Thus, an HCV-specific IG, anti-HCV immunoglobulin (HCIG), was developed that was enriched in antibodies to the virus (Piazza et al., 1999). The administration of HCIG to chimpanzees 1 h after challenge with infectious virus was found to extend the incubation period leading to acute hepatocellular disease, but did not delay or otherwise modify HCV infection (Krawczynski et al., 1996). The greatest clinical need for such a product would be in prevention of graft infection following liver transplantation in patients with chronic hepatitis C. However, in a randomized, open-label study involving such patients, the administration of 17 doses of HCIG (Civacir, Nabi Biopharmaceuticals) over a period of 14 weeks failed to suppress HCV infection or reduce viral RNA levels in transplant recipients (Davis et al., 2005). An expanded phase II study of Civacir is currently in progress.

HMAbs developed by XTL Biopharmaceuticals (Ab-XTL68 and Ab-XTL65, formulated as XTL-6865) recognize different conformational epitopes on the E2 glycoprotein. These antibodies were capable of inhibiting HCV infection and reducing viral load in infected mice with chimeric human livers (Eren et al., 2006). The administration of high doses of Ab-XTL68 also resulted in transient reductions in HCV RNA in a randomized, double-blind, placebo-controlled trial involving chronically infected patients undergoing liver transplantation (Schiano et al., 2006). However, in March, 2007, XTL announced that no statistically significant changes were observed in viral RNA levels in a phase I, ascending dose study of XTL-6865, which contains both antibodies. The current development status of XTL-6865 is uncertain. Genmab is currently pursuing the pre-clinical development of another human antibody with potential neutralizing activity against HCV (Hu-Max-HepC).

KEY ISSUES

- Immunity to HCV is very poorly understood. Acute infections progress to chronicity despite the induction of virus-specific CD4+ and CD8+ T cells and virus-neutralizing antibodies. However, prior infection protects against long-term persistence on rechallenge of chimpanzees, and this is dependent on CD4+ and CD8+ memory subsets. Although the role of antibodies in such protection is not well defined, a successful vaccine will likely need to induce both robust T- and B-cell responses.
- The capacity of HCV to persist for years in many infected persons may stem in part from its ability to mutate and thereby escape established CD8+ T cell responses and antibody-mediated neutralization.
- The six major genotypes of HCV have diverse genetic sequences. Evidence that immunity of any type can confer broad protection against infection with different genotypes is limited.
- Vaccine development is hindered by the absence of a small animal model of hepatitis C, and by the high costs and lack of availability of the chimpanzee model.
- Significant HCV-related disease (hepatic fibrosis, cirrhosis, and liver cancer) is typically associated with chronic infection. Acute infections are generally not severe. Thus sterilizing immunity is not required, and a vaccine that is capable of preventing persistent infection would be of substantial value.
- As current IFN-based treatment options for hepatitis C are inadequate, a therapeutic vaccine would be of value. Some candidates have entered clinical trials, but none has yet achieved the desired outcome of controlling or modifying the course of HCV infection.

ACKNOWLEDGMENTS

Human Immunodeficiency Virus

Farah Cassis-Ghavami, Marcel Curlin, Robert Geise and Ann Duerr
HIV Vaccine Trials Network, Seattle, WA, USA

OUTLINE

ABSTRACT

Human immunodeficiency virus (HIV) is one of the greatest worldwide public health challenges of the last century. Since being identified over 20 years ago, HIV has claimed an estimated 25 million lives. Currently, an estimated 33 million individuals are living with HIV/AIDS. Although it causes infections worldwide, this virus has especially targeted areas of the developing world, with prevalence rates nearing 50% among women of child-bearing age in some areas of sub-Saharan Africa.

Primary infection may be characterized by an acute viral syndrome or may be entirely asymptomatic, and individuals are often unaware of their infection. Symptomatic illness usually occurs several years after infection,

and is manifested by significant-to-severe immune suppression. Although antiretroviral therapy (ART) is generally effective at suppressing viral replication, treatment is not universally available and is often associated with serious side effects. Also, due to the high rate of mutation during viral replication, ART may become ineffective in noncompliant individuals.

The structure, genetics, and replication characteristics of HIV make it a challenging pathogen. HIV is a remarkably diverse virus, with two major types, and multiple subtypes and recombinant forms circulating worldwide. The viral envelope varies considerably from isolate to isolate, and has few conserved regions that can be effectively targeted by host antibody responses. Glycosylation of protein structures on the envelope coating hinder access by neutralizing antibodies, and widespread mutational change within the genome permits escape from cellular immune mechanisms. HIV preferentially infects activated host immune cells, which are diverted from their normal cellular biosynthetic pathways to produce virus particles, and undergo premature apoptosis. However, infected CD4+ T cells may also remain transcriptionally silent, leaving the incorporated proviral HIV genome dormant for many years. This results in a reservoir of infected cells that persists despite apparently effective therapy.

The development of an HIV vaccine that is protective and easily and economically deliverable is a daunting endeavor for scientists, public health officials, and government agencies. The field of HIV vaccine development has met with a number of recent disappointments. Both the VAXGEN antibody-based vaccine and the Merck adenovirus T-cell-stimulating vaccine showed no efficacy in protecting from infection or reducing viral loads. In fact, the Merck product, tested in the Americas and South Africa, may have led to an increased susceptibility to HIV infection in individuals with evidence of preexisting serological immunity to the adenovirus vector.

A new paradigm of HIV vaccine effectiveness may need to be considered. This paradigm includes vaccines that may: (1) prevent infection; (2) allow infection that is subsequently cleared without clinical disease; (3) delay clinical progression in the vaccinated individual; or (4) minimally impact disease in the infected individual, but reduce infection of others. Several new approaches are actively being tested in HIV vaccine development. DNA and peptide-based vaccines, heterologous prime-boost regimens, and alternative viral vector are under consideration and development. Scientists continue to use many different methodologies to optimize immunogenic HIV insert sequences in order to overcome the tremendous variability presented by potential infecting viruses. Other approaches seek to increase the recognition of viral antigens through the use of adjuvants and optimized modes of immunogen delivery. The next decade will provide opportunities for these hurdles to be overcome, and will likely see the emergence of new challenges as second- and third-generation vaccines are developed. Multidisciplinary approaches to vaccination may ultimately lead to complete control of this pandemic.

INTRODUCTION

The ongoing worldwide epidemic caused by the human immunodeficiency virus type 1 (HIV-1) remains a major global health challenge. HIV-1 causes the acquired immunodeficiency syndrome (AIDS), which is responsible for tremendous human suffering and economic loss throughout the world. According to The Joint United Nations Program on HIV/AIDS (UNAIDS), in 2007 the AIDS epidemic claimed more than 2 million lives, and an estimated 2.5 million people acquired HIV (UNAIDS, 2007). The number of people living with the virus globally is approximately 33 million. Without wider access to antiretroviral therapy (ART), it is likely that nearly all of these people will die of AIDS in the next two decades. While recent efforts are moving forward to provide treatment and HIV-related care to those most in need in southern Africa, the pandemic continues to spread, encompassing such areas as India, China, and the former Soviet Union. Current projections suggest that an additional 45 million people will become infected with HIV between 2004 and 2010 unless the world succeeds in mounting a drastically expanded global prevention effort (UNAIDS, 2004). AIDS has become the leading infectious disease killer, and the fourth leading cause of death overall. In severely affected countries, life expectancy has fallen by more than 10 years (Dorling et al., 2006).

Since 1996, potent new ARTs, including combination regimens with protease inhibitors, have shown that HIV-1 infection can become a chronic, manageable disease among individuals with access to these medications. However, an effective vaccine remains our best chance of ultimately curtailing this epidemic.

HISTORY OF HIV

Discovery of HIV

AIDS was first recognized in the United States in 1981 following a sudden outbreak of opportunistic infections, including Pneumocystis carinii pneumonia and Kaposi's sarcoma (KS) among homosexual men (Durack, 1981; Gottlieb et al., 1981; Masur et al., 1981). Subsequent

epidemiologic studies implicated an infectious agent that was transmitted during sexual intercourse, through intravenous drug abuse, by therapies utilizing blood and blood products, and vertically from mother to child (Broder et al., 1994).

In 1983, Barre-Sinoussi, Chermann, and Montagier at the Pasteur Institute in Paris isolated a retrovirus from lymph node cells of a patient with lymphadenopathy; accordingly, this virus was designated lymphadenopathy-associated virus (LAV) (Wain-Hobson et al., 1991; Barre-Sinoussi et al., 1983). Several other laboratories were also searching for the agent responsible for AIDS. In 1984, Gallo and associates reported the characterization of another human retrovirus distinct from human T-lymphotropic virus (HTLV) that they called HTLV-III (Gallo et al., 1984; Popovic et al., 1984; Sarngadharan et al., 1984; Schupbach et al., 1984). Levy et al. (1984) simultaneously reported the identification of retroviruses that they named the AIDS-associated retroviruses (ARVs). Within a short time, the three prototype viruses (LAV, HTLV-III, and ARV) were recognized as members of the same group of retroviruses, and their properties identified them as lentiviruses. Their proteins were all distinct from those of HTLV (Rabson and Martin, 1985). The AIDS viruses had many properties distinguishing them from HTLV. For all these reasons, in 1986, the International Committee on Taxonomy of Viruses recommended giving the AIDS virus a separate name, human immunodeficiency virus (Coffin et al., 1986).

HIV isolates were subsequently recovered from the blood of many patients with AIDS, AIDS-related complex, and neurologic syndromes, as well as from the peripheral blood mononuclear cells (PBMCs) of several clinically healthy individuals (Salahuddin et al., 1985; Levy and Shimabukuro, 1985; Levy et al., 1985). The widespread transmission of this agent was appreciated and its close association with AIDS and related illnesses strongly supported its role in these diseases. Soon after the discovery of HIV-1, a separate epidemic caused by a related human retrovirus, HIV-2, was identified in West Africa (Clavel et al., 1987). Both HIV subtypes can lead to AIDS, although disease progression due to HIV-2 infection appears to be slower (Reeves and Doms, 2002; Whittle et al., 1994; Kanki et al., 1992).

HIV CLASSIFICATION AND STRUCTURE

HIV Structure

HIV is a member of the genus *Lentivirus* in the Retroviridae family. Retroviruses are so called because their RNA genome is transcribed into DNA within the cell using the viral enzyme reverse transcriptase (RT). This DNA then enters the nucleus and integrates into the cellular chromosome. A mature virion has a spherical shape and consists of an outer lipid bilayer membrane or envelope that surrounds the cone-shaped nucleocapsid (Fig. 25.1). The core appears to be attached to the viral outer envelope at its narrow end (Hoglund et al., 1992). The outer membrane contains approximately 10–20 spiked knobs (Zhu et al., 2003), which are assembled as trimers of the outer envelope protein gp120 bound to the transmembrane portion, gp41. The viral membrane is cholesterol-rich (Liao et al., 2001) and includes cellular proteins (Hoglund et al., 1992).

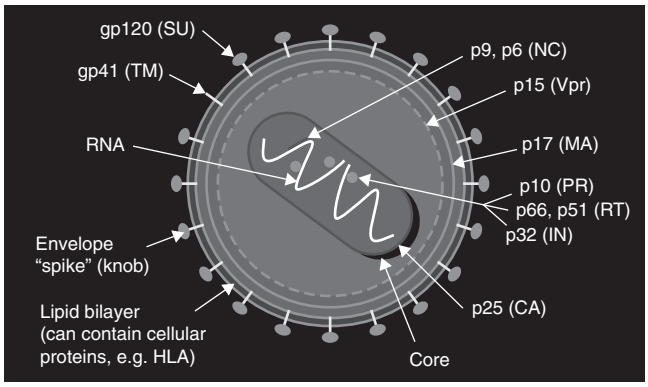

FIGURE 25.1 HIV virus structure. Reproduced with permission from Levy (2007).

Each mature virion is composed of two molecules of single-stranded RNA surrounded by three *gag* gene cleavage products: the p17 outer matrix protein; the p24 major capsid protein, which forms the capsid shell; and the p7 nucleoprotein, which binds tightly to the viral RNA. The nucleocapsid is composed of a p17 myristoylated outer-matrix protein sandwiched between the membrane-bound envelope and the p24 core capsid protein. The p7 protein binds the two positive-strand copies of complete viral RNA attached at the packaging site, and it also binds to p24. A number of other viral proteins required for the early phases of infection are incorporated with the virion. These include protease, which is essential for viral assembly, and reverse transcriptase and integrase, which are needed after entry for viral DNA synthesis and integration (Mandell et al., 2005).

HIV Genome

The HIV genome is approximately 9.8 kb in length (Muesing et al., 1985). Both ends of the provirus are

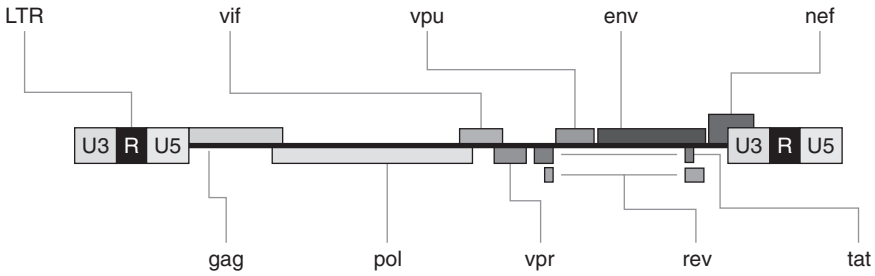

FIGURE 25.2 HIV genome. An overview of the organization of the approximately 9-kb genome of the HIV provirus. Reprinted with permission from Greene and Matija (2003).

flanked by a repeated sequence known as the long terminal repeat (LTR). The HIV proviral genome encodes at least nine proteins (Fig. 25.2) (Gallo et al., 1988). Table 25.1 lists the viral proteins and their functions.

HIV Phylogeny

Currently, based on full-length viral genome sequencing, there are three major HIV-1 groups called M (main), O (outlier), and N (non M or O) (Fig. 25.3). Eight HIV-2 groups have been identified (Peeters et al., 2003). HIV-1 group M has been divided into nine clades (or subtypes), designated A to D, F to H, J, and K (Peeters et al., 2003; Robertson et al., 2000). Some subtypes have been distinguished for groups O, but only a few isolates of group N have been identified. No subtypes of the HIV-2 groups have yet been identified (Robertson et al., 2000). Each HIV-1 M clade differs from the others in amino acid composition by at least 20% in the envelope region and 15% in the Gag region (Robertson et al., 2000).

In the HIV-1 M group, subtype A is found primarily in Central Africa, clade B in North America and Europe, clade C in South Africa and India, and clade D in Central Africa. Subtype F includes a few isolates from Brazil (Potts et al., 1993) and all of the viruses thus far characterized from children in Romania (Dumitrescu et al., 1994). Other group M subtypes include viruses from Russia (G) (Bobkov et al., 1994), Africa and Taiwan (H) (Los Alamos National Laboratory, 2001), Zaire (clade J) (Laukkanen et al., 1999), and Cameroon (clade K) (Roques et al., 1999). The M group also includes many circulating recombinant forms (CRF) (Korber et al., 2001; Thomson et al., 2002), which encode genetic structures from two or more subtypes (e.g., A/E = CRF01AE; A/G = CRF02AG). Presently there are 16 recognized CRFs derived from HIV-1 group M isolates (Peeters et al., 2003; Robertson et al., 2000).

PATHOGENESIS

Overview

HIV transmission to an uninfected host occurs across mucosal surfaces during sexual contact, parturition, and early infancy (Ruprecht et al., 1999), and by traumatic introduction of virus particles across the intact dermis during percutaneous exposure. Infectious virus particles attach to a restricted set of host target cells through specific receptor/ligand mediated interactions between viral and cell membrane surfaces. Following attachment, fusion of the viral lipid membrane and the host cell membrane results in the release of viral nucleocapsid contents into the cytoplasm. The host RNA genome undergoes reverse transcription during transit to the cell nucleus, and subsequently integration into the host genome. Transcriptionally active cells produce new virus particles by nonlytic mechanisms to complete the life cycle. Viral genes may also remain transcriptionally silent within long-lived lymphocytes cells, resulting in the presence of a latent reservoir. Host humoral and cellular responses mediate the lysis of infected cells and contribute to the rapid clearance of virus particles from blood, but generally do not result in suppression of viremia or elimination of infected cells. Infected CD4+ T lymphocytes undergo cell death by direct and indirect mechanisms, resulting in depletion of CD4 T-lymphocytes and profound immune dysregulation over a period ranging from years to decades. Host demise is ultimately precipitated by onset of opportunistic infections.

Transmission across the Epithelium

Horizontal transmission of HIV to an uninfected host generally occurs through either percutaneous exposure, or across a mucosal surface. During percutaneous infection, a source of replication-competent virus particles is introduced into the systemic circulation,

TABLE 25.1 HIV proteins and their functions

Proteins[a]	Size (KD[a])	Function
Gag	p24	Capsid (CA), structural protein
	p17	Matrix (MA) protein, myristoylated
	p7	Nucleocapsid (NC) protein; helps in reverse transcription
	p6	Role in budding (L domain)
Polymerase (pol)	p66, p51	Reverse transcriptase (RT); RNAse H-inside core
Protease (PR)	p10	Post-translation processing of viral proteins
Integrase (IN)	p32	Viral cDNA integration
Envelope	gp120	Envelope surface (SU) protein
	gp41	Envelope transmembrane (TM) protein
Tat[b]	p14	Transactivation
Rev[b]	p19	Regulation of viral mRNA expression
Nef	p27	Pleiotropic, can increase or decrease virus replication
Vif	p23	Increases virus infectivity and cell:cell transmission; helps in proviral DNA synthesis and/or in virion assembly
Vpr	p15	Helps in virus replication; transactivation
Vpu[b,c]	p16	Helps in virus release; disrupts gp160:CD4 complexes
Vpx[d]	p15	Helps in entry and infectivity
Tev[b]	p26	Tat/Rev activities

where direct contact between host CD4+ T lymphocytes and infectious virions presumably results in productive infection. Infection across mucosal surfaces of the genitourinary and gastrointestinal (GI) tracts generally takes place through sexual contact, during parturition, and after exposure through breastfeeding. Viral translocation across mucosal surfaces may occur through several mechanisms. Viruses are taken up and transported across the epithelium by intraepithelial dendritic cells (DC), which may either be directly infected, or trap intact virions on the cell surface in a form suitable for antigen presentation (Geijtenbeek et al., 2000; Kwon et al., 2002). HIV has also been shown to cross the epithelium through mechanical breaches caused by trauma or infection, allowing direct contact with and infection of local CD4+ T-cells and tissue macrophages. Infected DC (Kwon et al., 2002), T-cells, and macrophages present at the site of transmission travel via afferent lymphatic channels to regional lymph nodes (Pope et al., 1995), where surface-expressed and newly synthesized virus particles establish new rounds of infection. In this way, HIV subverts normal antigen-processing pathways to access suitable targets for viral replication within the host.

The Replication Cycle

Host Cell Binding

HIV replication cycle occurs through a series of partially defined steps from viral entry to the budding of new particles from the infected cell surface. Infectious virus particles attach to the host target cell through the interaction between a trimeric complex of three surface gp120 molecules (Earl et al., 1990) and three transmembrane gp41 molecules within the

viral envelope, and CD4 expressed on the host plasma membrane. Binding of viral gp120 with CD4 triggers a series of conformational changes which expose binding sites to an additional host cell coreceptor that is required for entry (Sullivan et al., 1998). Although 12 distinct chemokine receptor molecules have been shown to serve as chemokine coreceptors for HIV entry in vitro, only two appear to be important for viral pathogenesis in humans (Berson et al., 1996; Deng et al., 1996; Feng et al., 1996). Primary infection and chronic disease are generally characterized by viral populations tropic for CCR5, while viruses tropic for CXCR4 are observed in late infection in some individuals (Scarlatti et al., 1997), and may herald profound immune dysfunction.

Membrane Fusion

Transmembrane gp41 is present as a six helix bundle in a noncovalent association with gp120 in the viral envelope (Chan et al., 1997). Full binding of gp120 to CD4 and either CCR5 or CXCR4 induces major conformational changes within g41 (Chan and Kim, 1998), which dissociates from gp120, and inserts a hydrophobic fusion peptide "harpoon" into the host cell membrane. Gp41 subsequently folds back upon itself into a hairpin-like structure, drawing the viral and cell membranes into close proximity, immediately prior to fusion (Chan and Kim, 1998). Fusion of the viral and cell membranes is followed by release of the contents of the nucleocapsid into the cytoplasm. Following entry, both strands of the viral RNA genome are associated with reverse transcriptase, integrase, viral protein R (Vpr), lysine transfer RNA ($tRNA^{LYS}$), host cell actin filaments, and other host and viral proteins (Karageorgos et al., 1993; Bukrinskaya et al., 1998). This aggregation constitutes the reverse transcriptase complex which effectuates reverse transcription of the viral genomic RNA into DNA during transit to the cell nucleus (Karageorgos et al., 1993).

Entry and Reverse Transcription

Reverse transcription of the diploid single-stranded (+) RNA genome into double-stranded DNA is accomplished by the retroviral enzyme reverse transcriptase. Reverse transcription of the RNA template occurs through a series of well-defined molecular steps, beginning with the priming of an RNA strand by $tRNA^{LYS}$, proceeding through two-strand-transfer jumps in which a nascent DNA segment jumps to a complementary region of the template strand, and ultimately resulting in the polymerization of two complementary proviral DNA strands. During this process, the RNA template undergoes degradation catalyzed by the RNAse H portion of reverse transcriptase. Because RNAse does not have a proofreading function, reverse transcription is extremely error-prone, resulting in the frequent introduction of point mutations during each generation. In addition, strand-transfer errors may result in insertions, deletions, and recombination in the newly transcribed viral genome (reviewed in Gotte et al., 1999). These changes underlie the enormous genetic variability characteristic of HIV.

Nuclear Entry and Integration

After reverse transcription, the HIV preintegration complex (PIC), composed of double-stranded proviral DNA, integrase, and several additional proteins (Miller et al., 1997), enters the host cell nucleus. In contrast with other retroviruses, the HIV PIC may enter the nucleus of both dividing and nondividing cells (Weinberg et al., 1991). The size of the PIC is considerably larger than the 25 nm diameter of nuclear pores (Pemberton et al., 1998), and the precise mechanisms by which entry takes place are unclear (Dvorin et al., 2002). This process may involve binding of a "DNA flap" domain to host nuclear targeting proteins (Zennou et al., 2000), or transient herniations of the nuclear membrane with intravasation of cytoplasmic contents into the nucleus. Once in the nucleus, the viral integrase gene and poorly characterized cellular cofactors catalyze proviral DNA integration into the host chromosome, preferentially targeting active host gene regions. Proviral DNA may also undergo autointegration, resulting in episomic, replication-incompetent LTR circles (Li et al., 2001).

Transcription

The integrated HIV genome may reside in a dormant state within resting cells (Adams et al., 1994), or become transcriptionally active. The former circumstance accounts for the persistence of HIV within latent reservoirs despite therapy. Transcriptional activation of the integrated proviral genome appears to be dependent on several host cellular factors that are upregulated following cell activation, and is greatly enhanced by the presence of the viral tat protein (Kao et al., 1987). Tat acts in part to recruit transcriptional factors to the HIV LTR region, a process that is inefficient in the absence of tat (Wei et al., 1998). The HIV genome contains numerous donor (5′) and acceptor (3′) splice sites, allowing at least 30 alternative mRNA molecules to be made from a single HIV proviral gene. Transcription products include the full-length unspliced primary transcript (~9 kb) and a variety of partially and fully

spliced mRNAs encoding the viral *env* protein and the six accessory gene products of the viral genome (Saltarelli et al., 1996). Viral replication depends on a balanced production of unspliced and spliced transcriptional products.

Viral Assembly and Budding

Viral mRNA translation products (gag, gag-pol, vpr, and vif gene products) and two full-length viral genomic RNA molecules are assembled at the plasma membrane for packaging into a new virus particle (Fig. 25.4) (Wilk et al., 2001). Assembly and budding appear to require the action of both viral proteins and host cytosolic proteins (Zimmerman et al., 2002), which are diverted from their normal cytosolic functions. Host proteins involved in viral assembly and budding include tumor suppressor gene 101, which normally functions to direct products to incorporation within multivesicular bodies for degradation (Martin-Serrano et al., 2003; Bieniasz, 2006). Budding of virus particles takes place preferentially near cholesterol-rich rafts in the plasma membrane (Liao et al., 2001; Ono and Freed, 2001), resulting in enrichment of cholesterol within the viral membrane, a factor that may be important for subsequent fusion events during infection of a new host cell (Liao et al., 2001).

Viral Latency

Most T cells that become infected during successive rounds of replication are activated CD4+ T lymphocytes which go on to become productively infected cells producing progeny viruses, and ultimately die after several days due to viral cytopathic effects or host immune mechanisms. However, in some cases, T cells destined to become long-lived, quiescent memory T lymphocytes express sufficient CCR5 on the cell surface to become infected. These cells progress to a state of transcriptional inactivity, but contain one or more HIV proviral genomes, resulting in the maintenance of a long-lived latent viral reservoir (Finzi et al., 1997; Chun et al., 1997). Latently infected cells may undergo reactivation at a later time by exposure to antigen, resulting in upregulation of transcriptional activity and virus production. The size of the latent HIV reservoir in humans is unclear, but has been estimated to be approximately 10^6 cells, and may have a half-life in excess of 43 months (Finzi et al., 1997; reviewed in Pierson et al., 2000). The presence of the latent reservoir is responsible for persistent infection despite long-term effective therapy, and ensures that decades of continuous and complete inhibition of viral replication would be required to cure HIV through ART alone. "Flushing out" latently infected cellular reservoirs of HIV continues to be investigated as an approach to eradicating HIV from the host (Kulkosky et al., 2002; Stellbrink et al., 2002; Fraser et al., 2000).

Death of Infected Target Cells

A wide range of host cells are susceptible to HIV infection. However, the cell populations most directly involved in the process of transmission and virus production during all stages of illness are CD4-bearing cells of the host immune system, including DC,

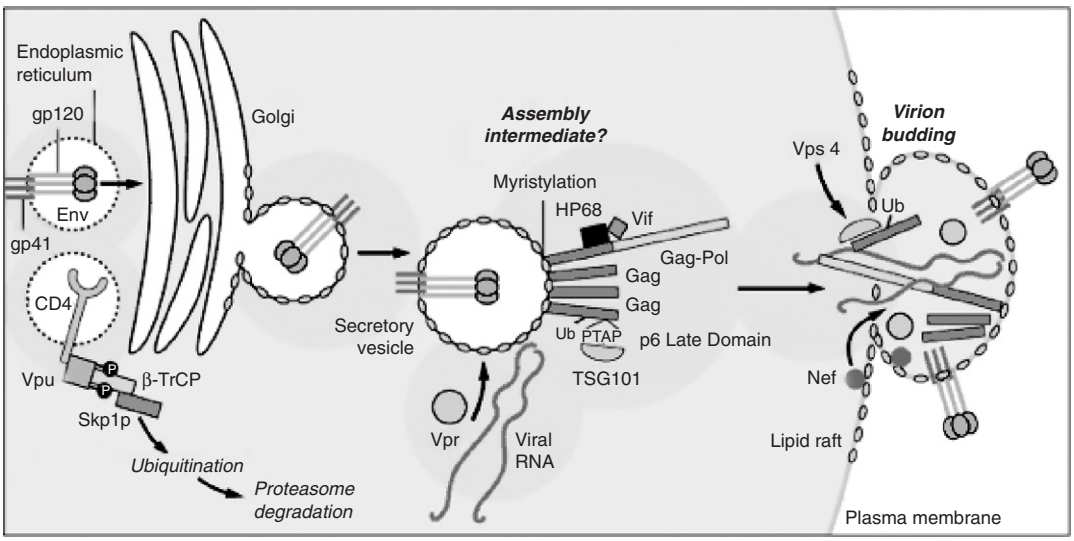

FIGURE 25.4 Viral assembly and budding. The figure depicts assembly of new virus particles, and budding from a cholesterol-rich raft in the plasma membrane. Adapted with permission from HIV InSite (see color plate section).

activated and resting memory CD4+ T lymphocytes, and macrophages. Of these, the activated memory CD4+ T cell, and in particular, the HIV-specific memory T cell (Douek et al., 2002), is preferentially infected in vivo. Other host cells may also support infection, including CD8+ T cells (Roederer et al., 1995) astrocytes and other cells of the central nervous system (Rothenaigner et al., 2007), capillary endothelial cells, columnar cells of the GI tract, pulmonary fibroblasts, renal tubular cells, and several other cell types. The full pathophysiologic significance of these other infected cell populations is unclear. Productively infected cells typically have a shortened life span. For example, the activated CD4+ T cell typically dies within several days of infection (Patki et al., 2000; Bolton et al., 2002; Lenardo et al., 2002). Infected tissue macrophages and DC may persist for weeks to months (Smith et al., 2001), respectively. Numerous mechanisms have been advanced to account for the profound loss of CD4+ T cells that occurs during primary HIV infection, including direct cell killing of host cells (Mattapallil et al., 2005; Li et al., 2005), cytopathic effects of HIV transcriptional products (Bolton and Lenardo, 2007; Sakai et al., 2006; Jones et al., 2007; Weinhold et al., 1989), host cytolytic activity, and bystander effects causing apoptosis of uninfected neighboring cells (Holm and Gabuzda, 2005). The relative contribution of direct and indirect mechanisms to CD4+ cell loss has been a matter of significant debate (Anderson et al., 1998; Grossman et al., 2002; Veazey and Lackner, 2005).

CD4 T-Lymphocyte Homeostasis

Primary HIV infection is typically associated with an abrupt fall in the peripheral CD4+ T-cell count, which is followed by a partial recovery and slow decline over years before reaching the levels associated with AIDS. However, the presence of a modest decline in CD4+ T cells in the periphery during early and chronic disease may mask a more significant state of immune dysregulation. Approximately 60–65% of all body CD4+ T cells are located within the GI tract (Cerf-Bensussan and Guy-Grand, 1991; Mowat and Viney, 1997), either as lamina propria lymphocytes or intraepithelial lymphocytes. Moreover, nearly all of these are activated cells (Zeitz et al., 1988) and thus ideal targets for HIV infection. Recent work has demonstrated that following infection by any route, there is early massive viral replication and nearly total CD4+ cell loss within the GI tract (Mehandru et al., 2004, 2006; Brenchley et al., 2004), and that CD4+ cell recovery in this site during chronic infection is very poor despite ART (Mehandru et al., 2006). The profound immunologic disruption at this site may underlie the immunologic changes leading to failure of the immune system during disease progression.

The gradual failure of CD4 T-cell homeostasis that occurs during chronic disease progression has been ascribed to a state of heightened immune activation (Giorgi and Detels, 1989; Bouscarat et al., 1996; Lederman et al., 2000; Hazenberg et al., 2000; Sousa et al., 2002), increased T-cell production and T-cell loss (De Boer et al., 2003). In the uninfected host, naïve CD4+ thymocytes may occasionally become activated in response to antigens, and then may enter the resting memory CD4+ pool, but more frequently undergo apoptosis (Patki et al., 2000). CD4+ T-cell loss is balanced by new thymic production of naïve CD4+ cells. In the otherwise healthy adult, abrupt depletion of CD4 cells is followed by gradual recovery that is limited by thymic output, and is attenuated in comparison with CD8 recovery (Atkinson et al., 1982; Watanabe et al., 1997; Mackall et al., 1997). During chronic HIV infection, after the profound CD4+ T-cell loss of primary infection, recovery of CD4+ T cells is further hampered by abnormally upregulated activation and apoptotic death of CD4+ cells, histological and functional disruption of lymphatic tissue, and impaired output from the marrow (Louache et al., 1992; Marandin et al., 1996) and thymus (Kalayjian et al., 2003). Thus, CD4 T-cell homeostasis during chronic infection is characterized by abnormally high cellular turnover (De Boer et al., 2003). The precise dynamic mechanisms leading to T-cell depletion over time remain a matter of some conjecture. According to one widely held view, failure is likened to a "tap and drain" model (Amadori et al., 1996), in which CD4 T-cell loss slightly exceeds production capacity, resulting in gradual CD4 T-cell depletion (Fig. 25.5).

Viral Diversity and Pathogenesis

The enormous rate of virus production (10^{10} particles each day) (Ho et al., 1995; Ramratnam et al., 1999) and high rate of error (10^{-5} changes per base pair per generation) (Mansky and Temin, 1995) characteristic of HIV replication permit the virus to accumulate a tremendous degree of genomic variation over time. For example, it has been estimated that the genetic diversity of the entire worldwide influenza A virus gene pool is approximately equal to the HIV-1 genetic diversity typically present within a single infected individual (Korber et al., 2001). The exceptional ability of HIV to change over time allows the infecting viral population to effectively adapt to environmental selective pressures. Through antigenic variation,

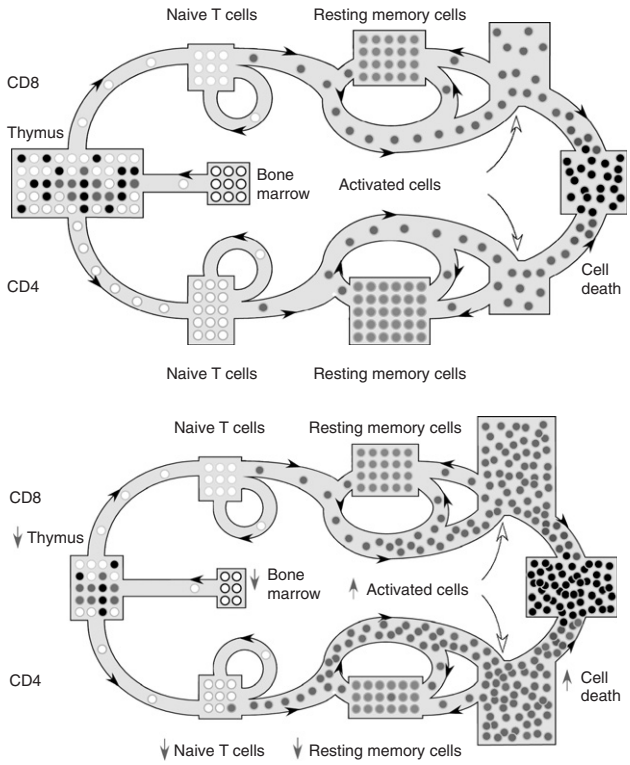

FIGURE 25.5 Disruption of normal T-cell homeostasis due to HIV infection. (A) Under normal conditions, losses from the resting memory CD4+ and CD8+ T lymphocyte pools through activation, and apoptosis are balanced by the input of new naïve T cells from the marrow and thymus. (B) During chronic HIV infection, increased activation of both CD4+ and CD8+ T cells results in increased cell turnover. CD4+ T-cell homeostasis is relatively impaired because of reduced output from marrow and thymus, resulting in a smaller pool of naïve T cells and resting memory CD4+ T cells. Naïve cells, clear center; resting memory cells, light gray center; activated cells, hatched center; dying cells, black center; HIV-infected cells, speckled center. Processes/cell populations affected by HIV infection are highlighted by upward and downward arrows Adapted with permission from Douek (2003) (see color plate section).

HIV is able to evade host humoral and cell-mediated immunity. Similarly, HIV readily evolves resistance mutations to nearly all known antiretroviral agents, leading to therapeutic failure during clinical management (Fournier et al., 2005; Haddad et al., 2000; Orkin et al., 2005; Raguin et al., 2004; Saag, 2004; Sabin et al., 2005). Finally, HIV is able to exploit a wide range of cellular niches. For example, by expanding its coreceptor tropism during disease progression to allow CXCR4 usage, HIV may infect a wider range of cells including naïve T cells, thereby further exacerbating host CD4 depletion (Scarlatti et al., 1997; Connor et al., 1997; de Roda Husman et al., 1997; Berkowitz et al., 1998). Thus, viral evolution drives many of the processes resulting in disease progression and poor clinical outcome in the human host.

PROTECTIVE IMMUNE RESPONSE

Overview

Both humoral and cell-mediated adaptive immune responses are elicited in response to HIV infection. Because cytotoxic T lymphocytes (CTL) can only recognize infected cells, cytolytic mechanisms cannot prevent infection, but are thought to be the primary immunologic mechanism in response to a variety of viral infections in mammals. Cytotoxic CD8+ T-cell responses appear to be the earliest meaningful responses following HIV infection, and are credited with reducing plasma viral load to steady-state levels from the peak levels seen during primary infection. Humoral immunity arises within weeks of primary HIV infection, and the detection of host antibodies (Ab) to HIV antigens forms the basis of the HIV enzyme linked immunosorbent assay (ELISA), the serological test that is most widely used to screen for HIV infection. Host Ab are capable of rendering virus particles inactive, and theoretically could provide sterilizing immunity from infection. However, neutralizing antibodies (nAb) are not believed to have a major role in controlling viral replication during chronic HIV infection. Less information is available on the role of innate immune mechanisms in controlling HIV.

Antibody Response to HIV

Humoral immunity constitutes one of the two major limbs of the adaptive immune system in mammals. Ab are elicited in response to most infections in humans, and are capable of providing protection from challenge by a wide range of bacterial and viral pathogens after vaccination or natural infection (Robbins et al., 1995). HIV-specific Ab are primarily directed against epitopes within the viral gp120 and gp41 proteins that are expressed on the surface of the viral plasma membrane (Hansen et al., 1990; Scanlan et al., 2002; Ugolini et al., 1997; Valenzuela et al., 1997; Sattentau and Moore, 1995). The antibody response to HIV is therefore confined to targets within a relatively narrow portion of the viral genome. HIV-specific Ab have been shown to interfere with HIV replication through several mechanisms. nAb, by definition, abrogate the ability of the virus to infect new host cells. Anti-HIV nAb generally function by binding to conserved epitopes on gp120 and gp41 necessary for engagement with CD4 (Ugolini et al., 1997; Zhou et al., 2007) or the host cell chemokine coreceptor (Decker et al., 2005; Trkola et al., 1996), or to domains necessary for fusion (Fig. 25.6) (Golding et al., 2002;

Gorny and Zolla-Pazner, 2000). Non-nAb may also impact viral replication, through antibody-dependent cellular cytotoxicity (ADCC) (Tyler et al., 1990; Koup et al., 1991; Jewett and Bonavida, 1990). Ab binding to viral peptides expressed on the surface of the infected cell stimulate engagement of cytotoxic cells bearing the Fc receptor, including NK cells, macrophages, and other cell types, resulting in cell-mediated lysis.

HIV has evolved several static and dynamic strategies to evade host humoral response. In its functional form, gp120 is present on the viral surface in a noncovalently bound trimeric configuration (Earl et al., 1990), in which sensitive epitopes are shielded from exposure to Ab. Binding to CD4 induces conformational changes which temporarily expose chemokine coreceptor binding sites (Sullivan et al., 1998; Sattentau and Moore, 1995) to allow completion of attachment and fusion. Because several important nAb epitopes are located within these binding regions, important targets for the nAb response are only transiently exposed to neutralization (Labrijn et al., 2003). In addition, monomeric gp120 and other fragmentary degradation products are copiously produced during the process of viral replication (Moore et al., 2006; Wyatt and Sodroski, 1998). While monomeric gp120 is highly immunogenic, Ab generated in response to monomeric gp120 are typically nonneutralizing (Sattentau and Moore, 1995). Immune responses are thereby diverted to decoy targets and are rendered ineffective in clearing circulating viruses. HIV has also been shown to evolve under selective pressure imposed by humoral immunity. The HIV *env* genes contain five hypervariable loops, V1–V5, which are the most highly variable regions of the genome. Extensive length polymorphism, particularly within V1 and V2, and point mutations throughout *env* permit viral escape from circulating Ab (Moog et al., 1997; Deeks et al., 2006; Albert et al., 1990; Geffin et al., 2003). Studies have also demonstrated that bulky glycan sidechains inserted at N-linked glycosylation sites (NLGS) may protect important epitopes within gp120, and that virus escape from nAb in vivo and in vitro can be directly attributed to the evolution of new NLGS within env under antibody-mediated selective pressure (Wei et al., 2003). Thus, the virus particle may be protected from nAb by an "evolving glycan shield."

Following natural infection in humans, anti-HIV Ab arise within weeks and continue to persist and evolve throughout chronic infection (Wei et al., 2003), before waning in intensity in some individuals with the onset of AIDS. Most Ab produced by the host are ineffective at neutralizing circulating virus particles. Host plasma has been shown in some laboratory studies to neutralize viruses that had been circulating at earlier times, but most studies suggest that the host-specific nAb

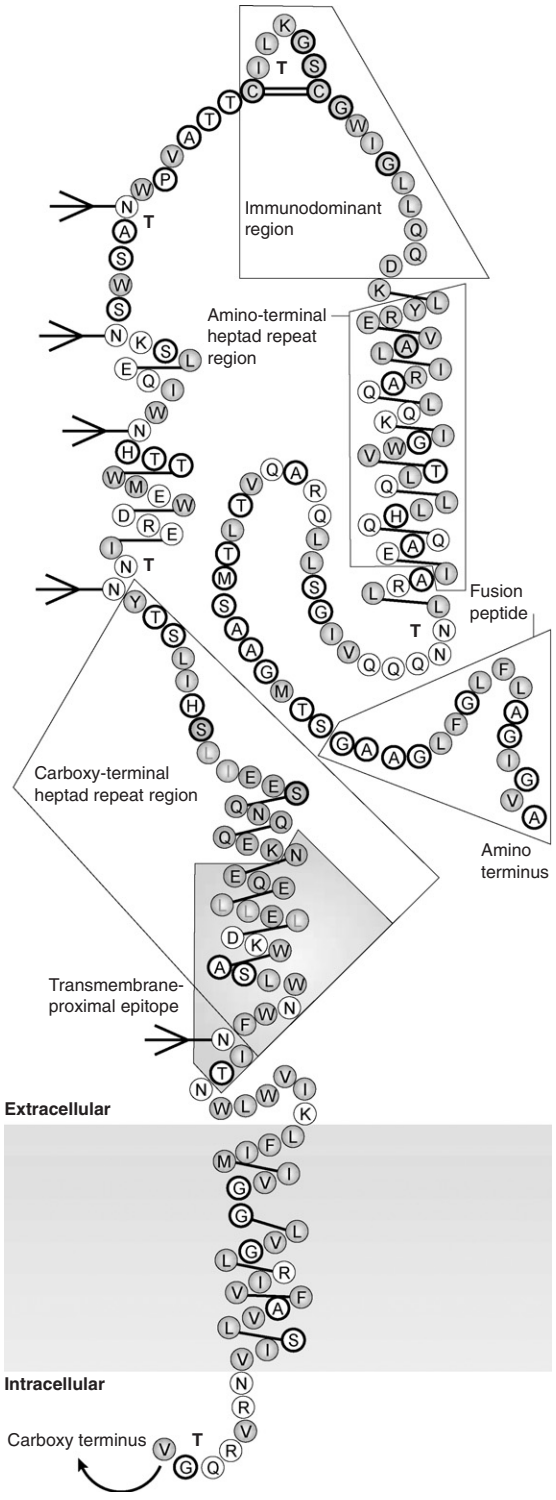

FIGURE 25.6 HIV gp41. Schematic diagram of HIV transmembrane protein gp41, depicting functional regions important for virus entry into the host cell, and sites important for immune responses. Hydrophobic amino acids shown in gray, charged amino acids shown as unfilled circles, neutral amino acids outlined in bold, potential N-linked glycosylation sites shown as branched stick figures. Important antibody epitopes are presented in turquoise, pink, and yellow. Adapted from Zolla-Pazner (2004) (see color plate section).

response lags significantly behind viral evolutionary changes (Moog et al., 1997; Albert et al., 1990; Wei et al., 2003), and is thus poorly able to neutralize contemporaneous virus populations. Passive immunity studies have shown that antibody responses can block infection in macaques and chimpanzees (Emini et al., 1992; Gauduin et al., 1995; Shibata et al., 1999; Mascola et al., 2000). However, there is relatively little evidence for a relationship between nAb responses and clinical outcome during natural infection. Some, but not all, studies in long-term nonprogressors have suggested an association between the nAb response and slowed disease progression (Harrer et al., 1996; Montefiori et al., 1996; Binley et al., 1998). Two large phase III efficacy trials based on eliciting Ab to *env* epitopes failed to demonstrate protection from infection. The impact of humoral immunity on infection and disease progression and the importance of Ab in providing protection from HIV challenge after vaccination continue to be a matter of debate.

Cell-Mediated Immunity to HIV

Cytotoxic CD8+ T cells recognize infected host cells through a highly specific interaction with viral proteins that are coexpressed on the surface of infected cells in association with major histocompatibility (MHC) class I molecules. These complexes arise when viral proteins produced during HIV replication are cleaved into short peptides of 8–11 amino acids by cell peptidases, and redirected to the endoplasmic reticulum for binding to MHC molecules and eventual transportation to the plasma membrane. The CD8+ T cell engages infected cells through binding of the T-cell receptor (TCR) with viral antigen–MHC complexes. TCR binding is epitope-specific, and CD8+ T cells are restricted to a single epitope based on the configuration of the TCR. After binding, several mechanisms mediate killing of the infected target cell (Kagi et al., 1994). Following the release of lysis granules, perforin may insert into the target cell plasma membrane, creating ion channels which cause osmotic dysregulation of and lysis of the target cell. Binding of Fas ligand (Fas-L) with Fas expressed on the target cell surface causes apoptotic cell death through a series of programmed cytoplasmic and nuclear events (Nagata and Golstein, 1995). Activated CD8+ cells also release interferon gamma (INF-γ), as well as the beta chemokines MIP-1α, MIP-1β, and RANTES, the natural ligands of CCR5 (Cocchi et al., 1995). Release of these soluble products cause neighboring cells to become intrinsically more refractory to viral infections, or less susceptible to HIV by reducing the surface expression and/or binding availability of CCR5 (Cocchi et al., 1995).

A number of factors act to limit the effectiveness of the CD8+ cytotoxic response in humans. CD8+ T cells from HIV-1 infected individuals have shown numerous defects, including dysregulated cytokine expression (Tanaka et al., 1999; Garba et al., 2002; Barker et al., 1995), abnormal skewing towards preterminally differentiated maturation states (Champagne et al., 2001), upregulation of immunomodulatory surface receptors (Trautmann et al., 2006), impairment of granule-dependent lysis (perforin and granzyme A) (Yang et al., 2005; Andersson et al., 2002; Chiang et al., 1996; Trabattoni et al., 2004), anergy in the presence of HIV antigens (Lichterfeld et al., 2004), and increased susceptibility to apoptotic signals (Petrovas et al., 2004). Finally, HIV-1 may interfere with CD4 helper function by causing depleting CD4 cells (Douek et al., 2002; Brenchley et al., 2006), or by inducing an inappropriate skewing of the CD4 helper function toward a Th2 rather than a Th1 pattern of cytokine response, favoring antibody over cellular immune mechanisms. Because virus-specific CD4+ T-helper function appears to be required to maintain maximally effective CD8 responses (Matloubian et al., 1994; Battegay et al., 1994; Hasenkrug et al., 1998; Kalams et al., 1999), dysregulation of CD4 T-cell function is likely to further weaken cytotoxic immunity during disease progression.

Vigorous CTL responses to HIV infection are typical (Betts et al., 2001; Migueles and Connors, 2001; Gea-Banacloche et al., 2000; Pantaleo et al., 1994), and several lines of evidence indirectly suggest that cytolytic mechanisms are of primary importance in response to HIV infection. In animal models, depletion of CD8+ T cells abrogates the usual dip in viral load from peak viremia following primary infection (Matano et al., 1998) and interferes with host ability to maintain steady-state viral loads (Jin et al., 1999; Schmitz et al., 1999), suggesting that control is mediated in part by cytolytic mechanisms. In the SIV model of HIV infection, vaccination studies have shown that robust CTL responses may result in some degree of control of infection (Amara et al., 2001; Shiver et al., 2002; Barouch et al., 2000). In humans, a dip in peak viremia is also typically observed at some time following primary infection, and this has been correlated with the appearance of HIV-specific CTL (Borrow et al., 1994; Koup et al., 1994). Furthermore, disease progression has been shown to be profoundly influenced by host human leukocyte antigen (HLA) class 1 genotype (Carrington and O'Brien, 2003; Kaslow et al., 1996; Carrington et al., 1999; Gao et al., 2001). Because of the prominent role of HLA in antigen presentation and CTL lysis, this observation implies that CTL mechanisms play a significant

role in the host response to infection. Several studies have shown relatively strong CTL responses in long-term nonprogressors, suggesting that CTL mechanisms may be a significant determinant of disease progression (Harrer et al., 1996; Rinaldo et al., 1995; Betts et al., 1999). Moreover, finding a direct link between the targeting of particular CTL epitopes and disease progression has been elusive.

EPIDEMIOLOGY

Since the first cases of AIDS were reported in 1981, HIV infection has grown to pandemic proportions, resulting thus far in an estimated 65 million infections and 25 million deaths (CDC, 1981; UNAIDS, 2006). An estimated 33.2 (30.6–36.1) million people worldwide live with HIV-1 (UNAIDS, 2007). In 2007, there were 2.5 million new HIV-1 infections and 2.1 million AIDS deaths (UNAIDS, 2007). Today, this pandemic has left no region of the world untouched (Inciardi and Williams, 2005) (Fig. 25.7). Currently, more than 6800 persons become infected with HIV and more than 5700 persons die from AIDS each day, mostly because of inadequate access to HIV prevention and treatment services. The HIV pandemic remains the most serious infectious disease challenging public health (UNAIDS, 2007).

Worldwide, heterosexual contact is the most common mode of transmission, accounting for about 85% of all HIV-1 infections (Simon et al., 2006). In the United States, sexual contact between men remains the most common means of sexual transmission, accounting for approximately 40% of the new cases (UNAIDS, 2006). Intravenous drug use is an increasing mode of HIV-1 transmission, particularly in Eastern Europe and Southeast Asia (UNAIDS, 2006). The rapid spread of infection of HIV-1 in these regions through injecting drug use is important, since it provides a bridge for rapid establishment of more generalized epidemics (Simon et al., 2006).

Sub-Saharan Africa remains the most seriously affected world region, with AIDS established as the leading cause of death there (UNAIDS, 2007). With only about 10% of the world's population, this region contains more than two-thirds (68%) of all people who are HIV positive, and more than three-quarters (76%) of all AIDS deaths in 2007 occurred here (UNAIDS, 2007). Transmission in this region is primarily through heterosexual contact. Southern Africa is the epicenter of the AIDS epidemic. This subregion accounts for 35% of all people living with HIV and almost one-third (32%) of all new HIV infections and AIDS deaths globally (UNAIDS, 2007). All countries in the region except Angola have an estimated adult (i.e., aged 15–49 years) HIV prevalence exceeding 10% (UNAIDS, 2006). Although sub-Saharan Africa continues to bear a disproportionate burden of HIV-1 infections, an increasing number of countries now report stabilization or decline in prevalence (e.g., Zambia, Tanzania, Kenya, Ghana, Rwanda, Burkina Faso, and Zimbabwe) (UNAIDS, 2006). There is some evidence to attribute these reductions to changes in sexual behavior, such as postponement of sexual debut, reduction in casual relationships, and more consistent condom use in casual relationships (Halperin and Epstein, 2004; Cates, 2005).

Unlike other regions, the majority of people living with HIV in sub-Saharan Africa (61%) are

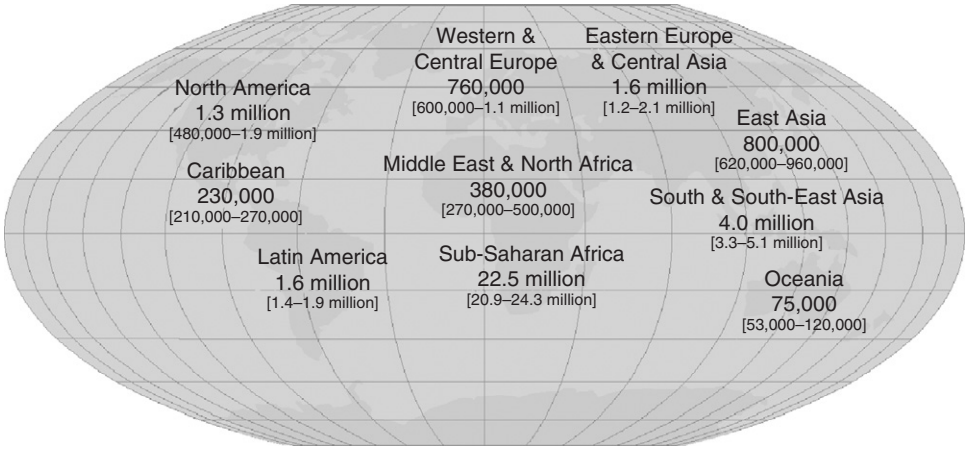

FIGURE 25.7 Global HIV epidemiology. Adults and children estimated to be living with HIV, 2007. Reproduced with permission from UNAIDS (http://www.unaids.org).

women (UNAIDS, 2007). Overall, a quarter of all new HIV-1 infections occur in persons younger than 25 years (UNAIDS, 2006). HIV-1 infection rates are three to six times higher in female adolescents than in their male counterparts (UNAIDS, 2006 Abdool-Karim and Abdool-Karim, 2002; Shisana and Davids, 2004; Pettifor et al., 2005); this difference is attributed to widespread sexual coupling of young women with older men. The increasing burden of HIV infections in women in this region has important implications for mother-to-child transmission as well as the large number of orphaned children. An estimated 11.4 million children in this region have been orphaned due to HIV and AIDS (Marston et al., 2005).

CLINICAL DISEASE

Clinical signs and symptoms of HIV may not become apparent until several years after infection. People who are HIV infected through sexual exposure can be viremic in 4–11 days (Kahn and Walker, 1998). During this early time period, a clinical "acute-retroviral" syndrome is reported in 40–80% of the infected individuals. Symptoms include fever, rash, lymphadenoapthy, headache, pharyngitis, aseptic menegitis, arthralgias, and myalgias. Symptoms are often mistakenly attributed to another viral illness, and usually resolve within 14 days. In one study, 94% of individuals sought medical attention during this period, but only one in four received the diagnosis of acute HIV infection (Schacker et al., 1996). During primary infection, individuals typically have very high plasma virus levels. In fact, one study showed that individuals with acute infection were the source for half of all new infections in a large urban setting (Brenner et al., 2007).

After this initial viremic period, an infected individual that goes unrecognized and/or untreated may be without symptoms from their infection. The median time from infection to progression to AIDS is 8–10 years, with a general decline of CD4 counts of 50–75 cells/year and increasing plasma viral load in untreated individuals (Lyles et al., 2000). However, irreversible immunologic changes appear to occur soon after infection, with severe depletion of CD4+ lymphocytes particularly in lymphoid tissue of the GI tract (Brenchley et al., 2004). The pace of disease progression is generally influenced by an individual's viral load, general health, and other concomitant infections and illnesses. The risk of developing an AIDS-defining illness in a 3-year period is correlated with plasma viral load and peripheral CD4+ T-cell count (Mellors et al., 1997).

Individuals with CD4 counts greater than 500 cells/μl are generally asymptomatic, but may experience lymphadenopathy, a variety of dermatologic conditions, and appear to be at increased risk of acquiring hematologic malignancies such as non-Hodgkins lymphoma. Individuals with a CD4 count between 200 and 500 may continue to be asymptomatic or may present with mild disease. Recurrent mild viral disease (herpes simplex, zoster infections, oral hairy leukoplakia), fungal infections (vaginal or oral candidiasis), and bacterial infections (sinusitis, recurrent pneumonias) may manifest at this point. Complaints of fatigue, weight loss, and various myalgias and arthralgias are common. As CD4 counts decline to between 50 and 200, untreated individuals often begin to experience more significant manifestations of immune compromise. These may include pneumocystis pneumonia (which remains the most common opportunistic infection in AIDS patients), toxplasmosis encephalitis, parasitic diarrheal illnesses, and oncologic conditions such as invasive carcinoma of the cervix, rectum, or anus.

Severely immunocompromised untreated HIV-infected individuals (CD4 counts less than 50) are at risk for additional opportunistic infections such as disseminated Mycobacterium avium complex disease (manifested as fever, weight loss, bone marrow involvement, as well as a number of less common organ involvements), cryptococcal meningitis, a number of diarrheal illnesses (bacterial, viral, and parasitic), disseminated endemic mycoses, and HIV wasting syndrome and encephalopathies.

MANAGEMENT AND TREATMENT OF HIV

Initial management of a newly diagnosed HIV patient includes taking a detailed medical history and performing a thorough physical examination. Key elements in evaluating an HIV-infected individual include information regarding social and sexual history to identify the risk factors associated not only with HIV acquisition but also HIV transmission. This history should also include information on patient sexual practices including type and number of sexual partners and use of barrier methods of protection, history of sexually transmitted infections (STIs), drug and alcohol use, the exchange of sex for money or drugs, and intravenous or other drug use. This history should be an opportunity to counsel patients on ways to prevent the acquisition of concurrent STIs and decrease the risk of HIV transmission. It is also a time to address barriers to successful management and treatment of HIV infection, and to identify current medical

issues that may limit use of antiretroviral drugs. Certain laboratory, radiologic, and clinical studies will also assist with management (Table 25.2). Genotypic viral resistance assays are currently part of the recommendation for all HIV-infected individuals as they enter care, regardless of how long they have been infected, to assess for transmission of resistant viral isolates (Hammer, 2005). These assays are not universally available. Infected individuals should be screened annually for tuberculosis, STIs, and age-appropriate health screenings as recommended by a number of professional societies including the American Cancer Society, the Infectious Disease Society of America, the Centers for Disease Control, and the American College of Physicians.

Prior to the availability of effective therapy in the mid-1990s, HIV infection was predictably associated with gradual host decline leading to death many years after infection in most individuals. This pattern is still widespread in many developing countries with high prevalence of HIV infection and limited access to HIV therapy. The advent of highly active ART in certain areas has a marked impact on survival from HIV disease. In eight large US cities, mortality declined from 29.4 per 100 person years in 1995 to 8.8 per 100 person years in the second quarter of 1997 (Palella et al., 1998). Over the past decade, ART has continued to improve with less toxic medications and better dosing schedules. Also, the number of drugs and number of classes of available agents dramatically increased. There are presently five classes of FDA-approved medications encompassing 23 different individual drugs (Table 25.3). The five classes (entry inhibitors, nucleoside/nucleotide reverse transcriptase inhibitors, nonnucleoside reverse transcriptase inhibitors, protease inhibitors, and integrase inhibitors) interrupt different stages of the HIV life cycle, both at extracellular and intracellular stages in viral production.

Presently, standard therapy includes using at least three different drugs from two classes of medications. Current recommendations from a number of international bodies recommend starting therapy prior to significant immune compromise (Hammer et al., 2006). This approach should be balanced against the long-term side effects from medications, which may include metabolic abnormalities, increased cardiovascular events, dysmorphic body changes, and significant GI intolerance. Also, in developing countries, there are significant limitations to access that impact the choice and timing of ARTs. In general, individuals with symptomatic HIV disease or CD4 counts less than 200 should be initiated for appropriate ART. Individuals with CD4 counts greater than 350 do not require immediate initiation of therapy, although those with very high viral loads (greater than 100,000) should consider therapy soon, as such a high viral load predicts a more rapid decline in CD4 count and faster progression to AIDS. For those with CD4 counts between 200 and 350, the decision to commence therapy should be made on an individual basis. Issues to consider in starting therapy include concomitant medical issues and medications, social situations that might impact compliance, and drug or alcohol issues that may create a barrier to successful therapy.

Another aspect of HIV infection management is monitoring for and treating opportunistic infections and giving appropriate prophylaxis when patients are immune compromised. Pathogens for which primary prophylaxis is recommended include: *Pneumocystis jiroveci* (CD4 counts less than 200—prophylaxis with trimethoprim/sulfamethoxazole [TMP/SMX]), *Toxoplasma gondii* (CD4 counts less than 100—prophylaxis with TMP/SMX), *Mycobacterium avium* complex (CD4 counts less than 50—prophylaxis with azithromycin), and *Mycobacterium tuberculosis* (any individual with a positive PPD without evidence of disease should receive 9 months of isoniazid (INH) therapy, as well as proper vaccine management against influenza, pneumococcus, and hepatitis A and B). In some cases, prophylaxis can

be discontinued when the immune system recovers after ART.

VACCINES

HIV vaccine trial research received impetus from the US government as early as 1984. At that time, Margaret Heckler, Secretary of Health and Human Services, predicted that an HIV vaccine would be in human trials within 2 years. Perhaps the greatest political push came from President Bill Clinton, who in 1997 challenged researchers to find an effective vaccine within 10 years, evoking the imagery of John F. Kennedy and his challenge to the NASA science program to put a man on the moon. A wide variety of HIV vaccine design approaches have been pursued, and over 50 candidates have been tested in clinical trials. Of these candidates, only few have advanced to phase 2B or 3 clinical efficacy testing (Table 25.4).

The first HIV vaccine efficacy trials, initiated in the 1990s, focused on the attempt to elicit neutralizing antibody responses using recombinant HIV envelop glycoprotein (rgp120) antigens produced from cell-line adapted HIV strains. In experiments in animal models and in the early-phase clinical trials that preceded efficacy studies, the glycoprotein candidate immunogens (rgp120 and rgp160) were safe and immunogenic (Keefer et al., 1997; Migasena et al., 2000; Wright et al., 1999; McElrath et al., 2000; Dolin et al., 1991). Experiments in nonhuman primates indicated that this approach elicited nAb, although the antibody response was narrow in most cases. In experimental systems, the elicited response was capable of neutralizing only HIV strains that closely resembled the vaccine antigen, and did not protect against challenge with primary or heterologous challenge virus (Arthur et al., 1989; Berman et al., 1988). Despite these results, two large efficacy trials were launched by the VaxGen Company, fueled in part by uncertainty about whether animal studies would accurately predict efficacy in humans. The trials were huge undertakings and proved that HIV efficacy trials can be successfully conducted at multiple international sites with good community support. The VAX004 study tested a bivalent, subtype B rgp120 vaccine (AIDSVAX B/B) among 5403 volunteers in the US, Canada, and Europe. The vaccine did not protect against infection (vaccine efficacy = 6%, 95% CI = [−17%, 24%]) and did not affect HIV disease course (HIV viral load or rate of ART) in participants who became infected (Flynn et al., 2005). The second trial tested AIDSVAX B/E, which included both subtype B and subtype E rgp120 antigens, among 2546 injecting drug users in Thailand. Vaccine efficacy was estimated at 0.1% (95% CI, −30.8% to 23.8%; $P = .99$, log-rank test) and no significant effects on disease course were seen (Pitisuttithum et al., 2006).

The failure of the VaxGen trials underscored the difficulty of eliciting broadly nAb that could block infection with HIV. Most subsequent trials of HIV vaccine candidates have involved products that aim to induce HIV-specific cytotoxic T-cell responses. These cells recognize HIV epitopes displayed on cell surfaces in conjunction with HLA and act against infected cells but not free virus. They limit the spread of infection by destroying infected cells via apoptosis, or by secreting chemokines and cytokines that interfere with subsequent rounds of infection. It is anticipated, based on studies in nonhuman primates, that this type of

TABLE 25.4 Ongoing phase 2 and phase 3 HIV preventive vaccine trials (as of November 1, 2007)

Trial name and description	Organizer/manufacturer	Site locations	Description of vaccine
Phase 3			
RV 144: A trial of live recombinant AVLAC –HIV priming with VaxGen gp120 B/E boost—enrollment complete and in follow-up	Walter Reed Army Institute of Research (WRAIR), Armed Forces Research Inst., Thai MoH, Thai AIDS Vaccine Evaluation Group. Manufacturers: Aventis Pasteur and VaxGen	Thailand	Live canary pox with a clade B env and gag-pol fusion boosted with a subunit clade B/E gp120
Phase 2 and 2b (test of concept)			
STEP and Phambili (*HVTN 502 and 503*): Multicenter test of concept trial using 3-dose regimen. Enrolment and further vaccination suspended September 2007	Merck, US Division of AIDS (DAIDS), HIV Vaccine Trials Network (HVTN), South African AIDS Vaccine Initiative (SAAVI)	North and South America, Australia, and South Africa	Replicative incompetent Ad5 with clade B gag, pol, and nef inserts
Phase 2			
HVTN 204: Clinical trial evaluating the safety and immunogenicity of DNA plasmid vaccine followed by adenovirus boost. Enrolment completed and in followup	DAIDS, HVTN. Manufacturer: VRC	North and South America, South Africa	VRC 6 plasmid DNA of ENV A, B and C plus clade B gag, pol, and nef. Boosted with Ad5 vector with a ENV A, B, and C and a gag-pol fusion insert
IAVI A002: Placebo-control double-blind trial evaluating the safety and immunogenicity of AAV vaccine	International AIDS Vaccine Initiative (IAVI). Manufacturer: Targeted Genetics	South Africa, Uganda, and Zambia	Adeno-associated virus 2 with a gag, pol, and ΔRT
ANRS VAC 18: Randomized double-blind trial evaluating the safety and immunogenicity of LIPO-5 versus placebo	Agence Nationale de Recherches sur le SIDA (ANRS). Manufacturer: Aventis Pasteur	France	5 lipopeptides containing CTL epitopes from gag, pol, nef

response will not prevent infection but will ameliorate disease course by limiting viral replication.

In the second wave of HIV vaccine trials, a variety of "T cell" vaccine candidates were tested; the first major candidates employed pox-virus vectors. The prototype for this approach is vaccinia, the poxvirus that was used as a vector in the global smallpox campaign. Vaccinia itself was abandoned as an HIV vaccine vector due to safety concerns raised by a case of fatal disseminated vaccinia in an immune-compromised, HIV-infected individual (Redfield et al., 1987). A number of attenuated pox-virus vectors have been tested. Of these, constructs based on canarypox were studied most extensively in humans, including efficacy testing. These viral vectors are host-range-restricted and undergo abortive replication in human cells. The HIV insert sequences are expressed and presented without replication of the vector itself. In clinical trials involving over 400 HIV-infected participants and more than 1500 uninfected participants (Franchini et al., 2004), canarypox (ALVAC) vaccine candidates were safe and immunogenic (Gupta et al., 2002; de Bruyn et al., 2004). While nAb responses were limited, initial trials found T-cell responses in 30–40% of trial participants when multiple time points were tested (Duerr et al., 2008). In a pivotal trial, the second-generation ALVAC

prime (vCP1452) and recombinant gp120 (AIDSVAX™ B/B subunit) boost regimen failed to meet the preset immunogenicity criteria and did not move forward to efficacy testing (Russell et al., 2007). A similar regimen (the canarypox vector vCP 1521 containing the HIV-1 clade B *env*, *gag*, and protease genes, in combination with AIDSVAX clade B and E rgp120) is being tested in a 16,000-person efficacy trial in Thailand. The trial's primary objective is to evaluate the regimen's ability to prevent HIV infection; results are expected in 2009. The rationale for this trial has been questioned (Burton et al., 2004) due to poor performance of the components (or closely related ones) in earlier trials. The sponsors of the trial defended the decision to advance the regimen to efficacy testing based on responses to the combined regimen seen in nonhuman primate studies and earlier clinical trials that met predefined milestones, as well as the extensive review process prior to initiation of the efficacy trial (McNeil et al., 2004). Additional pox-virus-vectored HIV vaccines are also being moved forward in human trials. A modified vaccinia ankara product (MVA) is scheduled to enter phase 2 studies late in 2008.

The most recent wave of HIV vaccine testing has been dominated by replication-defective adenovirus serotype 5 (Ad5) vectors, used alone or in combination with DNA. One such product, produced by Merck, uses an admixture of three adenoviruses containing codon-optimized subtype B *gag*, *pol*, or *nef* genes, respectively. This product was tested as a three-dose regimen. Early clinical testing indicated excellent safety and immunogenicity (the vaccine elicits a robust T-cell response, which is somewhat diminished among individuals with preexisting immunity to Ad5), and experiments in nonhuman primates showed protection against SHIV, but not SIV, challenge (Casimiro et al., 2005). This vaccine was evaluated in two large efficacy trials. The first, called the STEP Study, was conducted in North and South America, the Caribbean, and Australia among 3000 at-risk volunteers, half of whom had evidence of prior exposure to Ad5. The second trial, which began 2 years after the first, was scheduled to enroll 3000 at-risk heterosexual men and women in South Africa. These companion studies sought to evaluate vaccine efficacy among men who have sex with men and heterosexuals, and in individuals living in countries with HIV subtypes B and C epidemics. A joint endpoint of efficacy for prevention of HIV acquisition and efficacy for amelioration of disease course (measured as reduction of set-point viral load) was evaluated in both trials. Vaccinations were discontinued in both trials in September 2007, when an interim analysis of data from the STEP study showed no efficacy for either outcome. In the study population examined in this interim analysis (participants with baseline Ad5 < 200), there were 24 infections among 741 vaccinees and 21 infections among 762 placebo recipients; the geometric mean plasma vRNA level was similar in infected vaccine vs. placebo recipients (~40,000 vs. ~26,000 copies/ml, respectively). Among all men who participated in this trial (women were excluded from further analysis as only one infection occurred among a woman), 49 HIV infections occurred in 914 vaccine recipients and 33 in 922 placebo recipients (Merck Research and Development News, 2007). Initial multivariate analyses suggested that any increased risk associated with vaccination was limited to men with evidence of prior exposure to Ad5, and uncircumcised men. The treatment hazard ratio (vaccine vs. placebo) was 0.8 (0.4, 1.6) in circumcised men with baseline Ad5 titers ≤ 18, 1.4 (0.6, 3.2) in circumcised men with baseline Ad5 titers > 18, 2.5 (0.8, 8.0) in uncircumcised men with baseline Ad5 titers ≤ 18 and 4.3 (1.7, 11.0) in uncircumcised men with baseline Ad5 titers > 18 (Merck Research and Development News, 2007). The reasons for this apparent increase in susceptibility to HIV associated with vaccination among men with prior Ad immunity and uncircumcised men are presently unclear, but continue to be investigated.

The second Ad5 candidate, developed by the US National Institutes of Health's (NIH) Vaccine Research Center (VRC), is designed to provide multiclade protection. The vaccine regimen consists of a six-plasmid DNA vaccine expressing subtype B *gag*, *pol*, *nef*, and subtype A, B, C envelop genes, respectively, given as a prime at 0, 1, and 3 months. This priming regimen is followed by a boost at 6 months consisting of a mixture of four adenoviruses containing inserts comprised of a subtype B *gag-pol* gene fusion product, and envelope genes from HIV-1 subtypes A, B, and C. In animal models, this vaccine regimen was immunogenic (Shiver et al., 2002); it did not prevent infection but was associated with decreased viral load, less frequent progression to AIDS, and preservation of central memory cells (Letvin et al., 2006; Mascola et al., 2005; Santra et al., 2005). The regimen was found to be well tolerated and immunogenic in phase 1 and 2 trials and is scheduled for efficacy testing in early 2009.

The extensive previous experimental use of adenovirus vectors in gene therapy and vaccinology, and the established safety and immunogenicity properties of these vectors continue to make adenoviruses attractive for use in vaccine development. However, in light of the STEP study, alternatives to adenovirus 5 vector constructs are being investigated, using serotypes with lower incidence of natural infection. Less frequently occurring adenovirus subtypes, such as adenovirus

serotype 26 and adenovirus serotype 35, as well as chimeric products of several adenoviruses, can be used as vectors to elicit an immune response and are entering clinical trials in humans (Abbink et al., 2007; Lemckert et al., 2005). Other potential vectors include adeno-associated virus (AAV) and vesicular stomatitis virus (VSV). AAV requires a helper virus for replication, and is not known to cause human disease. Studies using an SIV insert in macaques that were later challenged with SIV showed that the vaccinated animals had better virologic suppression and control than placebo recipients (Johnson et al., 2005). AAV has been employed as a gene vector for the treatment of other conditions including cystic fibrosis, hemophilia, and rheumatologic disorders. However, the use of this vector suffered a setback when a participant receiving AAV-based therapy for inflammatory arthritis died from disseminated histoplasmosis. Although later found not likely to be associated with the AAV product, this event has slowed the development of AAV as a vaccine vector. A recombinant rabies-VSV product with an SIV insert has also been used in macaques that were later challenged with a pathogenic SHIV, and those that were vaccinated also had attenuated disease progression (McKenna et al., 2007). These potential vectors are in late-phase preclinical or early clinical testing and will be used alone or in prime-boost regimens.

In the field of HIV vaccine research, a number of alternative approaches have been studied to increase immunogenicity and delivery of antigen. One of these methods, a heterologous prime-boost vaccine strategy is being used in about half of the presently ongoing trials. This technique uses a "prime" vaccine that initially stimulates the immune system generating memory T and B cells. Later, a boost is given with a different vector, a different insert, or sometimes both. Conceptually, this approach may work by circumventing immunity that might have developed to the initial vector. However, there is limited data to show that this approach elicits better immune responses.

Additionally, novel delivery methods have mechanically improved vaccine immunogenicity and antigen delivery. The Biojector® is one such device. It uses a single, needleless, syringe-based device that injects a vaccine product under high pressure by compressed carbon dioxide cartridges. This device is used primarily to inject DNA vaccine product into the tissues, theoretically allowing for increased cellular uptake. However, immunogenicity results obtained with this technique have been inconsistent (Brave et al., 2007; Meseda et al., 2006; Rao et al., 2006). Electroporation is a second method that is being developed to help improve the immunogenicity of DNA vaccines. Already used experimentally in gene therapy and cancer vaccines, electroporation increases the permeability of cell membranes and theoretically enhances the uptake of the immunogen into cells. In nonhuman primates (Luckay et al., 2007), electroporation has increased immune response 10- to 40-fold at one-fifth the dose of immunogen compared to conventional needle-and-syringe delivery.

Adding adjuvants to HIV vaccine candidates is another area of ongoing research. Many of the current vaccine strategies do not produce immune responses that are robust, long-lived, and appropriately focused on production of nAb or cytotoxic responses. Adjuvants could overcome this problem by targeting the antigen to antigen-presenting cells, or increasing immune response by stimulating production of cytokines and costimulatory molecules, or both. Adjuvants such as polymeric microspheres (e.g., polylactide-coglycolide or PLG) have been tested with HIV vaccine candidates to increase immune response through facilitating interactions with antigen-presenting cells (Singh and Srivastava, 2003). Other adjuvants being tested in conjunction with HIV vaccine candidates attempt to increase induction of relevant cytokines and upregulate costimulatory molecules. CpG, unmethylated cytosine-guanine dinucleotides, which acts as a ligand for toll-like receptor 9 (TLR9), is one example (Kojima et al., 2002). Stimulation of TLRs, in turn, enhances and directs the immune response. A related approach is the administration of vaccine candidates with costimulatory molecules such as interleukin-12 (IL-12), IL-15, or granulocyte-macrophage stimulating factor (GM-CSF) in an attempt to manipulate the immune response and increase cell-mediated immunity to the coadministered HIV vaccine antigen (Calarota and Weiner, 2004).

When potential genetic inserts are considered for vectors, the biological diversity of HIV becomes a significant issue. One the major challenges of the HIV epidemic is the significant viral diversity of the target pathogen. The rate of mutation of HIV is so rapid that the diversity of virus circulating within an infected individual's blood may be broader than the genetic diversity of influenza circulating worldwide (Fig. 25.8) (Korber et al., 2001). It is also unclear that inserts based on a single clade or several limited clades will provide protection against genetically diverse isolates. Although the responses generated by natural infection have been shown in vitro to have cross-clade reactivity, this protection has not been demonstrated in humans (Coplan et al., 2005; Cao et al., 1997).

Several approaches have been used to select genetic inserts for vaccines. Gene segments from one or more "representative" naturally-occurring viral sequences may be selected. Alternatively, artificial insert sequences may be designed by a variety of methods, to maximize the chances of inducing broadly reactive

immune responses of protective value following heterologous challenge. Consensus sequences are constructed by simply using the most common amino acid at each position in the genome among naturally occurring strains (Gaschen et al., 2002). Ancestral sequences are developed using methods based on phylogenetic analysis of existing sequences: maximum likelihood analysis of circulating sequences is used to infer the most likely genetic makeup of an "ancestor" for currently circulating viruses (Gaschen et al., 2002). Center-of-tree design approaches seek to find a phylogenetically determined ancestral sequence which minimizes the genetic distance to current isolates (Gaschen et al., 2002; Mullins et al., 2004). Finally, epitope-based methods include a series of nucleic acid sequences encoding immunogenic epitopes of high frequency within the circulating HIV genome.

CONCLUSIONS

HIV is one of the greatest public health challenges faced worldwide over the last century. Despite advances in therapy that have made HIV a manageable chronic illness in areas where ART is available, the best approach to stemming the epidemic globally will be to develop a vaccine that is capable of reducing the incidence of transmission and/or attenuate disease progression in infected individuals. Unique aspects of the epidemiology and pathophysiology of HIV infection have made the development of an effective and economically feasible vaccine a challenging endeavor for scientists, public health officials, governments, and populations at risk. In the face of these difficulties, the research community may be required to consider vaccines that meet only some of the properties of an ideal vaccine. As we move forward, several questions will need to be addressed, including: (1) What would be the impact of a vaccine that mitigates disease but does not directly prevent infection in vaccinees? What data would be necessary to support the development and distribution of such a vaccine? (2) What would be the effect of such a vaccine on mucosal viral shedding and the subsequent risk of HIV transmission from the vaccinated individual? (3) What role would such a vaccine have in multifaceted prevention programs? and (4) Could slower disease progression due to administration of a "therapeutic" vaccine aid the implementation of treatment programs in resource-limited settings, by making the number of individuals needing therapy more manageable? The next decade will provide the opportunities for these and other questions to be answered, and will likely see the proposal of a number of new questions as second- and third-generation vaccines are developed. Multidisciplinary approaches with vaccination as one element of a combined strategy may ultimately lead to complete control of this pandemic.

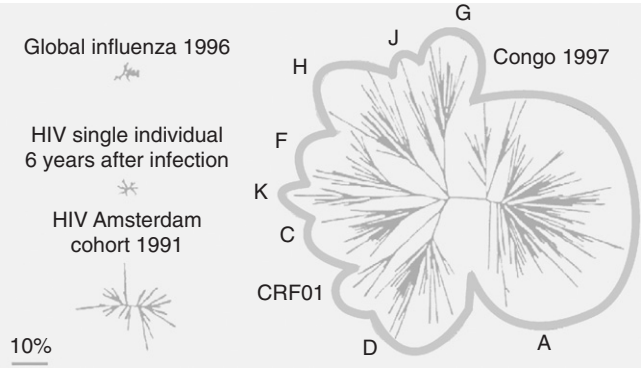

FIGURE 25.8 HIV genetic diversity. Comparison of genetic diversity of global influenza in a calendar year, HIV in an individual, a single city cohort in 1991, and a single sub-Saharan country in 1997. Reproduced with permission from Duerr et al. (2008) and Garber et al. (2004).

KEY ISSUES

- HIV has claimed an estimated 25 million lives, and there are currently 33 million infected persons.
- The HIV epidemic has had a significant socioeconomic impact in virtually all developing and developed nations, but disproportionately afflicts populations at its epicenter in sub-Saharan Africa.
- The HIV epidemic continues to expand into large population centers in Asia and other regions around the world.
- In most untreated individuals, HIV infection eventually leads to collapse of the immune system and death due to opportunistic infections.
- Rare individuals may remain entirely asymptomatic, but there have been no documented cases of spontaneous cure from infection.
- While ART may arrest disease progression in some, treatment is costly and unavailable to most infected individuals.
- There is presently no cure for HIV, nor a preventative vaccine.
- An effective vaccine will be critical to controlling the epidemic.
- Current vaccine efforts seek to find a vaccine that can either reduce the likelihood of infection, or attenuate disease progression in infected individuals.
- Vaccine design is impeded by the tremendous antigenic variation characteristic of HIV.

- Early vaccine development efforts sought to elicit nAb responses; recent vaccine efforts have focused on eliciting a protective T-cell response.

ACKNOWLEDGMENT

Human Papillomavirus

William Bonnez
School of Medicine and Dentistry, University of Rochester, Rochester, NY, USA

OUTLINE

ABSTRACT

Human papillomaviruses (HPVs) include over 100 different genotypes that infect the stratified squamous epithelia and may cause proliferative lesions. Some of the HPVs are responsible for cutaneous warts, while one subset of HPVs is found in the skin lesions of epidermodysplasia verruciformis, a condition that leads to the development of cutaneous squamous cell carcinomas. A third subset of HPVs is associated with infections that can cause benign, premalignant, and malignant lesions not only of the genital tract, the anus, but also of the oropharynx. These lesions include external genital warts, intraepithelial neoplasias of the penis (PIN), anus (AIN), vulva (VIN), vagina (VAIN), and cervix (CIN), as well as cancer of the cervix. Cervical cancer is the second most commonly acquired cancer in women worldwide. This significant disease burden explains the great importance of genital (or mucosal) HPVs. The availability since 2006 of highly effective vaccines to prevent a large fraction of these morbidities has been a major advance whose promises are growing. The two vaccines available, Gardasil and Cervarix, are based on the expression of the major viral capsid protein in yeast or insect cells, and the spontaneous assembly of this protein into a noninfectious capsid called a virus-like particle (VLP), because it retains the appearance, size, and immunologic properties of the native, infectious viral particle.

Gardasil is made of the VLPs of HPV types 6 and 11 that account for 90 of external genital warts, and of HPV types 16 and 18 that account for over 70% of cervical cancers worldwide. Cervarix is a bivalent vaccine that includes only HPV VLP of types 16 and 18. Trials have shown that these vaccines protect virtually 100% of the subjects against the immediate precursor to cancer, high-grade CIN, caused by the vaccine HPV types the subjects are naive to. Gardasil has received indications in the United States not only for the prevention in 9–26-year-old women of cervical cancer and CIN of all grades, but also for the prevention of VIN and VAIN grades 2 and 3, as well as of external genital warts. The most effective use of the vaccine is when administered before sexual debut, at a time the subject is naive for the infections caused by the HPV types included in the vaccine. The efficacy of the HPV vaccine has now been demonstrated up to the age of 45 years in women. Trials in men for the prevention of external genital warts are in progress, and could serve as a basis for the immunization of both males and females. The HPV vaccine, especially when it covers a broad range of viral types, holds the promise of not only affecting cervical cancer and its screening, but also of reducing the burden of the other cancers attributable to HPV, such as those of the vulva, vagina, penis, and anus, as well as a majority of oropharyngeal cancers. To attain these goals, maintenance of safety, favorable cost–benefit ratios, and broad delivery and accessibility of the vaccine will need to be achieved.

INTRODUCTION

Papillomaviruses are small (55 nm in diameter), non-enveloped, icosahedral viruses, containing a double-stranded, circular DNA genome about 8000 base pairs long. They are found throughout higher vertebrates, mostly mammals and birds, causing cutaneous and mucosal tumors. The over-100 distinct human papillomavirus (HPV) genotypes are restricted to man and the squamous stratified epithelia. The tumors they cause range from benign (warts, papillomas, condylomas) to malignant (mostly squamous cell carcinomas). A subset of about 40 of these viruses have assumed a great medical and public health importance for the infections and diseases they cause in the anogenital tract. Cervical cancer is the best-established example of the causal link between HPV and cancer. The availability since 2006 of effective vaccines to prevent this disease and others has been a major public health advance whose scope of application is likely to grow.

SHORT HISTORY OF THE DISEASES

Cutaneous and anogenital warts, as well as anogenital cancers, have been recognized since antiquity (Routh et al., 1997). The transmissible nature of warts was established by Jadassohn in 1895, the first of several investigators to perform experimental inoculations in man of infectious materials derived from warts (Rowson and Mahy, 1967). Ciuffo reported in 1907 that the agent was filterable, and the viral nature was further confirmed in 1949 with the demonstration by electron microscopy of viral particles in warts (Ciuffo, 1907; Strauss et al., 1949). The DNA of the first HPV—type 1—was cloned in 1975 from a plantar wart, and the existence of more than one type of HPVs was established in 1977 (Favre et al., 1975; Orth et al., 1977; Gissmann et al., 1977). HPV6 and 11, the main agents of genital warts, were identified in 1980 and 1982, respectively (Gissmann and zur Hausen, 1980; Gissmann et al., 1982). HPV-11 was first isolated from a laryngeal papilloma, a condition that gained recognition in 1871, and for which a papillomavirus etiology was first suspected in 1973 (Mackenzie, 1871; Boyle et al., 1973).

In 1935, Rous and Beard had shown that benign papillomas induced by the cottontail rabbit papillomavirus (CRPV) (Shope rabbit papillomavirus) could progress to invasive carcinomas (Rous and Beard, 1935). This observation, as well as the description in 1922 by Lewandowsky and Lutz of epidermodysplasia verruciformis, followed by the identification in 1966 of papillomavirus particles in the disease's lesions, which later in life may convert to a squamous cell carcinoma, provided the original insight into the potential oncogenicity of HPV (Lewandowsky and Lutz, 1922; Ruiter and van Mullem, 1966). A relationship between HPV and cancer of the cervix was first clearly proposed in 1975 (zur Hausen et al., 1975; Munoz and De The, 1975). The isolation in cervical carcinomas of HPV-16 (Durst et al., 1983) in 1983 and of HPV-18 (Boshart et al., 1984) a year later marked the beginning of the experimental and epidemiologic quest that eventually established the causal link between a subset of HPVs and various malignancies of the anogenital tract, as well as of the respiratory and upper digestive tracts. An important landmark in that respect was the demonstration that 99.7% of cervical carcinomas worldwide contain HPV DNA (Walboomers et al., 1999).

ETIOLOGIC AGENTS

Classification

HPVs belong to the genuses *Alpha*, *Beta*, *Gamma*, *Mu*, or *Nupapillomavirus* of the family Papovaviridae (see http://www.ncbi.nlm.nih.gov/ICTVdb/Ictv/index.htm). Some of the genuses are further divided into species, each represented by a species type. For example, HPV type 16, an Alphapapillomavirus, is the representative type of species 9, which also contains types 31, 33, 35, 52, 58, and 67 (de Villiers et al., 2004). In contrast to many viruses, the taxonomy of HPVs is based on genotyping, not on serotyping. A new type is one that differs from others by more than 10% in the nucleotide sequence of the L1 open reading frame (ORF), which encodes for the major capsid protein. Subtypes differ from one another by 5–10%, while variants do by more than 2%, but less than 5% (de Villiers et al., 2004). As of mid-2007, 107 types have been assigned, but this is a classification in progress with some type assignments that have been changed (e.g., types 46, 55, and 64).

From a clinical standpoint, it is practical to identify three groups of diseases that approximate the delineation of different HPV genuses. The first group is made mostly of cutaneous warts (most notably hand, plantar, flat warts), corresponding essentially to the Gamma, Mu, and Nupapillomaviruses. The second is the rare genodermatose epidermodysplasia verruciformis that is associated with the Betapapillomaviruses. The third is the large group of genital and/or mucosal HPVs made of the *Alphapapillomaviruses*.

Antigens Encoded by Agent

The antigenicity of HPV is a complex and unsettled field, particularly as it relates to the immune response during natural infections (Egelkrout and Galloway, 2007). This section is limited to the salient findings.

The papillomavirus major capsid protein when heat-denatured under reducing conditions harbors an antigen shared by all papillomaviruses tested (Jenson et al., 1980). This has been exploited for the development of a cross-specific antibody (sometimes referred as the "DAKO" antibody) that is useful, although not very sensitive, for the histologic diagnosis of papillomavirus infection by immunocytochemistry (Jenson et al., 1985). Although results have been discordant, it does not appear that this antigen is recognized during a natural infection (Dillner et al., 1990; Kirnbauer et al., 1994).

The study of the HPV capsid antigens was long hampered by the difficulty of obtaining HPV virions by either culture or lesion extraction. This obstacle was lifted in the 1990s by the possibility of creating virus-like particles (VLP) by expressing the major papillomavirus capsid protein in a suitable, usually eukaryotic, expression system—the same technology that was the basis for the development of the current HPV vaccines. The investigation of the antigenic properties of VLPs from different HPV genotypes demonstrated a generally good agreement between serotype and genotype (Rose et al., 1994a, 1994b; Giroglou et al., 2001). This was not entirely surprising since both entities are directly or indirectly dependent on the L1 nucleotide sequence. For the same reason, at least partial antigenic cross-specificity was noted for closely related genotypes, such as types 6 and 11 (Bonnez et al., 1991; Touze et al., 1998; Wang et al., 2003a). Several hypervariable regions are present on L1. Some of these regions, which form exposed loops, bear some of the conformational type-specific antigenic determinants of the capsid. Although the number and locations of these determinants are not completely defined, it appears that for HPV-6 the main type-specific determinant is borne by loops EF and BC, by loops FG and HI for HPV-16, and by loop EF for HPV-31 (Christensen et al., 2001; McClements et al., 2001; Carter et al., 2003, 2006; Wang et al., 2003b). Most of these conformational epitopes are neutralizing. For example, for HPV-16 such epitopes are found in loops DE, FG, and HI (Carter et al., 2003; White et al., 1999; Varsani et al., 2006; Culp et al., 2007; Ryding et al., 2007; Day et al., 2007). Although neutralizing linear epitopes have been described, they are probably less important than the conformational ones (Christensen et al., 1996a, 1996b; Combita et al., 2002). HPV L1 VLPs are currently the best antigens for diagnostic serology (Egelkrout and Galloway, 2007; Dillner, 1999). However, the sensitivity of adequately specific immunoassays based on these antigens is approximately 50–80%, an unsatisfactory standard that has limited the use of these tests to seroepidemiology.

The L2 minor capsid protein contains subdominant, broadly cross-neutralizing epitopes (Roden et al., 2000; Slupetzky et al., 2007; Kondo et al., 2007). These epitopes are linear, and for HPV-16, are located in the amino-terminus portion of the polypeptide (Gambhira et al., 2007).

Full or partial polypeptides encoded by the non-structural ORFs E2, E4, E6, and E7 have been used for serological testing. Immunoassays based on these antigens are insensitive, particularly if one tries to preserve specificity, and often lead to variable results from study to study (Egelkrout and Galloway, 2007; Galloway, 1992). Nevertheless, E6 and E7 polypeptides seem to generate a consistent antibody response in about half of patients with cervical cancer (Müller et al., 1992; Meschede et al., 1998).

PROTECTIVE IMMUNE RESPONSE

Antibody

The humoral response to the viral capsid through the generation of neutralizing antibodies appears to be the sole source of protective immunity against HPV infection. However, as detailed later, this protective immune response requires immunization with HPV L1 VLPs to fully develop. During a natural infection, as shown, for instance, with HPV-6, -11, and -16, there is a seroconversion to HPV L1 VLP in about half of the patients in whom HPV DNA is detected, but this antibody response is insufficient to provide protection from either a future infection or disease (Kirnbauer et al., 1994; Heim et al., 1995; Eisemann et al., 1996; Wikstrom et al., 1997; Studentsov et al., 2003; Viscidi et al., 2004; Tachezy et al., 2006). The reason is likely related to the weak neutralizing antibody titers generated by a natural infection.

Cross-specific neutralizing antibodies to the L2 polypeptides can be generated in animal models of papillomavirus infection (Roden et al., 2000; Slupetzky et al., 2007; Kondo et al., 2007; Gambhira et al., 2007). Whether the magnitude of this antibody response would be sufficient to prevent human HPV infection or disease has not yet been established.

CMI

Although cell-mediated immunity is important in the control of established HPV-related tumors and the resolution of HPV infections, it appears to play no role in their prevention (Eiben Lyons et al., 2007; Kanodia et al., 2007; Sheu et al., 2007).

EPIDEMIOLOGY

HPV infections are extremely ubiquitous, more so than was ever appreciated. Prevalence studies of cutaneous HPV infections have shown rates of 80% in immunocompetent hosts, and approaching 95% in immunosuppressed patients (Antonsson et al., 2000). These infections also tend to persist, as half of infected individuals will retain the same infection when sampled 6 years later (Hazard et al., 2006).

Genital or mucosal HPV infections are less prevalent than cutaneous HPV infections. It has been estimated that worldwide 10.4% of women with normal cervical cytology have a genital HPV infection (Burchell et al., 2006). Nevertheless, prevalence varies considerably according to age. No more than 1% of newborn babies have oral or genital HPV infections (Smith et al., 2004). However, by 20 years of age, at the peak-prevalence, about 23% of women worldwide who have normal cervical cytology have a cervical infection (Burchell et al., 2006). This reflects the sexual mode of transmission of genital HPV. The prevalence thereafter steadily decreases with age, but there are clearly geographic variations in the age–prevalence profiles, whereby the curve may stay relatively flat, or decrease, but present a second smaller peak in older age (Burchell et al., 2006; Smith et al., 2006). Genital HPV infections are rapidly acquired. For example, in a cohort of university women who had a negative HPV DNA cervicovaginal lavage at baseline, 2 years later the cumulative incidence of infection was 32%. In a study of 18–20-year-old male students, the cumulative incidence of any HPV infection of the genitalia after 2 years was 62% (Partridge et al., 2007).

These HPV infections can lead to clinical manifestations. Cutaneous warts, in at least one of their three main manifestations—common (hand and feet), plantar, and flat warts—eventually affect a majority of the population with prevalence rates reported to be as high as 20% (Williams et al., 1993; Larsson and Lidén, 1980). However, they peak during childhood and adolescence, and thereafter eventually disappear in virtually all subjects. One exception to this pattern is the hand warts observed in butchers, meat packers, and fish handlers—lesions that are strongly associated to HPV-7 (Bonnez, 2002a).

The peak age for genital warts is 20–29 years. In the United States, in a large population survey of 18–59-year-olds, 5.7% of subjects (7.4% women and 3.9% men) reported having had genital warts (Dunne et al., 2005). In a study of about 70,000 women aged 18–45 years from Finland, Norway, Sweden, and Denmark, the equivalent figure was 10.6% (Kjaer et al., 2007). Although data are limited, genital wart incidence appears to be increasing (Centers for Disease Control and Surveillance, 2003; Koshiol et al., 2004). A related condition, recurrent respiratory papillomatosis, is rare, with a prevalence of 11 cases per 100,000 for the more common juvenile-onset variant (Derkay, 2001).

HPV infection is a necessary, if not sufficient, condition for the development of cervical cancer (Schiffman et al., 2007). In 2002, with 493,343 new cases and 273,505 deaths, cancer of the uterine cervix ranked second in incidence after breast, and third in mortality after breast and colon, in women worldwide (Parkin et al., 2005). As shown in Fig. 26.1, the geographic distribution of this cancer is unequal, with the developing countries most severely affected (Parkin et al., 2005). In the United States, 2007 estimates place cervical cancer 14th in incidence (11,150 new cases)

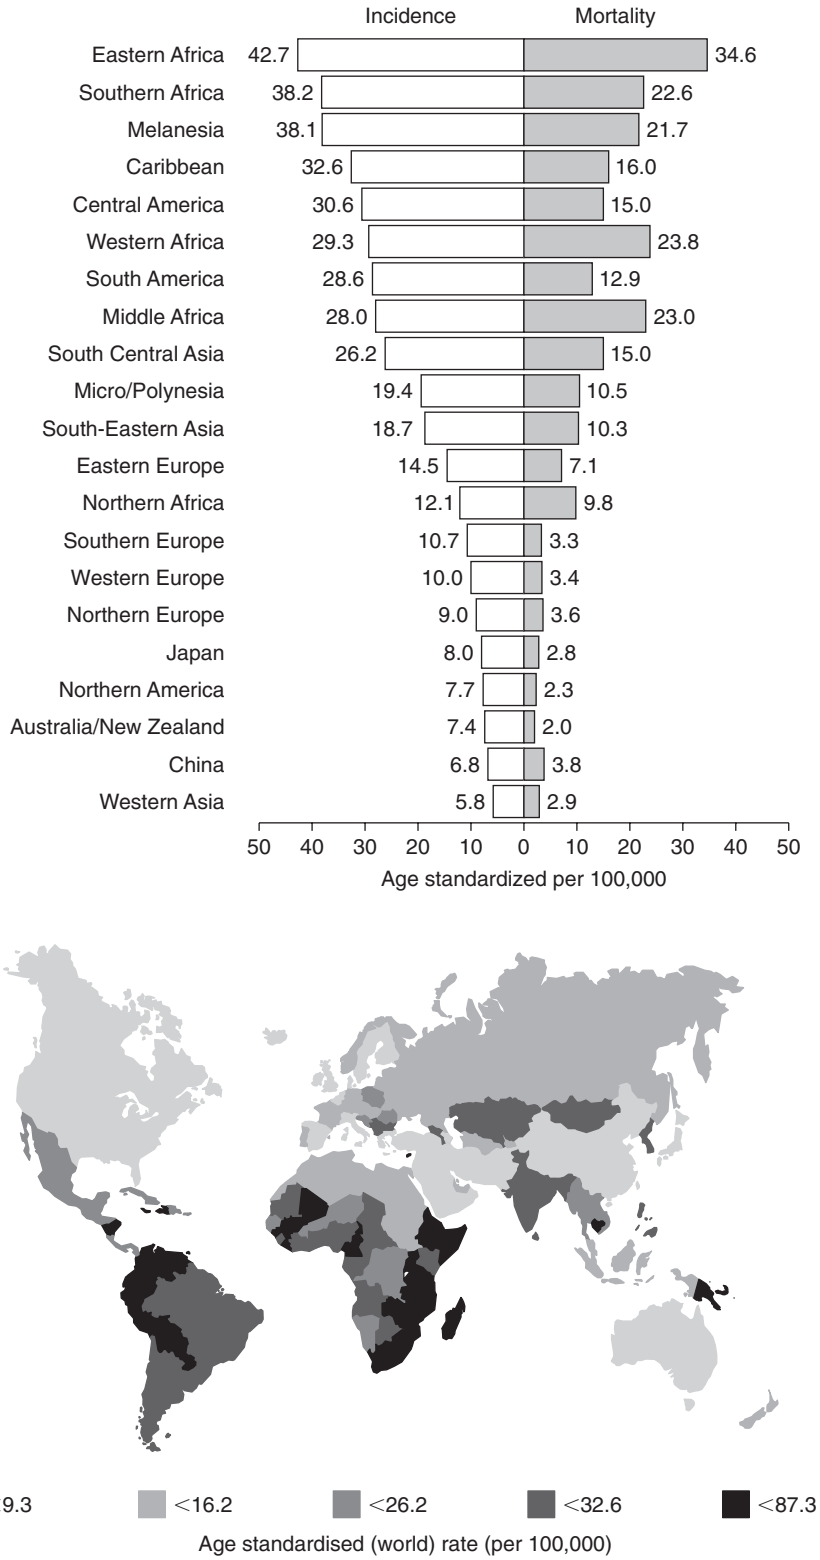

FIGURE 26.1 Age-standardized incidence and mortality rates for cervical cancer (per 100,000) (reproduced from Parkin et al. (2005). Data shown per 100,000.

and 16th in mortality (3670 deaths) among all female cancers (Jemal et al., 2007). Given that cervical cancer only represents approximately 1% of the HPV-related precursor lesions detected on cervical cytology, it is obvious that the public health impact of HPV is much larger that the one limited to cervical cancer (Stoler, 2000). In the United States, the economic burden of genital HPV infection has been estimated to be $3.9 billion in 2000, with cervical cancer representing only 5% of these costs (Chesson et al., 2004). The causal link between some HPVs and cancer is not limited to the cervix, for which the evidence is the strongest, but also extends to some histologic variants of cancers of the vulva, vagina, penis, and anus. HPV accounts for 40–90% of the cancers in these locations (Parkin and Bray, 2006). Altogether, these other cancers represent in the United States about one-third of the HPV attributable cancer burden (Jemal et al., 2007; Parkin and Bray, 2006). It has also recently become clear that HPV plays a dominant role in a majority of oropharyngeal cancers distinct from those related to alcohol and tobacco use (D'Souza et al., 2007). Altogether, the incidence of these non-cervical HPV-associated cancers is as high in women as that of cervical cancer (Jemal et al., 2007) (Fig. 26.2).

Although HPVs are pathogenic, and for some types even oncogenic, they are ubiquitous and not potential biothreat agents. The reasons are that their transmission requires direct contact with the susceptible anatomic areas of the target host, their incubation is long, and only a small percentage of the infections ultimately lead to cancers, which take years to develop.

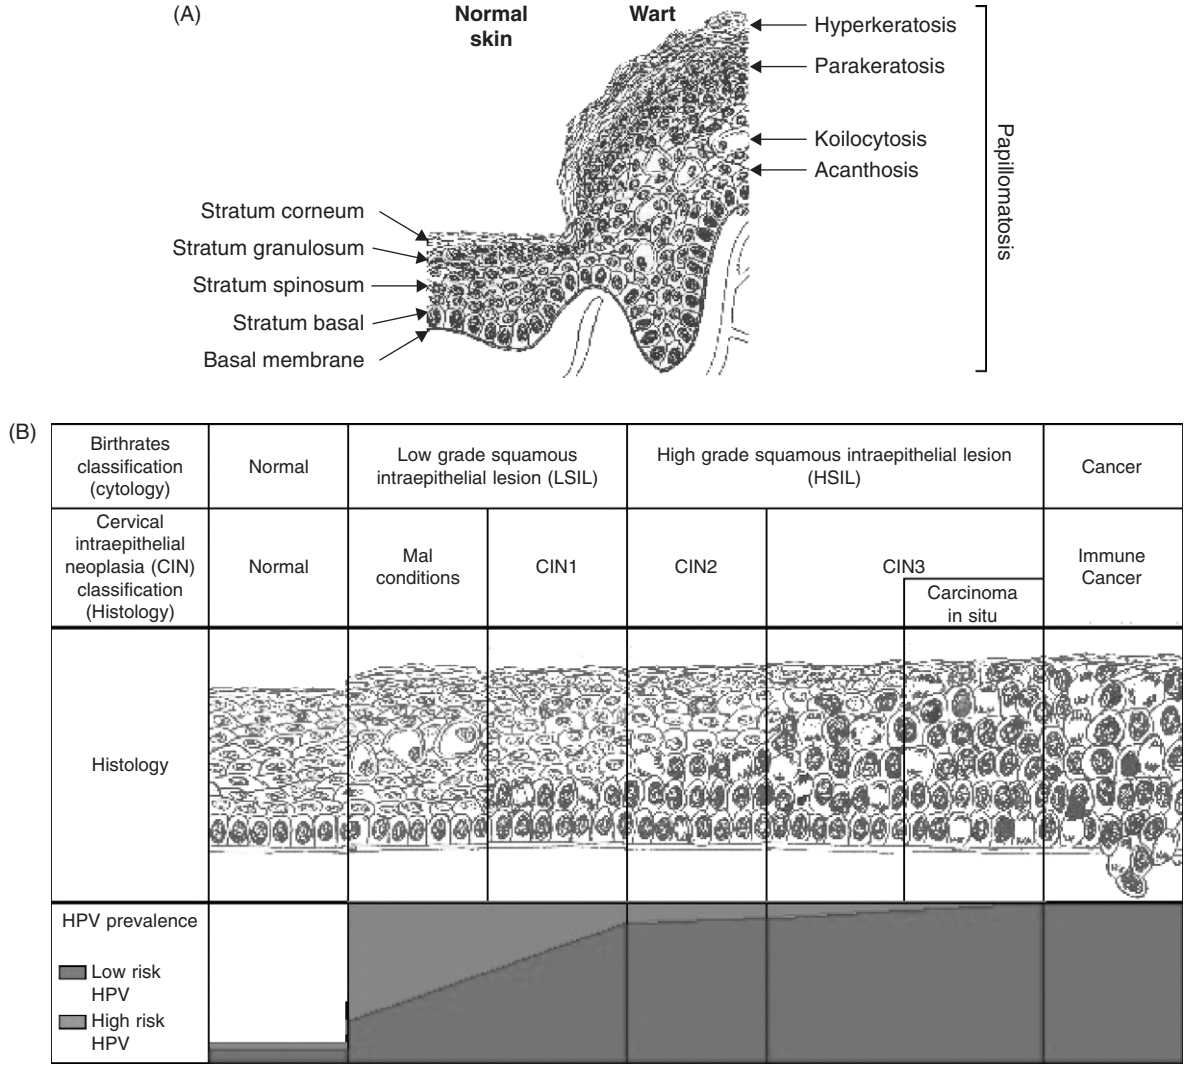

FIGURE 26.2 (A) Histologic features of a genital/cutaneous wart. (B) Histopathogenesis of cervical HPV-associated lesions (see text for details).

CLINICAL DISEASE

Most HPV infections are asymptomatic, latent, or subclinical, and involve the squamous, stratified epithelia of the body as well as the glandular epithelium of the uterine cervix. Consequently, the clinical manifestations arise in those tissues and range from benign proliferative lesions, warts, papillomas, and condylomas, to malignant tumors, namely squamous cell carcinomas and cervical adenocarcinoma.

Cutaneous warts are typically distributed over the acral extremities and the face. They are mostly caused by HPV types 1, 2, and 4. They include common warts (verrucae vulgaris), the most usual form, which are found on the dorsum of the hands, between the fingers, and around the nails. They can also be found on the foot soles where they tend to aggregate and form flat, mosaic warts. Distinct in appearance is the deep plantar wart (verruca plantaris) that is usually solitary, raised, with a ragged surface and a deep base. Plane warts (verrucae planae, juvenile warts) are typically found on the face of children, but can also be found on the extremities.

Epidermodysplasia verruciformis is a rare genodermatosis involving the whole body skin, which is remarkable not only for the HPV types that appear predominantly associated with it such as types 5, 8, 9, 12, 14, 15, and 17, but also for the high propensity for the resulting lesions, which range from plane warts to brown-to-red papules, to progress, by the fifth decade, into squamous cell carcinomas in the sun-exposed areas. This disease has been the earliest model of an association between HPV and cancer (Orth, 2006).

Anogenital warts [condyloma(-ta) acuminatum (-ta), venereal warts] develop on the external genitalia and perineal area. Over 95% of them are caused by either HPV-6 or -11 (Brown et al., 1999). Commonly, a patient will present with 5–6 lesions, each rarely exceeding 1 cm in diameter. In the uncircumcised male, the preputial cavity is the site of predilection, in contrast to the circumcised male, in whom the penile shaft is most often involved. The pubic area, the groin, and the urethral meatus can be involved, but the scrotum much less commonly. In females, lesions are typically present on the posterior introitus extending toward the perineum, but the labia majora and minora are also often involved. Some lesions can be hard to discern either because of their small area or for being very flat. The aid of a magnifying instrument, such as a colposcope, with the prior application of 3–5% acetic acid (white vinegar), facilitates the identification of these lesions. There is evidence that penile flat papules contribute to disease transmission (Bleeker et al., 2002, 2003). In contrast, genital warts can form very large, giant condylomas that tend to have a local invasive behavior, thus forming verrucous carcinomas. *Buschke-Löwenstein* tumors are related, but distinct tumors.

In both males and females, warts can be observed around the anus, sometimes extending into the anal canal, up to the pectinate line. Anal sexual play, including anal intercourse, contributes to this occurrence. Different HPV-related lesions can arise on the vaginal wall in the form of either flat or spiked condylomas. Condylomas can also be observed on the cervix. Papillomas may also grow in the larynx, on the vocal cords causing airway obstruction. This unusual condition, called recurrent respiratory papillomatosis, is caused mostly by the same HPVs causing genital warts, types 6 and 11 (Derkay, 2001; Derkay and Darrow, 2006). Its age distribution is bi-modal, with a more common juvenile-onset and an adult-onset form.

Different HPV-related lesions can be found in the oral cavity (Bonnez, 2002b). Oral squamous cell papillomas (also called squamous papillomas) are the most common, and with oral condylomata acuminata—a different histologic entity—they are largely caused by the genital HPV types 6, 11, and 16. Oral verruca vulgaris are histologically distinct and caused by cutaneous HPV, such as types 2, 4, 57. Focal epithelial hyperplasia of the oral cavity (Heck's disease or Archard's disease) is a rather unique, diffuse, and usually transient oral disease caused predominantly by HPV-3 and -13 (Syrjanen, 2003).

TREATMENT

The benign and self-limited nature of most HPV lesions, combined with the limitations of the current treatment options, makes observation without treatment an acceptable approach in many instances of HPV disease. Nevertheless, physical or cosmetic discomfort, psychological burden, and reduction of the transmission risk are treatment considerations. The treatment options rely on the physical or chemical destruction of the lesions, as well as on immunomodulation. Their use rests on evidence of widely varied quality.

Cutaneous warts are treated mostly with the topical application of preparations containing salicylic acid, a keratolytic agent (Micali et al., 2004; Gibbs and Harvey, 2006). These preparations can be found over the counter, often in combination with lactic acid and collodion. Glutaraldehyde, silver nitrate, and formaldehyde are some of many other chemicals that have been used. A major adjunctive measure is the removal prior to

treatment of any superficial cornified layers by soaking the area and using a pumice stone, sandpaper, or an emery board. Cryotherapy is an alternate option that can be applied with over-the-counter cryogenics, although better freezing is obtained in the medical office with liquid nitrogen delivered by spray, probes, or cotton applicators. The therapeutic application on the wart of an occlusive dressing with duct tape has received a lot of attention, especially after the results of a randomized clinical trial (Focht et al., 2002). However, two subsequent trials failed to replicate these results (Wenner et al., 2007; de Haen et al., 2006).

Imiquimod, an imidazoquinoline amine compound that stimulates the local production of interferon and other cytokines, has been a useful addition to the treatment of genital warts, as it allows self-treatment (Garland, 2003; Skinner, 2003; Chang et al., 2005). It is available as a 5% cream (Aldara) that is applied three times a week on alternate days for 8 weeks, and up to 16 weeks. Complete response rates are about 60%, better for females than for males (Garland et al., 2001). Another self-administered treatment is podofilox, as a 5% solution or gel (Condylox) that is applied three consecutive days per week, for up to four cycles (Longstaff and von Krogh, 2001; Lacey et al., 2003). The recurrence rate is high, resulting in a net complete response rate of 30–50%. Among the practitioner's applied treatments, podophyllotoxin, a mitotic spindle inhibitor, has fallen out of favor because of its poor efficacy–toxicity profile (von Krogh and Longstaff, 2001). Podofilox, one of the active components of podophyllotoxin, has replaced it. Bi- or trichloracetic acid, cryotherapy, laser surgery, and electrosurgery are among the treatment methods for genital warts most commonly employed by health practitioners (Bonnez, 2002c; Lacey, 2005; Workowski and Berman, 2007). There is no firm basis to compare their respective efficacy, but they vary substantially in cost, and their indications do not completely overlap (Alam and Stiller, 2001). The selection is usually guided by the technique's availability to the practitioner.

The treatment of intraepithelial neoplasias outside the cervix is not well codified, and is generally based on the use of observation, imiquimod, cryotherapy, electrosurgery, laser therapy, or local blade excision (Lacey, 2005). Elaborate consensus guidelines have been developed for the management and treatment of the different stages of cervical intraepithelial neoplasia (http://www.asccp.org/) (Wright et al., 2007). They incorporate observation, ablation (laser surgery, cryotherapy), and excisional (electrosurgery, cold-blade surgery) treatment. The treatment of recurrent respiratory papillomatosis is mostly by surgical debridement, with the use of a microdebrider device that is preferred to laser surgery or cold steel mircrosurgery (Derkay and Darrow, 2006). Adjuvant therapy includes systemic interferon and intralesional cidofovir injections. A therapeutic vaccine, HspE7, based on the fusion protein of the heat-shock protein 65 of *Mycobacterium bovis* BCG and E7 of HPV-16, has shown encouraging results in an open-label trial (Derkay et al., 2005).

PATHOGENESIS

Description of Disease Process

HPV diseases are the consequence of the proliferation of the epidermal layers. In a benign lesion, the strata spinosum, granulosum, and corneum are thicker than in the normal epithelium, resulting in acanthosis, parakeratosis, and hyperkeratosis, respectively. In addition, within the stratum spinosum the presence of koilocytes is quasi-pathognonomic of HPV. Koilocytes are large keratinocytes with a perinuclear halo. By histology, the nuclei may appear shriveled, but on cytology they are more easily revealed to be binucleated, and typically larger and with a more effaced chromatin than normal nuclei. The relative magnitude of the different histologic features, and the position and abundance of the koilocytosis are features that are related to the HPV type causing the infection and the nature of the lesion, for instance a common wart as opposed to a genital wart. The infection also leads to a change of the cytoarchitecture within the lesion, with a deepening of the rete ridges in the basement membranes and the protrusion of the lesion above the normal epithelium, a phenomenon called papillomatosis. In an inverted papilloma, such as encountered in the nasal passages, this proliferative process extends toward the dermis rather than above the surface.

In malignant lesions, some of the above features may be retained in the milder histologic grades, but the main change is the proliferation of the basal layer with cells that acquire malignant characteristic with a higher nuclear to cytoplasmic ratio and frequent mitoses, some abnormal. According to the fraction of the epithelium this dyskaryotic proliferation occupies, three grades are recognized in what is called an intraepithelial neoplasia (also improperly called dysplasia). In grade 1, the mildest, the lower third of the epithelium is involved; in grade 2, more than one-third, but less than two-thirds is involved; and in grade 3 more than two-thirds is involved. If the whole epithelium is involved, as in the ultimate grade 3, this is carcinoma in situ, the breach of the basement membrane signaling invasive carcinoma. Cervical intraepithelial neoplasia is shortened as CIN,

while the vulvar, vaginal, anal, and penile forms go by the acronyms of VIN, VAIN, AIN, and PIN, respectively. The cytologic diagnosis of these lesions in the cervix has been based on the Bethesda classification (Solomon et al., 2002). Low-grade squamous intraepithelial lesions (LSIL) regroup cervical condyloma and CIN1, while high-grade squamous intraepithelial lesions (HSIL) correspond to CIN2 and 3. The same dichotomic division between low- and high-grade intraepithelial neoplasias is recommended by some for the purpose of histologic classification.

These pathologic changes are the result of viral transcription (Hebner and Laimins, 2006; Snijders et al., 2006). This interaction starts in the dividing basal keratinocytes where, under the control of an early promoter located in the upstream regulatory region of the viral genome, transcripts that are produced encode the ORFs of E6, E7, E1, and E2. E1 and E2 proteins are involved in viral DNA replication, which has to harness the replicative enzymes of the host cell. E6 and E7 proteins are involved with oncogenicity for the high-risk HPVs. As one of the daughter cells ascends and differentiates through the epithelium, viral transcripts are then made from a late promoter located in the E7 ORF. This leads to the expression of the E1, E2, E4, E5, as well as L1 and L2 ORFs. The role of the E4 and E5 proteins is poorly understood, but they associate with the cytokeratin network and the Golgi apparatus, respectively. L1 and L2 proteins are the major and minor capsid proteins, respectively, and are thus necessary for the production of viral particles. The viral capsid is composed of 72 capsomeres, each being made of five L1 and one L2 proteins.

Among the best-understood aspects of HPV molecular pathogenesis are the functions of the E6 and E7 oncoproteins. They interfere with two important cellular tumor-suppressor proteins, p53 and the retinoblastoma (Rb) proteins, respectively. Both of these cellular proteins control the G1/S transition of the cell cycle. E6 also interacts with the function of the PSD-95/discs large/ZO-1 (PDZ) proteins that are important in cell signaling and cell-to-cell adhesion. It also activates the telomerase, thus increasing cell longevity, and in concert with E7 immortalizes keratinocytes. E7 itself can derepress the class I histone deacetylases (HDACs) that are important in blocking the transition of the cell cycle into the S phase. It can also promote chromosomal instability. Methylation of selected sites in the upstream regulatory region of the viral genome and chromosomal alterations (polyploidy, aneuploidy, deletions) are some of the signaling events that mark the transition from benign to malignant (Garnett and Duerksen-Hughes, 2006). Integration of the viral genome into the host genome is another such event. Even if its true significance is in question, integration causes the derepression of E6 and E7. E5, E6, and E7 individually and together, contribute to the inhibition of apoptosis, a process that would normally eliminate abnormal cells (Garnett and Duerksen-Hughes, 2006).

Immune Response to Infection

HPV infection itself can blunt the immune response (Eiben Lyons et al., 2007; Kanodia et al., 2007; Sheu et al., 2007). HPV-16 E5 down-regulates the expression of HLA-A and HLA-B, the major histocompatibility class I proteins responsible for the presentation of viral peptides to cytotoxic T lymphocytes (Ashrafi et al., 2006). Nevertheless, the host is capable of containing, even eliminating HPV infection, by opposing these mechanisms of immune evasion. Cytokines such as interleukin 2 (IL-2) and interferon gamma (type II interferon), as well as interferons alpha and beta (type I interferons) and tumor necrosis factor (TNF) alpha, are important defense mechanisms that are mediated by natural killer cells. In addition to this innate immune response, an adaptative cytotoxic immune response driven by a CD4T cell response can be noted, and is mostly directed at E6 and E7. This response is not HPV type specific, and its effectiveness is unclear, but it appears important enough to account for the greater HPV disease burden encountered in immunodeficient or immunosuppressed subjects (Scott et al., 2001; Nicol et al., 2005). A humoral immune response can probably develop to most of the viral HPV proteins, but it is usually in a minority of subjects. The most important response is to L1. As seen with HPV-6, -11, and -16, only half of the patients with a new HPV infection will develop antibodies to HPV L1 VLP, but the magnitude of this antibody response is insufficient to provide protection from a future HPV infection or disease (Kirnbauer et al., 1994; Heim et al., 1995; Eisemann et al., 1996; Wikstrom et al., 1997; Studentsov et al., 2003; Viscidi et al., 2004; Tachezy et al., 2006).

VACCINES

History

It is in man that the first vaccines against HPV disease were developed (Biberstein, 1944). These vaccines were aimed to be therapeutic and were autogenous—the vaccine was made from the patient's own genital warts to eradicate the remaining lesions (Biberstein, 1944; Abcarian and Sharon, 1982). The results of several case series were very good, but they failed to be confirmed in a double-blind, cross-over,

placebo-controlled, randomized study (Malison et al., 1982). The trend favored the vaccine. Unfortunately, the study was underpowered to show a difference. The prophylactic efficacy of such vaccines, or vaccines prepared directly from a lesion, was never studied in man, but some protection was observed in the cow with bovine papillomavirus (BPV) and in the domestic rabbit with the cottontail rabbit papillomavirus (Jarrett et al., 1990; Evans et al., 1962a, 1962b). Nevertheless, as these animal models are sufficiently different from HPV disease in man caution is always required in extrapolating the results. For example, BPV types 1 and 2 infect the epidermis and dermis (Jarrett, 1985), BPV-4 causes disease in the alimentary tract (Jarrett et al., 1978), and CRPV causes a different pathology in its natural host than in the domestic rabbit (Kreider and Bartlett, 1985). It is likely that these limitations are an important reason why none of the vaccine concepts tried in these models made it into the clinic until the advent of the VLP-based HPV vaccine. An example of these inconsequential leads were the positive results obtained with BPV-4 and CRPV full L1 fusion proteins (Pilacinski et al., 1986; Jin et al., 1990; Lin et al., 1992, 1993). Conflicting results were obtained using a full L2 fusion protein, depending on the type of BPV used, or when using CRPV (Lin et al., 1992; Jarrett et al., 1991; Campo et al., 1993). Similarly, immunization with a fusion protein containing the C-terminus of L2 or the full E2 gave different results with BPV-4 and CRPV (Campo et al., 1993; Christensen et al., 1991; Chandrachud et al., 1995; Selvakumar et al., 1995). Favorable results were seen with a full unfused L1 protein (Pilacinski et al., 1986), a combination of L1 C and N-terminus fusion proteins (Jarrett et al., 1991), a L2 N-terminus fusion protein (Chandrachud et al., 1995), a full E1 fusion protein (Selvakumar et al., 1995), a combination of full E1 and E2 fusion proteins (Selvakumar et al., 1995), and E7 and combined E7 and L2 fusion proteins (Campo et al., 1993). No protection was conferred by immunization with fusion proteins made from CRPV L1 C-terminus, middle segment, N-terminus, or a combination of the C-terminus and middle segment (Lin et al., 1993; Christensen et al., 1991).

Several groups of investigators independently pursued the idea of an HPV vaccine with the conviction that it would be based on the expression of the major capsid protein in its native conformation. Although it had been shown that HPV-1 virions purified from plantar warts were the best antigens to detect a specific serologic response in patients with cutaneous warts, it then was not possible to either grow or purify genital HPV virions (Kienzler et al., 1983). With the description of the human xenograft nude mouse model, it became possible to grow HPV-11 virions (Kreider et al., 1985). Using them as antigen, one could detect with great specificity antibodies in genital or recurrent respiratory patients (Bonnez et al., 1991, 1992a, 1992b). The nude mouse model also allowed to demonstrate that the HPV-11 virions could induce strong neutralizing antibodies in the rabbit (Christensen and Kreider, 1990; Bonnez et al., 1990, 1992). This gave the impetus to find a noninfectious substitute as a vaccine. Intracellular, native L1 protein appeared to be made when HPV-1 L1 was expressed in simian cells, using an SV-40 vector (Ghim et al., 1992). In 1991, the synthesis and purification of HPV-16 VLPs with a vaccinia vector was reported (Zhou et al., 1991). This was promoted as a potential vaccine, but other than the fact that no immunologic evidence was given to this effect, the authors asserted that VLPs could be made only with L1 + L2 alone. This was amply proven wrong. Moreover, when other investigators tried to replicate that work with what should have been the same HPV-16 strain, VLPs failed to materialize (Kirnbauer et al., 1993). This was shown to be due to a single point mutation in that particular strain. This explained why these original 'VLPs' did not have the size and appearance of the papillomavirus VLPs made by other investigators, then and since (Kirnbauer et al., 1992; Rose et al., 1993a). It was then shown that HPV VLPs could be made with L1 alone, and that they had the same immunologic properties as the intact virions, in particular that immunized rabbits could generate neutralizing antibodies against an HPV-11 skin infection (Rose et al., 1993a, 1993b, 1994). These experiments done entirely with human viruses and tissues offered the most coherent basis for the current vaccine. Subsequent work revealed that a human HPV vaccine would have to be multivalent, as different HPV genotypes also corresponded to different serotypes (Rose et al., 1994a).

Papillomavirus VLPs were then tested in different animals, and excellent protection was seen against challenge with the homologous virus in a canine oral papillomavirus (COPV) model (Suzich et al., 1995), as well as in CRPV and BPV-4 models (Christensen et al., 1996b; Kirnbauer et al., 1996). Passive immunization was also protective in the COPV and CRPV models, indicating the key role of neutralizing antibodies in the vaccine efficacy (Suzich et al., 1995; Breitburd et al., 1995).

The first clinical trials began in 1997 with the successful demonstration of the initial safety and immunogenicity of monovalent HPV L1 vaccines against HPV-11 and HPV-16 (Evans et al., 2001; Harro et al., 2001). Production of very high neutralizing antibody titers to the immunizing VLPs was demonstrated. It should be noted that the cellular immune response

induced by HPV VLPs, as measured by lymphocyte transformation assays, was not type specific (Evans et al., 2001; Pinto et al., 2006). This work opened the clinical development of the current vaccines.

Current Licensed Vaccines

There are currently two vaccines, both containing HPV L1 VLPs that have been licensed for administration in at least some countries: Gardasil and Cervarix. The approval for Cervarix is very recent, and does not concern the United States yet. The major significant differences at this point between these two vaccines are that Gardasil is quadrivalent, directed at HPV types 6, 11, 16, and 18, and contains an alum adjuvant whereas Cervarix is bivalent, including only HPV-16 and -18 and contains alum and monophosphyl lipid A adjuvant system. This difference means that only Gardasil is approved for the prevention of external genital warts. Otherwise, for HPV-16 and -18 cervical infections and diseases, the two vaccines appear at this point to have very similar immunogenicity, safety, and efficacy profiles. Less published information is available for Cervarix than for Gardasil, which will be covered first.

Gardasil

Clinical Trials

Phase I The development of Gardasil was preceded by dose-escalation studies that evaluated the immunogenicity and tolerance of monovalent HPV11 and HPV-16 L1 VLP vaccines (Fife et al., 2004; Brown et al., 2004; Poland et al., 2005). An initial study enrolled HPV DNA negative and HPV seronegative subjects for the type tested and found good neutralization titers with intramuscular doses equal to or higher than 40μg for HPV-16 and 50μg for HPV-11 VLP (Fife et al., 2004). Neutralization antibodies in this study and all subsequent studies were measured by competition for VLP binding against a labeled mouse monoclonal with known specificity for the neutralizing epitopes of the HPV type tested (Opalka et al., 2003; Dias et al., 2005). The retention of the antibody response was high after 3 years. A post-hoc assessment of the vaccine efficacy for the prevention of persistent HPV-16 infection was conducted in one of the population originating from this trial (Brown et al., 2004). There were 5 cases per 100 person-years at risk in the control group compared to none in the vaccine group. A dose ranging study (0, 10, 20, 40, and 80μg) of HPV-16 L1 VLP was conducted in women regardless of their baseline cervical HPV DNA and HPV serostatus (Poland et al., 2005). It showed no difference in local or systemic reactions among treatment groups. The titers after immunization in the subjects who were seronegative at baseline were 36–78-fold higher than those in the subjects who had mounted a serologic response to HPV-16 after a natural infection. Moreover, post-immunization titers were 1.1–2.4-fold higher in the subjects who were seropositive at baseline, compared to those who were seronegative.

Gardasil, the quadrivalent vaccine preparation including HPV-6, -11, -16, and -18 VLPs, was evaluated in a dose-escalating study, followed by a dose-ranging study in 16–23-year-old women (Villa et al., 2006a). This study led to the selection of the current vaccine dosing, and confirmed the high immunogenicity for each of the HPV types of the vaccine preparation, with serologic responses being sustained for up to 3 years.

Phase II It was the study by Koutsky et al. (2002) that firmly established the clinical value of the HPV VLP vaccine. The investigators enrolled 2392 women aged 16–26 years who had had no more than five lifetime sexual partners to be randomized to receive either HPV-16 L1 VLP (40μg) formulated with amorphous aluminum hydroxyphosphate sulfate adjuvant or adjuvant alone given intramuscularly at day 0, month 2, and month 6. Genital samples to test for the presence of HPV DNA were obtained at enrollment, one month after the last immunization, and every six months thereafter. The patients were monitored with cytology, and colposcopy if indicated by protocol. The endpoint of the study was the presence, starting one month after the third immunization, of HPV-16 infection on two or more consecutive visits (persistent infection). A predetermined number of cases of persistent infection was reached after a median follow-up of 17.4 months. Excluding from the analysis those women who had been HPV-16 DNA positive or HPV-16 seropositive at baseline, the analysis showed that none of the 768 vaccinees, as opposed to 41 of the 765 placebo recipients, had developed a persistent infection. In the secondary analysis, 10 of the cases of persistent HPV-16 infection had developed related CIN, thus pointing to a disease prevention effect as well. Although pain at the injection site was the most common side effect, there was no difference in the rates of adverse reactions between the two study groups.

The analysis after 48 months of follow-up of the study populations showed 7 cases of HPV-16 persistent infections in the 755 vaccine recipients, but 111 cases in the placebo group, yielding an efficacy of 94% (95% CI, 88–98%) (Mao et al., 2006). Three cases each of CIN2 and CIN3 were noted in the placebo recipients,

but none in the vaccine group. As in the phase I studies, the HPV-16 VLP serum titers peaked after the third immunization, then declined, but by month 18 reached a plateau still many folds higher than the levels attained after a natural infection.

An extension of the dose-ranging study that led to the dosing selection for Gardasil offered an opportunity to look up to 5 years post-enrollment at the combined incidence of HPV-6, -11, -16, and -18 infection and disease (CIN and genital warts) in placebo (adjuvant) and vaccine (the formulation that was later approved as Gardasil) recipients who were seronegative and HPV DNA negative for the vaccine types analyzed (Villa et al., 2006b). This endpoint was reached in 2 of 235cases in the vaccine group and in 46 of 233 in the placebo groups—a vaccine efficacy of 96%. The efficacy was 100% when looking at disease only, with no cases of CIN or genital warts in the vaccine recipients, but 6 in the placebo recipients. In order to study the immune memory response, those subjects whose study had been extended beyond 3 years received a fourth injection at month 60 (Olsson et al., 2007). This fourth immunization with the vaccine induced a strong anamnestic response. The antibody titers reached stable levels higher than one month after the third immunization.

The clinical development of the HPV vaccine presented two particular problems. It was anticipated that in order to achieve maximal efficacy, the vaccine would have to be administered before the acquisition of HPV infection. Therefore, HPV persistent infection or disease could not be used as an endpoint of vaccine efficacy in an essentially sexually naive population. A protective neutralizing titer after immunization was regarded as an adequate surrogate to bridge the results in 16–26-year-olds to 9–15-year-olds. The second difficulty was the complete or near-complete efficacy of the vaccine in 16–26-year-olds. This meant that it was impossible to determine a neutralizing antibody level below which either persistent HPV infection or, more importantly, disease would start breaking through. The vaccine had to be shown to induce at least equivalent antibody titers in pre-adolescents as in adolescent or adult women. This "bridging" efficacy was established in a randomized, double-blind trial of Gardasil immunization in 506 girls (10–15-year-old), 510 boys (10–15-year-old)—boys and girls being sexually naive—and 513 women (16–23-year-old) (Block et al., 2006). The resulting antibody titers to HPV-6, -11, -16, or -18 VLPs in boys and girls were non-inferior to those in women. They were in fact 1.7–2.7-fold higher, with a trend showing higher titers in boys. These results were repeated in a study done in boys and girls 9–15 years old that compared the vaccine against a non-aluminum adjuvant (Reisinger et al., 2007). In the first study, boys and girls were more likely to have fevers after vaccination, 13.8 and 12.8%, respectively, than women, 7.3%. In the second study, vaccine recipients reported one or more injection site–related adverse events more often than the placebo recipients, 75.3% vs. 50.0%.

Phase III The primary endpoint of the phase III trials was the demonstration that the vaccine not just prevented infection, but that it also reduced disease incidence. In contrast to cervical HPV infection, CIN2/3 was regarded as the proper surrogate endpoint for cervical cancer because of the following factors: (a) it was the immediate precursor for cervical cancer; (b) it would be amenable to secondary prevention measures when found; (c) its detection and removal had been shown to prevent cancer; and (d) it was fully treatable (Kang and Lagakos, 2004). The trial results are summarized in Table 26.1 (Garland et al., 2007; Koutsky, 2007; Ault, 2007; Joura et al., 2007; Luna et al., 2007). They clearly show that the greatest benefit of the vaccine was in subjects that were seronegative and HPV DNA negative for the vaccine HPV types, indicating that maximum benefit of vaccination occurs before sexual debut (Hildesheim and Herrero, 2007). Nevertheless, even in women with virological (serology or PCR) evidence of preexisting vaccine-type HPV infection, the vaccine was 100% effective at preventing incident CIN2/3 or cervical adenocarcinoma in situ (AIS) by vaccine HPV types for which the women were negative at enrollment (FUTURE II Study Group, 2007). Similarly, vaccination was 94% effective in preventing vaginal or vulvar HPV-associated lesions, including external genital warts. In this combined study of 15–26-year-old women, 26.8% of the enrollees had current or past evidence of at least one vaccine-type HPV infection.

HPV-16 and -18 account for only 70% of cervical cancers and a smaller fraction of CIN, especially low grade. The vaccine has little impact on the infections and diseases caused by the other HPV types. The "intention-to-treat population—any lesion regardless of type" analysis (Table 26.1), which also includes women not naive for the vaccine types, provides a look at the overall effectiveness rather than just efficacy of the vaccine. The results are substantially worse, and it has been pointed out that the vaccine efficacy of 17% noted in that analysis of protocol 017 implies that "129 women would need to be vaccinated in order to prevent one case of CIN2/3 or AIS" (Koutsky, 2007; Sawaya and Smith-McCune, 2007).

[a] The subjects were randomized 1:1 between the vaccine and placebo groups, and the two groups were tightly balanced. Except where noted (Protocol 019), the subjects were 16–26-year-old women, and results are based on 3 years of follow-up.
[b] This was the population used for the primary endpoint analysis. Subjects were seronegative and HPV DNA negative at day 1 for the HPV types included in the vaccine. They had a normal Pap smear, received all 3 immunizations, and cases were counted starting 1 month after the third immunization.
[c] Protocol 019 enrolled 24–45-year-old women, and the disease endpoint was assessed by cytology at a mean 1.65 years of follow-up. In that study, the vaccine was 91% effective preventing persistent infection, external genital warts, or CIN caused by HPV-6, -11, -16, or -18.
[d] This population included subjects who were seronegative and HPV DNA negative at day 1 for the HPV types included in the vaccine, but it included protocol violators, individuals who had received less than 3 doses, who had developed HPV DNA positivity during the vaccination phase, and who had an abnormal Pap smear at day 1. Case counting began 1 month after the first immunization. About a quarter of the subjects were positive by HPV DNA or serology at day 1 for at least one of the vaccine types.
[e] This population was identical to the Unrestricted Susceptible Population, except that it included subjects who were HPV seropositive and/or HPV DNA positive for the vaccine types at day 1.

This is a pessimistic and restrictive interpretation for several reasons. These low-efficacy figures are those observed at 3 years of follow-up. As long as the vaccine is effective, they should improve with further follow-up, because the placebo recipients continue to acquire lesions at a higher rate than the vaccinees. This increase in efficacy in the general population has been verified with Cervarix with 5-year follow-up (Harper et al., 2006). The figures also vary according to the geographic area, possibly reflecting different HPV type distributions. The vaccine efficacy for CIN2/3 and AIS in North America in the "intention-to-treat" population was double that of Asia (Ault, 2007). HPV-16 and -18 are more oncogenic than the other HPVs, and preventing one case of CIN2/3 caused by one of these two types should have more impact on cervical cancer than preventing one case of CIN2/3 caused by one of the non-vaccine types (Schiffman et al., 2005). Finally, vaccination cannot be dismissed when it is the only preventive measure available for HPV-associated cancers other than those of the cervix. Even with cancer of the cervix, half of the affected women are those who have never been screened, and another 10% has not been screened in the previous 5 years ((NIH) NIoH, 1996; Leyden et al., 2005). Given that the socioeconomic barriers to cervical cancer screening are different from those applying to vaccination, vaccination might be the only preventative option for some women (Hewitt et al., 2004).

A further analysis of the phase II/III trials examined the impact of baseline characteristics on the immunogenicity of the vaccine (Giuliano et al., 2007). As already observed, age at vaccination was inversely proportional to the antibody titers induced by immunization. Preexisting HPV antibodies resulted in a higher serologic response than in the absence of baseline antibodies. Otherwise, there was no detectable effect of race/ethnicity, region of residence, lactation status, hormonal contraceptive usage, smoking status, Pap smear diagnosis, immunosuppressant, or anti-inflammatory drug use, and number of sex partners. The absence of effect of anti-inflammatory drug use on vaccine immunogenicity is preliminary, but reassuring in light of animal and human in vitro experiments that had shown an inhibitory effect of cyclooxygenase-2 inhibitors (Ryan et al., 2006).

Agent/Strain Used in Vaccine, How Produced, Number of Doses Administered to Give Protective Immunity Gardasil (also sold in some countries as Silgard) is made by Merck and is distributed in European countries by Sanofi Pasteur, a joint venture of Merck and Sanofi-Aventis. It was first marketed in June 2006. This quadrivalent vaccine is made in a *Saccharomyces cerevisiae* yeast expression system, and contains L1 VLP of HPV types 6, 11, 16, and 18 at concentrations of 20, 40, 40, and 20μg, respectively. A 0.5ml dose also includes approximately 225μg of an amorphous aluminum hydroxyphosphate sulfate proprietary adjuvant. The preparation is sterile and does not contain a preservative or antibiotics. The vaccine is administered as three doses at months 0, 2, and 6. It is given intramuscularly, preferably in the deltoid area of the upper arm or in the higher anterolateral area of the thigh.

Protective immunity is believed to be exclusively provided by the neutralizing antibodies induced by immunization. A protective antibody threshold has not yet been established given the very high efficacy of the vaccine. It is therefore unclear after how many doses immunity is established. It was however noted that the vaccine retained a very high efficacy, even when the analysis included patients who had not received all three injections (see Table 26.1). Clinical studies are in progress to examine the effectiveness of abbreviated immunization schedules (Advisory Committee on Immunization Practices, 2007, www.cdc.gov/vaccines/recs/acip/downloads/acip_min_feb07.pdf). Gardasil package insert (https://www.merckvaccines.com/gardasilProductPage_frmst.html) indicates that neutralizing antibody titers measured one month after the third dose are the highest for all the vaccine HPV types if the second dose is administered on time or early (36–50 days after dose 1) and/or if the third dose is administered on time or late (138–160 days after dose 2).

Clinical and serological endpoints have been followed up to 5 years at this point , and there is still no evidence that a booster immunization is or will be necessary (Villa et al., 2006b; Olsson et al., 2007). Nevertheless, a booster immunization was evaluated 5 years after the first immunization in a subgroup of 104 16–23-year-old female vaccine recipients (Olsson et al., 2007). For each of the HPV types, the neutralization titers were superior to titers observed one month after the third immunization, demonstrating a very strong memory response. In that study, subjects who had received the placebo for their first three immunizations were also boosted, and among those who had been seropositive but PCR HPV DNA negative at enrollment, the titers after this single vaccine administration were comparable to those measured after three initial immunizations in the seronegative subjects.

Vaccine Recommendations, Including Potential to Administer with Other Vaccines The Advisory Committee on Immunization Practices (ACIP), which is part of Centers for Disease Control and Prevention and a leading group on immunization recommendations in the United States, recommends the vaccine

to 11–12-year-old girls, with a catch-up immunization for 13–26-year-old girls (Markowitz et al., 2007) (Table 26.2). The Vaccine for Children Fund for free vaccination, a federally mandated program administered by each state and targeted to the underprivileged population, is applicable to the 9–18-year-old female population.

In the 11–12-year-old group for which the vaccine is indicated, two other vaccines are recommended, the tetanus and diphtheria toxoids and acellular pertussis vaccine (Tdap) and the meningococcal vaccine (MCV4) (FUTURE II Study Group, 2007). At this date the ACIP and the American Academy of Pediatrics (AAP) recommend administering these single-dose vaccines with one of the HPV vaccine doses. It is recommended to use a different site for the injection of each vaccine. Although there are no theoretical reasons for concern, there are no data currently available evaluating the safety and efficacy of this practice. This should change by the end of 2008, as a study is currently underway (ClinicalTrials.gov Identifier: NCT00325130). A catch-up immunization with the hepatitis B vaccine may also be necessary in the same age group, and a study has shown no effect on the safety and immunogenicity of the HPV vaccine (Markowitz et al., 2007; Gardasil Package Insert, 2007, www.fda.gov/cber/label/hpvmer040307LB.pdf).

Several American professional organizations have endorsed the use of the vaccine with recommendations usually similar to those of the ACIP. They include the AAP (American Academy of Pediatrics Committee on Infectious Diseases, 2007, http://www.cispimmunize.org/ill/pdf/HPVprovisional.pdf), the American College of Obstetricians and Gynecologists (ACOG) (ACOG Committee, 2006), the American Association of Family Practitioners (AAFP) (Armstrong, 2006), the Society for Adolescent Medicine (SAM) (Friedman et al., 2006), the American College Health Association (ACHA), (ACHA guidelines, 2006) and the American Cancer Society (ACS) (Saslow et al., 2007). The ACS guidelines do not recommend the vaccine for the 19–26-year-old female population.

It is important to note that HPV immunization does not change in any way as the current guidelines for cervical cancer screening (Pap smear) (Saslow et al., 2002; ACOG Practice Bulletin, 2003; Screening for cervical cancer, 2003, http://www.ahrq.gov/clinic/3rduspstf/cervcan/cervcanrr.pdf).

TABLE 26.2 HPV quadrivalent vaccine, Gardasil, recommendations (United States)

Indications

- 11–12-year-old girls
- Catch-up immunization for 13–26-year-old girls
- Can be administered to girls as young as 9 years
- Most effective if administered before sexual debut
- Given as 3 intramuscular doses, at months 0, 2, and 6
- May be given at the same time as the hepatitis B (Hep B), the tetanus and diphtheria (Td), the tetanus, diphtheria, acellular pertussis (Tdap), or the meningococcal (MCV4) vaccines
- Can be given to patients with genital warts, an equivocal or abnormal Pap smear, or the presence of cervical high-risk HPV DNA (Hybrid Capture II assay), but the subject should be advised that the vaccine is not therapeutic and does not protect against diseases by already established HPV types
- May be given to lactating women
- May be given to immunosuppressed or immunodeficient patients, but efficacy may be reduced
- Cervical cancer screening (Pap smear) recommendations are unchanged for vaccine recipients and should be reminded to the subject
- Protective sexual behaviors (including abstinence, monogamy, limiting the number of sexual partners, using condoms) should be continued since the vaccine does not protect against all HPV infections and does not affect other sexually transmitted infections
- An interrupted immunization series should be resumed (not restarted at dose 1) as soon as it becomes possible

Contraindications

- Immediate hypersensitivity to yeast or any of the vaccine components
- Pregnancy (if vaccinated during pregnancy report the case to the vaccine pregnancy registry, tel. 800-986-8999)
- Moderate or severe acute illness
- The vaccine does not contain thimerosal or mercury

Countries Where Vaccine is Licensed, Including Manufacturers As of the end of October 2007, Gardasil has been approved in 87 different markets, including the 3 North American countries (Canada, United States, and Mexico), 15 Caribbean and Central American countries, 6 South American countries, 38 European countries, 15 Middle Eastern and African countries, and 11 Asian or Pacific countries, and more applications are pending.

Indications for Vaccination/Target Populations (Who is Vaccinated?) In the United States, Gardasil has been approved for administration to females ages 9 through 26 years for the prevention of cancer of the cervix; cervical AIS; CIN grades 1, 2, and 3; VAIN grades 2 and 3; VIN grades 2 and 3; and genital warts.

The vaccine is recommended irrespective of cervical HPV DNA or Pap smear status at the time of immunization. It should be noted that some countries, such as Australia, have allowed for Gardasil to be administered to males, and in other countries the

recommended age of immunization differs. Most states in the United States do not plan to make the vaccine mandatory for school attendance, a very sensitive and controversial issue to date.

Duration of Immunity The efficacy of Gardasil has been established up to 3 years in over 10,000 subjects (see Table 26.1). More limited efficacy data on 241 subjects are available at 5 years demonstrating complete protection against cervical persistent infection and disease (Villa et al., 2006b). Sustained neutralizing titers for the different HPV types included in the vaccine have also been documented for at least 5 years (Olsson et al., 2007). The absence of events indicating vaccine failure has precluded the establishment of a neutralizing antibody titer threshold below which protection starts waning. A mass-screening program with central registries in place in the Nordic countries (Denmark, Sweden, Norway, and Finland) should allow to determine not only the duration of vaccine effectiveness, but also the impact on cervical cancer screening, and long-term safety (Lehtinen et al., 2006; Barnaba et al., 2006). Modeling of the decay of the antibody response would indicate neutralizing titers lasting for at least 12 years above those following a natural infection (Fraser et al., 2007).

Contraindications of Vaccination, Including Special Risk Groups The vaccine is contraindicated in subjects with a known history of allergy to yeast, or to any of the active substances or excipients included in the vaccine. Individuals who develop symptoms indicative of allergic reaction should not receive further doses.

The vaccine is also contraindicated during pregnancy and is classified as a pregnancy category B. During the clinical trials 1115 of 10,418 vaccine recipients and 1151 of 9120 placebo recipients reported at least one pregnancy. The outcome of these pregnancies was known for 996 in the vaccine group and for 1018 in the placebo group, and the rates of fetal loss were comparable, 38 and 40%, respectively (Miller, 2006). There were 15 cases of congenital anomalies, 5 of them occurring within 30 days of immunization in the Gardasil recipients and 16 in the placebo recipients (Miller, 2006). The anomalies were those expected to occur in women aged 16–26 years. The manufacturer maintains a pregnancy registry.

Although breast-feeding is not a contraindication to the vaccine, and 995 nursing mothers received the vaccine during the clinical trials, caution is advised as it is not known whether the vaccine antigens or the antibodies induced by immunization are excreted in human milk (Gardasil Package Insert, 2007, www.fda.gov/cber/label/hpvmer040307LB.pdf).

The vaccine is not intended to be used for the treatment of existing genital warts, cervical cancer, CIN, VAIN, or VIN. No therapeutic efficacy has been demonstrated on the cervical HPV infections already present at onset of vaccination (Koutsky, 2007). It will be important to examine whether HPV seropositive women who have cleared their vaccine-HPV infection are less likely to acquire another vaccine type-related disease (Advisory Committee on Immunization Practices, 2007, www.cdc.gov/vaccines/recs/acip/downloads/acip_min_feb07.pdf).

In general, the vaccine does not protect against diseases due to non-vaccine types, but a recent analysis demonstrates a 45% efficacy against CIN2/3 and AIS caused by either HPV-31 or -45, virus types related to HPV-16 and -18, respectively (Brown and The FUTURE Study Group, 2007). These two types account for 2.9 and 6.7%, respectively, of all cervical cancers (Munoz et al., 2004).

The vaccine does not contain any HPV DNA and is noninfectious. Therefore, it is not contraindicated in immunosuppressed or immunodeficient individuals. However, its efficacy in these populations has not been established.

Adverse Events Local adverse reactions were noted in about 85% of the Gardasil recipients, and this was a rate higher only by 6.5–9.4% than seen in the placebo recipients (Garland et al., 2007; Koutsky, 2007). They include pain at the injection site (85%) and swelling (26%) both of which are seen 10% more commonly than with the placebo. Fever in the vaccine and placebo recipients was seen in 13.5 and 10.2% of the subjects, respectively (Garland et al., 2007). Girls and boys younger than 16 years were 7–16% less prone than older females to experience pain at the injection site. They were, however, more likely to have fever after immunization (Block et al., 2006). In a combined population of over 17,000 subject events, serious adverse reactions were seen only once in each vaccine and placebo equal-sized groups. Similarly, there were no differences in the rates of other adverse effects.

As of June 30, 2007, more than 7 million doses of Gardasil had been distributed. The Vaccine Adverse Event Reporting System (VAERS) had received a total of 2531 reports (Anon, 2007, http://www.cdc.gov/vaccines/vpd-vac/hpv/downloads/hpv-gardasil-gbs.pdf). Less than 6% of the reports were classified as serious events defined according to the Code of Federal Regulations. This represents less than half the rate of serious adverse reactions for any vaccines

reported to VAERS. Thirteen cases of Guillain-Barré syndrome (GBS) had been reported by that date. Two met the case definition of GBS, occurring within 6 weeks after immunization to Gardasil alone, but both subjects had also received the meningococcal vaccine (Menectra). The number of observed GBS is consistent with the number expected by chance alone.

Thromboembolic events were rare in the prelicensure studies. One case was reported in both vaccine and placebo groups, and after licensure two additional cases were reported to VAERS. None of them, however, could be attributed to the vaccine (Iskander, 2007).

As of May 8, 2007, VAERS had registered 11 reports of syncopal episodes (Iskander, 2007). In the studies that led to licensure, 4.0% of 5088 vaccine recipients experienced dizziness as opposed to 3.7% of 3790 of placebo recipients (Advisory Committee on Immunization Practices, 2007, www.cdc.gov/vaccines/recs/acip/downloads/acip_min_feb07.pdf). This led the ACIP to recommend a period of 15 min of observation after vaccination (Advisory Committee on Immunization Practices, 2007, www.cdc.gov/vaccines/recs/acip/downloads/acip_min_feb07.pdf).

Cervarix

Clinical Trials

Phase I Cervarix is a bivalent vaccine, containing 20 μg each of HPV-16 and -18 L1 VLP formulated with an AS04 adjuvant made of 500 μg aluminum hydroxide and 50 μg 3-*O*-deacyl-4′- monophosphoryl lipid A (MPL). An initial study in human, mice, and monkey subjects demonstrated the ability for the vaccine given intramuscularly at 0, 1, and 6 months to induce higher binding and neutralizing antibody titers (1.6–8.5-fold) when formulated with AS04 than with aluminum hydroxide alone (Giannini et al., 2006). This antibody response persisted for at least 3.5 years.

Phase II The immunogenicity, tolerance, and efficacy of Cervarix was demonstrated in a phase II study enrolling 15–25-year-old women with no more than 6 lifetime sexual partners who were randomized 1:1 to receive either the vaccine or the adjuvant alone by intramuscular injection at months 0, 1, and 6 (Harper et al., 2004). The prevention of transient or persistent incident cervical infection with the vaccine HPV types in women that were HPV-16 and -18 DNA negative and seronegative at entry was the primary endpoint. A secondary endpoint was the prevention of persistent HPV-16 and -18 infection, or of cytologic or histologic atypical cell of unknown significance (ASCUS) or CIN. In the cohort analyzed according to protocol, at up to 18 months of follow-up, the vaccine efficacy in the 366 vaccinees and 355 placebo recipients was 91.6% (95% CI, 64.5–98.0%) for incident cervical HPV16 or 18 infections, 100% (95% CI, 47–100%) for persistent infections, and 92.9% (95% CI, 70–98.3%) for cytologic ASCUS or higher. When analyzed at up to 4.5 years, these results were still excellent, with similar vaccine efficacy figures of 96.9% (95% CI, 81.3–99.9%), 94.3% (95% CI, 63.2–99.9%), and 95.7% (95% CI, 83.5–99.5%), respectively (Harper et al., 2006). When CIN2/3 by cytology or histology was the endpoint, the efficacy was 100% (95% CI, −07.7 to 100%). In that study, Cervarix was shown to induce cross-protection against cervical infections caused by some non-vaccine types, with an efficacy of 54.5% against HPV-31, and 94.2% against HPV-45 (Harper et al., 2006).

The immunogenicity of Cervarix was demonstrated in 10–25-year-old females, with 100% seroconversion for binding antibodies to HPV-16 and -18 VLPs (Pedersen et al., 2007). As with Gardasil, the group of 10–14-year-old females had titers higher by about twofold than the titers in the 15–25-year-old females.

Phase III At present, only interim results of an ongoing phase III study of Cervarix (protocol HPV-008) have been presented (Dubin, 2007). This study has enrolled 18,644 women aged 15–25 years, unscreened for either cervical HPV DNA or cytology, to be randomized 1:1 to receive intramuscularly at least one of three vaccine doses (at months 0, 1, and 6) of either Cervarix or GSK hepatitis A virus (HAV) vaccine (control) that contains the same adjuvant as Cervarix. Cases are counted after the first vaccine dose. The endpoint is histologically proven CIN2 or higher (CIN2+) associated with HPV-16 or -18. The interim analysis was triggered when 23 cases of HPV-16/18 CIN2+ accumulated in the total vaccinated cohort. The per-protocol interim analysis carried out in women who were HPV-16 or -18 negative at baseline showed a vaccine efficacy of 99.3% (95% CI, 53.4–99.3%) at 15-month follow-up. When adjusted to include only those cases in which the HPV infection was present in preceding visits, the efficacy increased to 100% (95%, 74.2–100%). In this study, statistically significant cross-protective vaccine efficacy was also observed against 6-month persistent infections caused by HPV types 45 (vaccine efficacy of 59.9%), 31 (36.1%), and 52 (31.6%), a type related to HPV-16. The vaccine was well tolerated with serious adverse events noted in three patients in the Cervarix and five in the HAV group. General and local symptoms were slightly more common with Cervarix, 85.0 and 91.2%, respectively, than with HAV, 81.6 and 79.9%.

The vaccine reactogenicity profile was similar in all groups. There were also no differences between the two vaccine groups in the rates of abnormal or premature infants from the pregnancies that occurred during the study. The rates of unsolicited adverse events, including chronic and autoimmune diseases were comparable in both groups.

Agent/Strain Used in Vaccine, How Produced, Number of Doses Administered to Give Protective Immunity Cervarix is manufactured by GlaxoSmithKline Biologicals, and was first approved in Australia in May 2007. It is a bivalent vaccine made in insect cells (*Spodoptera frugiperda* Sf-9 and *Trichoplusia ni* Hi-5 cell lines), using a baculovirus expression system. It contains in a 0.5 ml dose, 20 μg each of HPV-16 and HPV-18 L1 VLP, mixed with an AS04 adjuvant (500 μg aluminum hydroxide and 50 μg MPL). The vaccine is given in three doses injected intramuscularly at months 0, 1, and 6.

Vaccine Recommendations, Including Potential to Administer with Other Vaccines It is unknown at present what recommendations will be issued by ACIP for Cervarix use in the United States, but they are likely to be very similar to those of Gardasil for cervical HPV diseases given the similitudes in content and results of the two vaccines. However, the absence of HPV-6 and -11 VLPs in Cervarix is likely to affect specific recommendations regarding the prevention against genital warts. Furthermore, no data have yet been presented on the impact of Cervarix on vulvar and vaginal intraepithelial neoplasias caused by HPV-16 and -18. Price is likely to be a consideration in the recommendations offered by third-payer agencies and insurance companies.

Countries Where Vaccine is Licensed Cervarix has been approved in Australia, Europe, the United Arab Emirates, Kenya, the Philippines, and Japan. Other approvals are expected, including in the United States.

Indications for Vaccination/Target Populations (Who is Vaccinated?) The data supporting the regulatory authorizations that led to Cervarix approval in different countries are not available at present. However, efficacy and safety data from the ongoing phase III study (HPV-008) done on a 15–25-year-old population of women unscreened for current or prior high-risk HPV infections and for cervical cytology have been presented to ACIP, and are a basis of approval for this population (Dubin, 2007). It should be noted that Australia, for example, has approved the vaccine in 10–45-year-old females, as well as in males. As with Gardasil, Pap smear or cervical HPV DNA status are not contraindications to vaccination with Cervarix.

Duration of Immunity It is unknown to what extent higher post-immunization titers predict the durability of protection. Higher titers of binding and neutralizing antibodies to HPV-16 and -18 were seen after immunization with AS04 than with aluminum hydroxide adjuvants (Giannini et al., 2006). The adjuvants in Gardasil and Cervarix differ in formulation, dose, and incorporation process into the vaccine. GSK is currently conducting a double-blind, comparative trial of the two vaccines to evaluate their respective immunogenicity (ClinicalTrials.gov Identifier NCT00423046).

Contraindications of Vaccination, Including Special Risk Groups No data are available on Cervarix contraindications, but it is anticipated that they will resemble those listed for Gardasil. In that respect, Cervarix is not intended for therapeutic use. A large-scale study has clearly demonstrated the absence of effect on existing cervical infection (Hildesheim et al., 2007). We do not yet know the impact of vaccination with Cervarix on the natural history of preexisting disease.

Adverse Events Cervarix causes the same type of adverse reactions as Gardasil. To the extent comparisons are legitimate, local pain and redness might be slightly more common, and redness was as common as swelling (Harper et al., 2004). The rates of systemic reactions did not differ between the vaccine and placebo groups (Harper et al., 2004, 2006). In the interim analysis of the HPV-008 study, general and local symptoms were 3.4 and 1.3 percentage points higher, respectively, with Cervarix than with the HAV vaccine control (Dubin, 2007). There were otherwise no differences between the two groups in the rates of unsolicited and serious adverse events. Likewise, no differences were observed in the rates of abnormal or premature births that occurred in the approximately 670 pregnancies recorded in each group.

Vaccines in Development

The yeast and insect cell expression systems are expensive biotechnologies, and this has stimulated the search for many alternative solutions to reduce the production costs. Two types of vaccines seem to be close to entering the clinical phase of development.

The first one is based on the production of HPV VLP and capsomeres in *Escherichia coli* (Li et al., 1997; Chen et al., 2001; Garcea and Gissmann, 2004; Schaedlich et al., 2007). A different vaccine approach relies on the use of HPV L2 polypeptides, particularly those derived from the N-terminus, which offer broad cross-neutralization among HPV types and other animal papillomaviruses (Roden et al., 2000; Slupetzky et al., 2007; Kondo et al., 2007). Solutions are being developed to augment the weaker immunogenicity of these types of vaccines compared to HPV VLPs (Karanam et al., 2007).

Rationale of Second/Third/New-Generation Vaccines

Other than the important issue of vaccine cost, an area of improvement for future prophylactic vaccine is the broadening of protection against HPV types non-included in the current vaccines. Such augmented vaccines could give not only added protection against cervical cancer, but also have a much more important impact on any intraepithelial neoplasias than the present vaccines. However, expanded vaccine will be more costly to manufacture.

PROSPECTS FOR THE FUTURE

Several ongoing studies should lead to an extension of the indications for the HPV vaccine. Gardasil has already demonstrated its immunogenicity, efficacy, and safety in women older than 26 and up to 45 years old (Luna et al., 2007). Cervarix is also being evaluated in the same age population. A randomized, double-blind, placebo-controlled trial (ClinicalTrials.gov Identifier NCT00423046) is evaluating its immunogenicity in 18–45-year-old women, while another study is focused on the 18–35-year-old female population (ClinicalTrials.gov NCT00306241). A third trial is examining the safety, immunogenicity, and efficacy of the vaccine in women older than 26 years (ClinicalTrials.gov Identifier NCT00456807).

The use of the vaccine in special populations is also being evaluated. The U.S. National Institute of Allergy and Infectious Diseases is sponsoring a study of the safety and immunogenicity of Gardasil in HIV-infected male and female 7–12-year-old children (ClinicalTrials.gov NCT00339040). Men who are infected or are the recipients of a solid organ or bone marrow transplant are at high risk for HPV infections and diseases. They are being considered for clinical trials of Gardasil (Advisory Committee on Immunization Practices, 2007, www.cdc.gov/vaccines/recs/acip/downloads/acip_min_feb07.pdf).

One issue of great importance is the place of male HPV immunization in the prevention of cervical cancer. Several studies have examined favorably the epidemiologic consequences and even the cost-effectiveness of this strategy (Hughes et al., 2002; Elbasha et al., 2007; Dasbach et al., 2006). An indication for male immunization with Gardasil will hinge on the results due in 2008 of a randomized, double-blind, placebo-controlled study in males for the prevention of genital warts (ClinicalTrials.gov Identifier NCT00090285).

It is essential to eventually demonstrate that HPV vaccination actually reduces the rates of cervical cancer. Both vaccine manufacturers have put in place in the Nordic countries studies that are either time extensions of current studies, or an examination of cancer registries with data matched to centralized immunization registries. A corollary question is to evaluate the impact vaccination might have on screening (Kulasingam and Myers, 2003). There are large costs to be saved if the vaccine, particularly one that includes more types than the current ones, has a large impact not only on cancer, but also on CIN of any stage. This could eventually lead to not only the recommendation of the vaccine in young males, but also to a more vigorous pursuit of immunization in general. If cervical HPV infection and disease prevalence decline, the screening approach will have to be redesigned to address the resulting increase in false positive results.

The current focus on the cervix, vagina, and vulva should not hide the potential importance HPV immunization may have in curbing diseases such as anal, oropharyngeal, even some penile cancers, as well as recurrent respiratory papillomatosis (Freed and Derkay, 2006). These possibilities are likely to fuel a great deal of interest in these vaccines in the foreseeable future.

KEY ISSUES

- Vaccination impact on cervical cancer—it remains to be demonstrated that vaccination reduces the rate of cervical cancer. The evidence for the efficacy of the HPV vaccine rests at the moment on the reduction of the rate of CIN2/3 and AIS caused by the HPV types included in the vaccine. However, an overwhelming body of concordant biologic and epidemiologic evidence indicates that an HPV infection by a high-risk type is the necessary, if not sufficient, condition for the development of CIN2/3 and then cervical cancer. Prevention

of cervical cancer by the vaccine is the last proof needed to irrefutably establish the causal link between HPV and cervical cancer. Failure of the vaccine to prevent cervical cancer would invalidate this paradigm. The realistic challenge, which will probably take more than a decade to be met, is to be able, with the means already in place, to demonstrate the beneficial effect of the vaccine on cancer. The same questions of course apply to vulvar and vaginal cancers, but they will be more difficult to answer because of the lower incidence of these tumors.

- Vaccination effectiveness—the vaccine efficacy is now well demonstrated in women, but vaccine effectiveness needs to be better defined, i.e., what is the impact of the vaccine in the general population on the HPV-associated diseases, regardless of the cervical HPV DNA status, serologic status, or the prevalent and incident HPV type exposures of the vaccinees. A high effectiveness of the vaccine could have a major impact on cervical cancer screening protocols and procedures. A related issue is the evaluation of HPV vaccination on herd immunity, as this might affect the efforts at disseminating the vaccination.
- Breadth of HPV coverage—vaccine effectiveness is related to the HPV types that are covered by HPV vaccination. In addition to the types included in the current vaccines, protection extends to some of the phylogenetically related HPV types. Because this protection is only partial, one may have to rely on the addition of other types to the vaccine to significantly increase its effectiveness.
- Duration of efficacy—the duration of efficacy of the current three-dose immunization is unknown. Although a booster immunization at 5 years has already been shown to induce a strong anamnestic antibody response, and could be used whenever protection wanes with time, this represents a significant cost that one hopes to avoid. Fortunately, current modeling of the antibody kinetics appears to suggest a long durability.
- Efficacy in men—the efficacy of the vaccine in men will not be known for Gardasil until the second part of 2008 in all likelihood. The endpoint of the current studies is the prevention of genital warts. The vaccine was already shown to be effective at preventing external genital warts in women. Given that vulvar warts occur on the mucosal surfaces as well as on the skin, there is strong reason to expect that the vaccine will also be effective in preventing warts on the male genitalia skin.
- Efficacy and effectiveness in special populations—now that early results indicate that Gardasil is effective in preventing CIN in women aged 26–45 years, vaccine effectiveness in that age group will have to be ascertained before broad guidelines could be developed and endorsed by insurance companies for the use of the vaccine in that age group. Other groups in whom HPV vaccination needs to be evaluated include immunodeficient (e.g., HIV) and immunosuppressed (e.g., transplant recipients) hosts, men who have sex with men, and the sexual partners of subjects with active HPV disease.
- Impact of the HPV vaccine disease natural history and HPV transmission—HPV vaccination has clearly no impact on established cervical HPV infection, but it remains to be seen whether it alters the natural history of HPV disease by, for instance, reducing the development of new warts, or decreasing the relapse rate of treated disease. Does vaccination reduce the risk of HPV transmission from a diseased subject to his sexual partner or from a pregnant mother with genital warts to her offspring at risk of developing recurrent respiratory papillomatosis?
- HPV type replacement—one concern is that the eradication of HPV types included in the vaccine would lead to the accelerated replacement by other oncogenic HPV types. Some found possible evidence of this in a study of Gardasil, but a subgroup randomization imbalance was a more likely explanation (Sawaya and Smith-McCune, 2007; FDA, 2006, www.fda.gov/cber/sba/hpvmer060806s.pdf). No such evidence of HPV replacement was found when looked for in a study of Cervarix (Harper et al., 2006). This question will undoubtedly remain, but several observations make this scenario unlikely. First, HPV-16 and -18 are the most oncogenic of all HPV types; hence, given the slow evolutionary clock of papillomaviruses, it is unlikely that the types not included in the vaccine would quickly acquire an increased oncogenic potential (Schiffman et al., 2005; Bernard, 2005). Second, multiple HPV infections show that infections with different types are not independent, but rather synergistic events. Consequently, the eradication of HPV-16 and -18, should lead to a decrease of the infections by the other HPV types that tend to be associated with types 16 and 18 (Elbasha and Galvani, 2005). A surge in other HPV infections could be artifactual. The eradication of the vaccine types might allow the PCR to pick up weak HPV DNA viral copy numbers heretofore undetected.
- Impact of vaccination on other HPV-associated diseases—the same HPV types responsible for

cervical cancer and included in the HPV vaccines, are even more common in anal cancers and variants of penile cancers. They are also responsible for up to 70% of oropharyngeal cancers. It should become a priority to try to establish at least for the anus and the oropharynx if HPV vaccination is beneficial. For these cancers, as well as for those of the vulva and vagina, in the absence of screening vaccination is the only potential preventative measure. Although recurrent respiratory papillomatosis is a relatively rare condition, it causes significant morbidity. Gardasil administered to the mother might prevent the development of laryngeal papillomas in the child.

- Vaccine safety—the HPV vaccines appear to be remarkably safe, and no area of genuine concern has emerged so far. Nevertheless, continued safety is essential for the sustained acceptability of the vaccine, and vigilance is necessary as with any novel biological product.
- Vaccine accessibility—the current HPV vaccines are among the most expensive ones. For example, each dose of Gardasil is charged $120 by the manufacturer in the United States. Prices of Gardasil or Cervarix in other countries are at this time generally similar or higher. This is clearly a major obstacle at the moment for the dissemination of HPV vaccination where it is most needed, especially the developing world. However, past experience with other vaccines is encouraging, and prices are likely to come down.

OUTLINE

ABSTRACT

Influenza virus is a globally important respiratory pathogen which is associated with a high degree of morbidity and mortality annually. The rapid evolution of influenza A and B viruses contributes to the annual seasonal epidemics (localized outbreaks) in humans as well as occasional pandemic (worldwide) outbreaks. Despite improvements in development of antiviral therapies during the last decade, vaccination remains the most effective method of prophylaxis. For those at risk of developing complications from influenza infection, annual vaccination is recommended as it induces a good degree of protection and is generally well tolerated by the recipient. Currently there are two types of influenza vaccines in use, the live-attenuated vaccine (LAV) given intranasally/orally, and the inactivated vaccine (IV) delivered subcutaneously or intramuscularly. The available trivalent IV (TIV) elicits good serum antibody responses but induces poor mucosal IgA antibody and cell-mediated immunity. In comparison, the LAV elicits a more complete (humoral and cellular) immune response, similar to the type of immune response produced in the development of natural immunity to a specific strain. IV and LAV vaccines for seasonal influenza are effective in preventing and curbing the spread of influenza-related disease, but new technologies such as reverse genetics, production of recombinant proteins and use of cell culture to manufacture vaccine stocks could be used to improve the production of seasonal vaccines and to develop pandemic vaccines in the future. These new methods of virus production should help to develop vaccines that would be safe, cross-protective against variant influenza strains, require less virus per dose than current vaccines, and take less time to prepare the large amounts of virus necessary for vaccine production. Furthermore, pandemic vaccines against highly virulent strains, such as the H5N1 virus, can be generated much faster using reverse genetics approaches. Other technological breakthroughs such as production of vaccines that promote the induction of innate immune responses by signaling through Toll-like receptors or the use of adjuvants that boost the immunogenicity of current vaccine formulations would decrease the amount of antigen required to promote a response in recipients. Finally, development of "universal influenza virus vaccines," which target conserved components of the virus that are not subject to change, would allow us to produce both seasonal and pandemic vaccines that would be protective against more strains than the strains circulating in any given year.

INTRODUCTION

There are three types of influenza virus termed A, B, and C. Influenza types A or B viruses cause epidemics which are localized outbreaks of disease every year. Type C influenza virus infection causes either a very mild respiratory illness or no symptoms at all and does not cause epidemics. It is estimated that influenza is responsible for an average of 51,000 deaths annually in the United States, with a range from about 7000 to about 72,000 deaths from localized epidemic outbreaks in any given year (Kilbourne, 2006). Three pandemics (worldwide outbreaks) have occurred in the previous century: "Spanish influenza" in 1918, "Asian influenza" in 1957, and "Hong Kong influenza" in 1968 (Simonsen et al., 1998a; Kilbourne, 2006). The 1918 pandemic killed an estimated 40–50 million people worldwide (Simonsen et al., 1998a; Bridges et al., 2002). It is because of this the 1918 influenza pandemic is considered one of the deadliest disease events in human history. Subsequent pandemics have been less severe causing an estimated 2 million deaths in 1957 and 1 million deaths in 1968 (Simonsen et al., 1998a; Bridges et al., 2002). Anyone can become infected with the influenza virus, and serious problems related to influenza can happen at any age. The most vulnerable population includes people aged 65 years and older, people of any age with chronic medical conditions, and very young children (Simonsen et al., 1998a; Bridges et al., 2002). Complications include pneumonia, bronchitis, and sinus and ear infections. Use of influenza vaccine has been shown to reduce influenza-related deaths and hospitalizations in all age groups. Because of public health concerns vaccination efforts have focused on influenza types A and B. The best way to limit effects of influenza in the general population is through annual vaccination. Both inactivated (i.e., killed virus) influenza vaccines (IV) and live-attenuated vaccines (LAV) are currently licensed and available for use in the United States (Nicas et al., 2005).

Influenza A virus is highly infectious, with high transmission rate, and respiratory secretions in people infected with influenza A virus have a large quantity of virus, which has the potential to become aerosolized when the patient sneezes or coughs (Nicas et al., 2005). Virus titers measured in nasopharyngeal washes peak approximately 2–3 days after infection and can reach very high levels [up to 10^7 50% tissue culture infective dose ($TCID_{50}$)/mL] (Knight, 1973; Nicas et al., 2005). Influenza viruses can be transmitted through aerosols, large droplets, or direct contact with secretions (or fomites) and these three modes are not mutually exclusive (Knight, 1973; Murphy et al., 1973;

Douglas, 1975; Nicas et al., 2005). The virus has a short-incubation period (1–2 days) with a 4–6-h replication cycle followed by release of virus for hours before cell death resulting in infection of adjacent cells by newly synthesized virus. The decay of virus infectivity increases rapidly at relative humidity >40%.[8] Increased survival of influenza virus in aerosols at low relative humidity has been suggested as a factor that accounts for the seasonality of influenza (Loosli et al., 1943; Hemmes et al., 1960, 1962; Alford et al., 1966; Lowen et al., 2007). Infection of animal models with influenza virus in controlled heat and humidity environments show that cold temperatures and low relative humidity are favorable to the spread of influenza virus (Hemmes et al., 1960; Alford et al., 1966; Knight, 1973).

SHORT HISTORY OF THE DISEASE

Of all the pandemics caused by the influenza viruses in the 20th century, the 1918 pandemic, or "Spanish influenza," was by far the most devastating. It was associated with an exceptionally high mortality rate, killing an estimated 40–50 million people worldwide (Alford et al., 1966; Kilbourne, 1977; Crosby, 1989; Glezen, 1996; Reid et al., 2001). The unusually high mortality among the 15- to 34-year-old population significantly lowered the average life expectancy in the United States (Kilbourne, 1977; Crosby, 1989; Glezen, 1996; Reid et al., 2001). This degree of morbidity and mortality was not seen in the later influenza pandemics of 1957 and 1968.

Influenza was first noticed as a respiratory disease in swine. In 1918, J.S. Koen, a veterinarian, observed an outbreak of a respiratory disease in pigs at a local state fair that was similar symptomatically to the disease seen in humans during the "Spanish" influenza pandemic of 1918 (Koen, 1919). Attempts to isolate the cause of the infection in pigs by Peter Olitsky and Frederick Gates by filtration of respiratory isolates was unsuccessful due to evaluation of the filtered material alone as a possible cause of the respiratory disease with no examination of material that passed through the filters (Hill, 1942). Eventually Richard Shope, working at the Rockefeller Institute for Comparative Pathology in Princeton, New Jersey, repeated the filtration experiments inoculating either the filtered material or the material that passed through the filter into pigs (Shope and Lewis, 1931). Shope demonstrated that pigs became ill only when the respiratory filtrate was used for inoculation and the disease could be transferred repeatedly between pigs (Shope and Lewis, 1931). Using techniques similar to Shope's, Wilson Smith, Christopher Andrewes, and Patrick Laidlaw at the National Institute for Medical Research in the United Kingdom soon isolated the virus from humans (Laidlaw, 1935). Both groups later demonstrated that sera from people infected with the 1918 virus could neutralize the effects of the pig virus suggesting that the swine virus was related to the 1918 human pandemic virus (Shope, 1936).

ETIOLOGIC AGENTS OF HUMAN INFLUENZA

Seasonal influenza or "common influenza" is caused by influenza A and B, two types of influenza viruses that cause epidemic human disease (Wright and Webster, 2001). Influenza type C viruses have been shown to cause mild illness in humans and do not cause epidemics or pandemics (Francis et al., 1950; Minuse et al., 1954; Wright and Webster, 2001; Coiras et al., 2003). Subtypes of influenza A cause disease in humans and are classified by the types of surface hemagglutinin (HA) or neuraminidase (NA) glycoprotein present. For influenza A there are 16 known HA subtypes and 9 known NA subtypes and many different combinations of HA and NA proteins are possible. There are three subtypes of influenza A virus that have been known to be transmitted from person-to-person and to circulate in humans, H1N1, H2N2, and H3N2 (Wright and Webster, 2001). Influenza B viruses are usually found only in humans. They can cause morbidity and mortality among humans, but in general, are associated with less severe epidemics than influenza A viruses and although influenza type B viruses can cause human epidemics, they have not caused pandemics (Baine et al., 1980; Wright et al., 1980; Wright and Webster, 2001). There have been reports of lower respiratory infections in children suggesting that influenza C virus infection in infants can be associated with high fever and respiratory symptoms severe enough to require hospitalization (Moriuchi et al., 1991; Calvo et al., 2006).

Avian influenza ("bird flu") is caused by influenza viruses that occur naturally among wild birds. There is no preexisting human immunity to these viruses and due to this lack of immunity avian viruses have the potential to become pandemic influenza viruses. Subtypes of influenza which have been documented to cause disease in humans include H5, H7, and H9 viruses (Katz et al., 1999; Alexander and Brown, 2000; Wright and Webster, 2001; Peiris et al., 2004; ; Kobasa and Kawaoka, 2005; Chen et al., 2006; Wong and Yuen, 2006; WHO, 2005, 2007).

The H5N1 virus is deadly to domestic fowl and can be transmitted from birds to humans. H5 infections, such as high pathogenicity avian influenza (HPAI) H5N1 viruses currently circulating in Asia and Europe, have been documented among humans and sometimes cause severe illness or death (Alexander and Brown, 2000; Wright and Webster, 2001; Peiris et al., 2004; Kobasa and Kawaoka, 2005; Chen et al., 2006; WHO, 2005, 2007). H7 infection in humans is rare but can occur among persons who have direct contact with infected birds (Wright et al., 1980; Alexander and Brown, 2000; Kobasa and Kawaoka, 2005; The World Health Organization, 2005; Wong and Yuen, 2006; WHO, 2007). Symptoms have included conjunctivitis and/or upper respiratory symptoms. H7 viruses have been associated with both low-pathogenicity avian influenza (LPAI) (e.g., H7N2, H7N7) and HPAI (e.g., H7N3, H7N7), and these viruses have caused mild-to-severe and fatal illness in humans (Alexander and Brown, 2000; Wright and Webster, 2001; Peiris et al., 2004; Kobasa and Kawaoka, 2005; The World Health Organization, 2005; Chen et al., 2006; Wong and Yuen, 2006; WHO, 2007). Influenza A H9 has rarely been reported to infect humans. However, this subtype has been documented in some cases in a low pathogenic form (Alexander and Brown, 2000; Wright and Webster, 2001; Kobasa and Kawaoka, 2005; WHO, 2005, 2007).

CLASSIFICATION

Influenza virus, a member of the Orthomyxoviridae family, consists of a segmented, negative-stranded RNA genome. Influenza virus types A and B have eight RNA segments. Subtype C has seven RNA segments (Lamb, 1983; Lamb and Krug, 2001; Tyler and Nathanson, 2001). For influenza A the multipartite genome is encapsidated, with each segment in a separate nucleocapsid [i.e., a ribonuclear protein complex (RNP)] (Fig. 27.1). Eight different segments of negative-sense single-stranded RNA are present; this allows for genetic reassortment in single cells infected with more than one virus and may result in multiple strains that are different from the parental viruses that infected the cell. The genome of influenza A consists of 10 genes encoding for different proteins. These include the following: three transcriptases (PB2, PB1, and PA) which form the viral polymerase, two surface glycoproteins HA and NA, two matrix proteins (M1 and M2), one nucleocapsid protein (NP), and two nonstructural proteins (NS1 and NS2) (Fig. 27.1). The virus envelope glycoproteins (HA and NA) are distributed evenly over the virion surface, forming characteristic spike-shaped structures. Antigenic variation in these proteins is used as part of the influenza A virus subtype definition (but not used for influenza B or C viruses). HA is found in the virion as a trimer and NA as well as M2 as tetramers. The matrix protein (M) underlies the lipid envelope (Lamb, 1983; Lamb and Krug, 2001; Tyler and Nathanson, 2001). For influenza A virus the HA, NA, and M2 proteins are inserted into the host cell-derived lipid envelope.

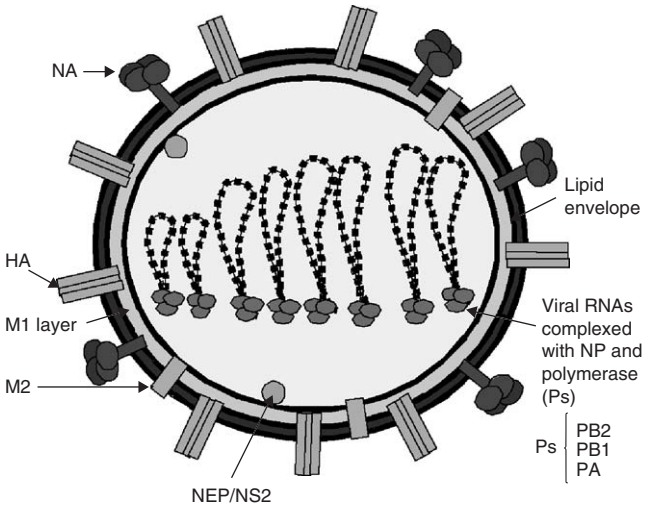

FIGURE 27.1 Schematic diagram of an influenza A particle. HA, hemagglutinin; NA, neuraminidase; M2, ion channel; NS2/NEP, nonstructural protein 2. Influenza virus RNA replication takes place in the cell nucleus and NS2/NEP is involved in the export of RNPs out of the nucleus. M, matrix protein; NP, nucleoprotein; Ps, the viral polymerase which is formed of three components PB1, PB2, and PA. RNP, the ribonucleoprotein complex containing the viral RNA; NP, nucleoproteins and the viral polymerase.

Influenza viruses are named according to (a) type of virus (A, B, or C); (b) where the virus was isolated; (c) the specimen number; and (d) the year the virus was isolated. For example, A/PR/8/34 indicates that the virus was type A, isolated from specimen number 8 obtained from a patient in Puerto Rico in 1934. This is a specific strain of influenza virus. An "H7N2 virus" designates influenza A subtype that has an HA 7 protein and an NA 2 protein. Similarly an "H5N1" virus has an HA 5 protein and an NA 1 protein.

ANTIGENS ENCODED BY THE AGENT

The structure of influenza A and B viruses are similar but influenza C is different. The HA of influenza A virus is responsible for the attachment of virus to the sialic acid-containing receptors on the host cell surface and also for fusion between the virus and endosome membranes resulting in release of viral RNPs into the

cytoplasm (Lamb, 1983; Lamb and Krug, 2001; Tyler and Nathanson, 2001). HA is a homotrimer of approximately 220 kDa and is a type 1 membrane protein that is anchored in the viral membrane by its C-terminus. The head of HA contains the receptor-binding site at the tip of each monomer and the five antigenic sites that bind neutralizing antibodies (Lamb, 1983; Gerhard, 2001; Lamb and Krug, 2001; Tyler and Nathanson, 2001). HA is the main determinant of virulence of the virus and plays an important role in the viral life cycle. As the major antigenic determinant, it is the key ingredient of influenza vaccines for both influenza A and B viruses.

The influenza A NA is a tetrameric glycoprotein of approximately 240 kDa and is a type 2 membrane protein that is anchored in the viral membrane by its N-terminus. The NA consists of a hydrophobic stalk and a globular head that contains the enzymatic and antigenic sites (Lamb, 1983; Lamb and Krug, 2001; Tyler and Nathanson, 2001). NA promotes release of virus progeny from infected cells, prevents viral aggregation and aids movement of virus through the respiratory tract. Neuraminidase sialidase activity seems to be conserved across virus subtypes and could potentially be an important target for antiviral therapy. Another influenza A membrane protein, the M2 ion channel, is a tetrameric membrane channel important for release of viral RNAs from the virion, is conserved across virus types, and also has the potential to be a target for development of antiviral therapy and vaccine development (Lamb, 1983; Lamb and Krug, 2001; Tyler and Nathanson, 2001).

PROTECTIVE IMMUNE RESPONSE

Immunity to primary infection with influenza is mediated by antibodies produced by the host to the major viral surface antigens, HA and NA (Gerhard, 2001; Lamb and Krug, 2001; Tyler and Nathanson, 2001). Antibody against one influenza virus type or subtype confers limited or no protection against another type or subtype of influenza. Furthermore, antibody to one antigenic variant of influenza virus often does not protect against a new antigenic variant of the same type or subtype (Lamb, 1983; Sugaya et al., 1994; Gerhard, 2001; Lamb and Krug, 2001; Tyler and Nathanson, 2001). Frequent development of antigenic variants through "antigenic drift" is the virologic basis for seasonal epidemics or localized influenza A outbreaks and the reason for the usual incorporation of one or more strains in each year's influenza vaccine. More dramatic antigenic changes, or "shifts," occur less frequently and can result in the emergence of a novel influenza virus with the potential to cause a pandemic (Lamb and Krug, 2001; Tyler and Nathanson, 2001).

Protection from primary infection with influenza virus is mediated by antibodies, cytotoxic T lymphocytes (CTL) and T-helper CD4+ cells, but protection from reinfection is largely mediated by antibodies directed against the surface glycoproteins, principally HA but NA also (Biddison et al., 1981; McMichael et al., 1983; Sugaya et al., 1994; Jameson et al., 1998, 1999). In humans little epidemiological evidence has been shown for the involvement of T cell-mediated immunity in protection from reinfection with influenza virus although some partial protection may occur (Biddison et al., 1981; McMichael et al., 1983; Sugaya et al., 1994; Jameson et al., 1998, 1999).

Most vaccinated children and adults develop post-vaccination hemagglutination inhibition (HAI) antibody titers (Nichol et al., 1995; Lamb and Krug, 2001; Tyler and Nathanson, 2001; Jefferson et al., 2005; Ashkenazi et al., 2006; Lewis et al., 2007; Belshe et al., 2007; Manzoli et al., 2007). These antibody titers are protective against the illness caused by strains similar to those included in the vaccine. The effectiveness of influenza vaccine depends primarily on the age and immunocompetence of the vaccine recipient and the degree of similarity between the viruses in the vaccine and those in circulation (Bell et al., 1978; Couch, 1999; de Bruijn et al., 1999; Jefferson et al., 2005; Yamanaka et al., 2005; Ashkenazi et al., 2006). Although response to vaccine may produce lower anti-HA antibody than healthy individuals some protection is provided (Bell et al., 1978; Couch, 1999; de Bruijn et al., 1999; Jefferson et al., 2005; Yamanaka et al., 2005; Ashkenazi et al., 2006). Influenza vaccination is highly effective in HIV-1-infected persons and does not seem to be associated with substantial changes in viral load or CD4 cell count (Couch, 1999; Yamanaka et al., 2005).

EPIDEMIOLOGY

Influenza is a globally important respiratory pathogen that causes nearly annual epidemics and occasional pandemics. Influenza epidemics generally occur in the winter months in the Northern hemisphere and in May–September in the Southern hemisphere (Lamb and Krug, 2001; Tyler and Nathanson, 2001; Wright and Webster, 2001). Antigenic variants of influenza A viruses emerge every year due to changes in the virus itself and this requires that updated vaccine formulations be prepared annually based on ongoing international surveillance of circulating strains of influenza virus

by the World Health Organization (Wright and Webster, 2001).

Influenza A viruses constantly evolve by two mechanisms (a) antigenic drift, which involves point mutations in the antigenic sites of the two major virion surface proteins HA and NA and (b) antigenic shift, the sudden replacement of HA or NA of one subtype by another subtype (Lamb and Krug, 2001; Tyler and Nathanson, 2001; Wright and Webster, 2001; Ferguson et al., 2003; Webby et al., 2007). Gradual changes that occur through mutations in the two genes that code for the main surface proteins, HA and NA are referred to as antigenic drift. These point mutations occur unpredictably and result in minor changes to these surface proteins. Antigenic drift produces new virus strains that may not be recognized by antibodies to earlier influenza strains. Influenza B viruses undergo antigenic drift less rapidly than influenza A viruses. Antigenic shift refers to the occurrence of an abrupt, major change in HA and/or NA to produce a novel influenza A virus subtype in humans that were not currently circulating among people. Antigenic shift can occur either through direct animal (poultry)-to-human transmission or through mixing of human influenza A and animal influenza A virus genes to create a new human influenza A subtype virus through a process called genetic reassortment (Lamb and Krug, 2001; Tyler and Nathanson, 2001; Wright and Webster, 2001). Since 1977, H1N1 and H3N2 viruses, and influenza B viruses have circulated globally in the human population. In 2001, influenza A (H1N2) viruses emerged after what was probably a genetic reassortment between human A (H1N1) and A (H3N2) viruses (Lamb and Krug, 2001; Tyler and Nathanson, 2001; Wright and Webster, 2001). The current hypothesis is that new influenza viruses emerge by genetic reassortment (shift), or exchange of genetic material between two influenza viruses. For example, a large number of influenza subtypes are found commonly in animal species and all subtypes have been isolated from birds (Webster et al., 2006; Webby et al., 2007). Aquatic birds, particularly wild ducks, are primary reservoirs of influenza viruses (Sugaya et al., 1994; Lamb and Krug, 2001; Wright and Webster, 2001; Webster et al., 2006; Webby et al., 2007). The virus multiplies in the gastrointestinal (GI) tract and usually causes no illness. It is excreted in the feces, and the droppings contaminate the water. Thus, aquatic birds and domestic fowl become infected in nature by coming into contact with contaminated water.

Human viruses preferentially bind to sialic acid (SA) linked to galactose by α-2,6 linkages that are the main type found on the epithelial cells of the human respiratory tract, while avian viruses tend to bind to α-2,3 linkages that are found on duck intestinal epithelium (Webster et al., 2006). The specificity for different receptors has long been one of the explanations for the species barrier between avian and human influenza viruses (Couceiro et al., 1993; Ito et al., 1998; Wright and Webster, 2001; Gambaryan et al., 2003; Matrosovich et al., 2004). The presence of both SA α-2,3 and α-2,6 linkages in the pig tracheal epithelium is the reason why pigs may serve as the "mixing vessel" for the genesis of new viral types through coinfection (Ito et al., 1998). Chickens may have a similar role, in that their lung and intestinal epithelia contain both types of linkages (Gambaryan et al., 2003; Matrosovich et al., 2004). In the human respiratory epithelium, it has been shown that α-2,3 and α-2,6 linkages are found on ciliated and nonciliated cells, respectively, thereby allowing human infection by avian influenza viruses (Matrosovich et al., 2004). Pigs are considered intermediate hosts for influenza viruses and they possess receptors for human and avian influenza viruses. They can be infected by coming into contact with infected birds or water contaminated by them. Avian viruses may also spread to other mammals such as whales, seals, and horses and occasionally may cause disease outbreaks (Lamb and Krug, 2001; Tyler and Nathanson, 2001; Wright and Webster, 2001). Pigs, however, may become infected with human influenza viruses if they come into contact with infected individuals. If an avian H5N1 virus infects a domestic pig, and concurrently the pig acquires H3N2 infection from a farm worker there is potential that a new virus subtype, H5N2, may emerge as a result of the genetic reassortment between the two viruses. The new H5N2 variant then could spread to humans. Since the human population does not possess antibodies to this new virus, it is possible that widespread epidemics may occur.

To become a pandemic virus capable of causing a global influenza outbreak with world wide spread three conditions must be met: (1) a new subtype of influenza A virus is introduced into the human population produced through genetic reassortment resulting in an antigenic shift, (2) the virus causes serious illness in humans, and (3) the virus can spread easily from person-to-person in a sustained manner. Influenza type A viruses can infect people, birds, pigs, horses, and other animals, but wild birds are considered the natural hosts for these viruses. There are substantial genetic differences between the influenza A subtypes that typically infect birds and those that infect both people and birds.

Avian influenza A virus strains are further classified as low pathogenic (LPAI) or highly pathogenic (HPAI) on the basis of specific molecular genetic and pathogenesis criteria that require specific testing. Most avian influenza A viruses are LPAI viruses that

are generally associated with mild disease symptoms in poultry. In contrast, HPAI viruses can cause severe illness that has a high mortality in poultry. Avian influenza A viruses of the subtypes H5 and H7, including H5N1, H7N7, and H7N3 viruses, have been associated with HPAI, and human infections with these viruses have ranged from mild (H7N3, H7N7) to severe and fatal disease (H7N7, H5N1) (Webster et al., 1981; Kurtz et al., 1996; Zhou et al., 1996; Yuen et al., 1998; Peiris et al., 1999, 2004; Tweed et al., 2004; Butt et al., 2005; Puzelli et al., 2005; The World Health Organization, 2005; Chen et al., 2006; Wong and Yuen, 2006; WHO, 2007). Human illness due to infection with LPAI viruses vary from very mild symptoms (e.g., conjunctivitis) to influenza-like illness (Webster et al., 1981; Kurtz et al., 1996; Zhou et al., 1996; Yuen et al., 1998; Peiris et al., 1999; Taubenberger et al., 2001; Tweed et al., 2004; Puzelli et al., 2005; The World Health Organization, 2005; Wong and Yuen, 2006). Examples of LPAI viruses that have infected humans include H7N7, H9N2, and H7N2. In general, direct human infection with avian influenza viruses occurs very infrequently, and has been associated with direct contact (e.g., touching) with infected sick or dead infected birds (domestic fowl) (Webster et al., 1981; The World Health Organization, 2005; WHO, 2007).

SIGNIFICANCE AS A PUBLIC HEALTH PROBLEM

Between 1889 and 1977 six pandemics of influenza have been recognized. Based on studies using sera obtained from persons who lived through the 1918–1919 pandemic period, the pandemic of 1918–1919 was caused by an H1N1 virus (WHO, 2007). Recently, the 1918 virus was further identified as H1N1 by complete sequencing of HA and NA from formalin-fixed, paraffin-embedded, lung tissue samples from patients who died of influenza during the 1918 pandemic, as well as from a frozen sample obtained by in situ biopsy of the lung of a victim buried in permafrost in Alaska since 1918 (Sims et al., 2003). Phylogenetic analysis suggested that the H1N1 virus had circulated between mammals and birds, and might have become adapted in humans before the 1918 pandemic (WHO, 2007). H1N1 was replaced by H2N2; the new subtype emerged to cause the Asian flu pandemic of 1957 (Simonsen et al., 1998a; Bridges et al., 2002; Nicas et al., 2005; Kilbourne, 2006). Eleven years later, another new influenza virus, H3N2 emerged to cause the Hong Kong flu pandemic of 1968 (Simonsen et al., 1998a; Bridges et al., 2002; Nicas et al., 2005; Kilbourne, 2006). The H3N2 subtype has persisted up to the present time. Currently both H3N2 and H1N1 viruses circulate together in the human population. Human H5N1 infections have been confirmed by WHO in Thailand, Vietnam, Indonesia, Cambodia, China, Turkey, and Iraq. A total of 385 cases with 243 deaths have been reported to the WHO as of June 19, 2008 with a mortality rate of greater than 50% (Sims et al., 2003; Peiris et al., 2004; The World Health Organization, 2005; Chen et al., 2006). Additional suspected human cases are under investigation in countries affected by agricultural outbreaks. Human H5N1 cases have been associated with direct exposure to infected poultry, and there is little evidence of human-to-human transmission (Sims et al., 2003; Peiris et al., 2004; The World Health Organization, 2005; Chen et al., 2006). The acquisition of characteristics enabling and sustaining transmission between people of H5N1 virus has been of great concern due to the potential to produce a pandemic with devastating global consequences.

Global Surveillance for Influenza

Since 1952 the WHO has coordinated global surveillance for influenza viruses in circulation worldwide. The objective of the surveillance system is to isolate and characterize currently circulating influenza strains in order to provide optimum antigenic and genetic matches for influenza vaccine production. Surveillance is accomplished through a network of 118 National Influenza Centers in 89 countries, coupled with 4 WHO Collaborating Centers located in the United Kingdom, Japan, Australia, and the United States. Recent concerns regarding the threat of pandemic influenza is facilitating the establishment of new National Influenza Centers in additional countries. Activities of the National Influenza Centers are guided by Terms of Reference as established by the WHO and agreed to by national Ministries of Health. Centers collect appropriate clinical specimens from patients throughout the year, but especially during influenza season. They report outbreaks to WHO and network partners, and they isolate and provide preliminary characterization of viruses in circulation. A representative sample of isolates made throughout the year, as well as unusual isolates and isolates obtained late in the transmission season, are forwarded to the four Collaborating Centers for more in depth characterization and sequencing, if deemed appropriate. The National Influenza Centers also notify WHO immediately of any unusual outbreaks that might suggest the emergence of a novel

influenza virus with pandemic potential. Weekly descriptive reports are submitted to WHO electronically throughout the influenza season, as well as in annual reports, and this data is posted on FLUNET, an electronic platform that is part of the WHO Communicable Diseases Global Atlas (http://gamapserver.WHO.INT/GlobalAtlas). The Centers provide training and provide technical advice within their countries and, if appropriate, regionally. WHO provides reagents annually to all Centers to facilitate standardized identification of influenza viruses, and reports results of antigenic and genetic characterization of viruses in circulation, and publishes reports on global influenza activity.

Representatives of the four WHO Influenza Collaborating Centers and key national laboratories meet at WHO Headquarters in Geneva twice a year, in February for the Northern hemisphere and in September for the Southern hemisphere, to recommend vaccine composition for the coming influenza season. Information regarding the antigenic and genetic characterization of viruses collected by the network of National Influenza Centers is shared along with epidemiological summaries of transmission patterns seen. Through these meetings an attempt is made to predict the characteristics of influenza viruses likely to be in circulation during the coming season. At the conclusion of these deliberations, the information is provide to global influenza vaccine manufacturers and published in WHO's Weekly Epidemiological Record and other publications. Specific strains of H1N1, H3N2, and influenza B are suggested for inclusion in the vaccine (Table 27.1). WHO also collaborates with national vaccine licensing agencies to provide viruses for vaccine production and vaccine potency testing.

Increasing global concern brought about by H5N1 avian influenza and other outbreaks in which avian influenza viruses have resulted in human infections has led to the creation by WHO of a working group on influenza research at the human–animal interface. This initiative provides a linkage between WHO and the two principle international agencies addressing animal health, the World Organization for Animal Health (OIE) and the Food and Agriculture Organization of the United Nations (FAO). In 2005 the FAO and OIE announced the creation of a new joint scientific network to support veterinary services in the control of avian influenza under the acronym OFFLU. The objectives of the new network are to collaborate with the WHO human surveillance networks on issues that affect both humans and animals, to include early definition of candidate vaccines for possible human use and to coordinate research activities on influenza viruses. Results of these efforts and other focused surveillance specific to H5N1 avian influenza human infections are periodically posted on the WHO website.

POTENTIAL AS A BIOTHREAT AGENT

Influenza virus is considered an NIAID category C priority biothreat agent. Agents in this category are emerging, readily available, and easily disseminated. In addition, these organisms are capable of causing high morbidity and mortality rates. Infection from many biothreat agents (e.g., *Bacillus anthracis* that causes anthrax, Lassa virus that causes Lassa fever) also produce flu-like symptoms. Accordingly, in the event of a bioterrorist attack, one of the problems facing first responders and health-care workers is the ability to distinguish bioagent infection from natural influenza infection. Without the quick and specific identification of influenza infection, a patient would likely be sent home only to die days later when infection with a biothreat agent moved beyond the treatable stage.

CLINICAL DISEASE

Influenza illness is characterized by the abrupt onset of respiratory signs and symptoms (fever, myalgia, headache, malaise, nonproductive cough, sore throat, and rhinitis) (Glezen and Couch, 1997; Wright and Webster, 2001). In children, otitis media, nausea, and vomiting have also been reported with influenza illness. Uncomplicated influenza illness typically resolves after 3–7 days, although cough and malaise can persist for more than 2 weeks (Monto and Kioumehr, 1975; Monto et al., 1985; Glezen and Couch, 1997). In people with underlying medical conditions such as pulmonary or cardiac disease, influenza infection can lead to the development of secondary bacterial pneumonia or primary influenza viral pneumonia, and can occur as a coinfection with other respiratory pathogens. Influenza-related deaths from pneumonia are usually caused by exacerbations of cardiopulmonary conditions or other chronic diseases. Infants and young children have the highest influenza infection and hospitalization rates in pediatrics (Piedra and Glezen, 1991; Belay et al., 1999; Heikkinen et al., 1999; Neuzil et al., 2000, 2002; Munoz et al., 2002; Wang et al., 2003). The immaturity of the infant's immune system and the absence of prior immunity and exposure to the virus are potential contributors. Although most children that suffer from influenza infection are otherwise healthy, underlying

chronic medical conditions further increase the risk for complications (Piedra and Glezen, 1991; Belay et al., 1999; Heikkinen et al., 1999; Neuzil et al., 2000, 2002; Munoz et al., 2002; Wang et al., 2003). Epidemics of influenza A are also accompanied by mortality, mostly among those 65 years and older. In the history of influenza pandemics, the only exception was the 1918 pandemic, which caused high mortality among young adults as well as the elderly.

Influenza caused by H5N1 shares some features with the virus responsible for the Spanish influenza pandemic of 1918 (Webster et al., 1981; Wright and Webster,

2001; Tyler and Nathanson, 2001; The World Health Organization, 2005; Chen et al., 2006; WHO, 2007). H5N1 or avian influenza has some of the standard seasonal influenza symptoms such as high fever, headache, and muscle aches, but people quickly become seriously ill and pneumonia, difficulty breathing, and multiorgan failure have been common among people who have been stricken with H5N1 influenza (Peiris et al., 2004; The World Health Organization, 2005; Chen et al., 2006; Wong and Yuen, 2006; WHO, 2007). Morbidity and mortality in those people with H5N1 are severe in previously healthy, young, and middle-aged persons. Diarrhea occurs more frequently than with influenza caused by the seasonal human-adapted subtypes that commonly circulate. The frequency of pneumonia and diarrhea distinguish avian from seasonal influenza. Over 50% of reported H5N1 influenza cases have been fatal. Death is primarily due to respiratory or multiorgan failure (Peiris et al., 2004; The World Health Organization, 2005; Chen et al., 2006; WHO, 2007). Unlike human-adapted subtypes, H5N1 is found in high titers in lower respiratory tract specimens, throat swabs and stool (Peiris et al., 2004; Puzelli et al., 2005; The World Health Organization, 2005; Chen et al., 2006; Wong and Yuen, 2006; WHO, 2007). The current H5N1 virus has also been isolated from serum (Puzelli et al., 2005). Although influenza caused by H5N1 is generally known for its aggressive disease course and associated high mortality rates, there is evidence that mild disease and asymptomatic infections occur.

TREATMENT

Vaccination is the best way to limit and control influenza infection and yearly vaccination is recommended (Fiore et al., 2007). In 1976, the US Food and Drug Administration (FDA) approved amantadine to both treat and prevent influenza type A in adults and children 1-year-old or older (Hayden and Pavia, 2006). FDA-approved rimantadine—a derivative of amantadine—in 1993 to treat and prevent influenza infection in adults and prevent influenza in children. These two drugs act against influenza A viruses but not against influenza B viruses. In 1999, FDA-approved two additional drugs to fight the flu: Relenza (zanamivir) and Tamiflu (oseltamivir), the first of a new class of antiviral drugs called NA inhibitors (Hayden and Pavia, 2006; Antiviral Agents for Seasonal Influenza: Information for Health Professionals). Zanamivir and oseltamivir inhibit both influenza A and B viruses. Studies have shown that all four drugs can reduce the duration of flu symptoms by 1 day if taken within 2 days of the onset of the illness. Amantadine is approved for treating and preventing uncomplicated influenza A virus infection in adults and children who are 1 year of age or older (Hayden and Pavia, 2006; Antiviral Agents for Seasonal Influenza: Information for Health Professionals). Rimantadine is approved for treating and preventing uncomplicated influenza virus A infection in adults and for preventing, but not treating, such infections in children. Zanamivir is approved for preventing influenza A and B virus infections in people 5 years of age and older, and for treating uncomplicated influenza A and B virus infections in people 7 years of age and older who have not had symptoms for more than 2 days. Oseltamivir is approved for treating uncomplicated influenza virus infection in people 1 year of age or older who have not had symptoms for more than 2 days (Hayden and Pavia, 2006; Antiviral Agents for Seasonal Influenza: Information for Health Professionals). Amantadine and rimantadine are taken orally in pill form. Zanamivir, available as a dry powder, can be inhaled using a device known as a "Diskhaler." The recommended dosage is two inhalations twice a day, morning and night, for 5 days. Oseltamivir is available as a pill and for adults is taken twice daily for 5 days. For children, the dose of oseltamivir depends on the child's weight. A liquid suspension of oseltamivir can be taken by children or adults who cannot swallow a capsule. Both amantadine and rimantadine have been shown to cause CNS and GI side effects. Amantadine has been associated with more frequent CNS adverse reactions than rimantadine, especially in the elderly (Couch, 2000; Hayden and Pavia, 2006; de Jong et al., 2005; Antiviral Agents for Seasonal Influenza: Information for Health Professionals). Since zanamivir is taken by inhalation, it should not be given to persons with underlying airway disease. The primary side effect of oseltamivir is nausea and vomiting; thus it should be taken with food.

Viral resistance to adamantanes has the ability to emerge rapidly during treatment because a single point mutation at amino acid positions 26, 27, 30, 31, or 34 of the M2 protein can confer cross-resistance to both amantadine and rimantadine (Couch, 2000; de Jong et al., 2005). Due to the high proportion of circulating influenza viruses in the US in recent years that have been resistant to the adamantanes, the CDC currently recommends that neither amantadine nor rimantadine be used for the treatment or chemoprophylaxis of influenza in the United States. Early therapy with NA inhibitors, either oseltamivir or zanamivir, reduces the duration of symptoms, the duration of disability, and the risk of lower respiratory tract complications (Couch, 2000; Hayden and Pavia, 2006).

Current WHO treatment guidelines for influenza A/H5N1 infection, the strain of concern in current pandemic planning, recommend NA inhibitors for treatment and prophylaxis. The guidelines also include a soft recommendation for the use of M2 inhibitors (amantadine and rimantadine) for strains of the virus still susceptible to these drugs. Recent isolates of influenza A H5N1 show varying resistance to the adamantanes (amantadine and rimantadine): the NA inhibitors, oseltamivir and zanamivir, are active against influenza A H5N1. However, the emergence of high-level resistance to oseltamivir during oseltamivir treatment has been demonstrated in some patients with influenza A H5N1 infections.

PATHOGENESIS

Influenza A is highly contagious causing infection of the upper and lower respiratory tract. Primary viral pneumonia is the most severe complication observed during influenza infection and is associated with high mortality (Bender and Small, 1992). Evaluation of the pathogenesis of influenza is influenced by both the physical and immunological status of the host as well as the virulence of the infecting strain of virus. A great deal of information regarding influenza pathogenesis has been learned from the study of animal models or from evaluation of highly pathogenic avian influenza viruses. However, the precise details of the pathogenesis in humans remains largely unknown at this time.

Respiratory epithelial cells are the primary targets for influenza virus infection and once the virus enters the respiratory tract where virus replicates in bronchial and alveolar epithelial cells (Matrosovich et al., 2004) infection can spread to adjacent resident alveolar macrophages (AM). Although the disease is often associated with systemic symptoms the majority of virus replication in uncomplicated influenza infection is thought to occur in the respiratory tract (Bender and Small, 1992).

Following infection, AM die predominantly by apoptosis, whereas epithelial cells have been shown to undergo necrotic death (Fesq et al., 1994). Cell infection as well as necrosis/apoptosis of infected cells triggers immune responses with production of cytokines such as tumor necrosis factor (TNF-α), interleukin (IL)-1, and chemokines such as monocyte chemoattractant protein (MCP)-1, RANTES, MIP-1α and β, interferon-induced protein (IP)-10 and IL-8 (Virelizier et al., 1979; Fujisawa et al., 1987; Bender and Small, 1992; Meerschaert and Furie, 1995; Braciak et al., 1996; Doherty, 1996; Friedland, 1996; Lehmann et al., 1996; Sprenger et al., 1996; Adachi et al., 1997; Hofmann et al., 1997; Kuziel et al., 1997; Bussfeld et al., 1998; Matsukura et al., 1998; Cox and Subbarao, 1999; Dawson et al., 2000; Julkunen et al., 2000; Van Reeth, 2000; Julkunen et al., 2001; Maus et al., 2002; Chan et al., 2005). Initial release of inflammatory mediators by infected lung epithelium, resident tissue macrophages, and AMs results in the initial extravasation of macrophages, and neutrophils and then later NK cells and T cells, from the peripheral blood into infected lung tissue within days after influenza A virus infection (Virelizier et al., 1979; Fujisawa et al., 1987; Bender and Small, 1992; Meerschaert and Furie, 1995; Braciak et al., 1996; Doherty, 1996; Lehmann et al., 1996; Sprenger et al., 1996; Adachi et al., 1997; Hofmann et al., 1997; Kuziel et al., 1997; Cox and Subbarao, 1999; Dawson et al., 2000; Julkunen et al., 2000, 2001; Maus et al., 2002; Chan et al., 2005). Although polymorphonuclear leukocytes and alveolar macrophages provide some early protection, resident tissue macrophages can become infected and induced to produce high levels of inflammatory cytokines (Fujisawa et al., 1987; Bender and Small, 1992; Doherty, 1996; Lehmann et al., 1996; Hofmann et al., 1997; Dawson et al., 2000; Julkunen et al., 2000). There is evidence that this early inflammatory pathology can contribute to severe disease, especially with the highly lethal H5N1 viruses (Chan et al., 2005).

Studies of isolates of avian influenza A (H5N1) from patients revealed that viral virulence factors include the presence of a highly cleavable HA that can be activated by multiple cellular proteases, a specific substitution in the polymerase basic protein 2 (Glu627Lys) which can enhance replication (Shinya et al., 2004; Guan et al., 2002; Perkins and Swayne, 2002; Zitzow et al., 2002; Li et al., 2004; Avian Influenza A, 2004; Horimoto et al., 2004; Sturm-Ramirez et al., 2004; Govorkova et al., 2004), and a substitution in nonstructural protein 1 (Asp92Glu) that confers increased resistance to inhibition by interferons and TNF-α in vitro and prolonged replication in swine, (Seo et al., 2002; Cheung et al., 2002) as well as greater production of cytokines, particularly TNF-α, in human macrophages exposed to the virus (Cheung et al., 2002).

DESCRIPTION OF DISEASE PROCESS

Cytokines and chemokines have long been thought to play a role in the extreme pathology associated with highly pathogenic influenza viruses (Cretescu et al., 1978; Akashi et al., 1994; Imashuku et al., 1996;

Taubenberger et al., 1997; Hayden et al., 1998; Fisman, 2000; Kaiser et al., 2001; Seo et al., 2002; Cheung et al., 2002; Perkins and Swayne, 2002; Zitzow et al., 2002; Govorkova et al., 2004; Kobasa et al., 2004; Sturm-Ramirez et al., 2004; Beigel et al., 2005; Tumpey et al., 2005; Buchy et al., 2007). While there is little direct evidence from the human pathology caused by the 1918 pandemic virus, it is thought that both the 1918 virus and avian H5N1 viruses cause a dysregulated and exaggerated production of inflammatory cytokines or "cytokine storm" that, in turn, results in pulmonary edema, primary and secondary pneumonias with acute bronchopneumonia. Recently, recombinant viruses generated by reverse genetics expressing the HA and NA of the 1918 influenza virus were shown to induce significantly higher levels of IFN-δ, TNF-α, MIP-2, and MIP-1α and MCP-1, MIP-1β, MIP-2, MIP-3α, IL-1, IL-6, IL-12, IL-18, and G-CSF in the lungs of infected mice (Akashi et al., 1994; Imashuku et al., 1996; Taubenberger et al., 1997; Hayden et al., 1998; Fisman, 2000; Kaiser et al., 2001; Cheung et al., 2002; Kobasa et al., 2004; Beigel et al., 2005; Tumpey et al., 2005; de Jong et al., 2006), providing some support that elevated chemokine and cytokine levels were a hallmark of the severe human disease caused by the 1918 virus (Kobasa et al., 2004; Beigel et al., 2005; Tumpey et al., 2005).

High virus levels were found in those infected with H5N1 and correlated with fatal outcomes (Peiris et al., 2004). High serum levels of IL-6, TNF-α, IFN-γ, and sIL-2R were found in patients during outbreaks in Hong Kong in 1997 of H5N1 (Akashi et al., 1994; Imashuku et al., 1996; Taubenberger et al., 1997 Fisman, 2000; Mou et al., 2006), while those infected in 2003 and 2004–2005 were shown to have had elevated serum concentrations of the chemokines IP-10, MCP-1, and monokine induced by IFN-γ (MIG), compared to patients with uncomplicated seasonal influenza infections. Studies have also demonstrated higher levels of induction of proinflammatory cytokines such as TNF-α and IFN-β, by H5N1 viruses compared to human-adapted H3N2 and H1N1 viruses (Kaiser et al., 2001). Generally, disease severity has correlated strongly with cytokine levels (Cretescu et al., 1978; Kaiser et al., 2001; Buchy et al., 2007) and highest levels of chemokines, and the neutrophil chemoattractant IL-8, were detected in individuals who died (Cretescu et al., 1978; Kaiser et al., 2001; Buchy et al., 2007). Abnormally high levels of IP-10 and MIG were also observed in other fatal cases of H5N1 influenza infection (Cretescu et al., 1978; Buchy et al., 2007) and other studies have highlighted the strong correlation between IL-6, IFN-α, and TNF-α levels and the severity of disease symptoms (Cretescu et al., 1978; Hayden et al., 1998; Kaiser et al., 2001; Buchy et al., 2007).

IMMUNE RESPONSE TO INFECTION

The humoral immune system, including both the mucosal and systemic responses, plays a major role in the development of immunity to influenza. During infection of humans, antibodies are produced to all the major viral proteins (Murphy et al., 1973; Potter and Oxford, 1979; Askonas et al., 1982) Antibodies to the surface glycoproteins, HA and NA, are associated with resistance to infection, whereas antibodies to the conserved internal antigens, M and NP, have not been shown to be protective (Gerhard, 2001). The CTL response is mainly directed against the matrix and nucleocapsid proteins (Biddison et al., 1981; McMichael et al., 1983; Jameson et al., 1998). Although the CTL response does not confer protection to infection, it is important for the clearance of virus and recovery from illness.

ANTIBODY

The mucosal tissues of the upper respiratory tract are the main portal of entry for influenza virus, and the mucosal immune system provides the first line of defense against infection. Both mucosal and systemic antibody production contributes to resistance to influenza infection and disease (Murphy et al., 1973; Askonas et al., 1982; Clements et al., 1983). Antibodies secreted locally in the upper respiratory tract are a major factor in resistance to natural infection (Artenstein et al., 1964; Murphy et al., 1973; Clements et al., 1983, 1986; Mazanec et al., 1995) and after natural infection secretory immunoglobulin A (SIgA) and serum IgG are involved in protection of the respiratory tract against reinfection with the same virus or an antigenically similar strain of virus. Nasal secretions have been shown to contain neutralizing antibodies to influenza HA and NA, which are primarily of the IgA isotype (Rossen et al., 1970; Jurgensen et al., 1973; Murphy and Clements, 1989; Yewdell and Hackett, 1989; Mazanec et al., 1995). During primary infection, all three major Ig classes (IgG, IgA, and IgM) specific to HA can be detected by enzyme-linked immunosorbent assay in nasal washings, although IgA and IgM are more frequently detected than IgG (Rossen et al., 1970; Jurgensen et al., 1973; Murphy and Clements, 1989; Yewdell and Hackett, 1989; Mazanec et al., 1995).

The humoral immune system produces antibodies against different influenza antigens, of which the HA-specific antibody is the most important for neutralization of the virus and thus prevention of illness. The NA-specific antibodies are less effective in

preventing infection, but they lessen the release of virus from infected cells.

Cell-Mediated Immunity

Influenza-specific cellular lymphocytes have been detected in the blood and the lower respiratory tract secretions of infected subjects. Cytolysis of influenza-infected cells is mediated by CTLs in concert with influenza-specific antibodies and complement (Quinnan et al.,1980; Ruben et al., 1980; Biddison et al., 1981; McMichael et al., 1983, 1986; Fleischer et al., 1985; Gerhard and Mozdanowska, 2001). The primary cytotoxic response is detectable in blood after 6–14 days (Ruben et al., 1980; McMichael et al., 1983, 1986). CTLs that recognize both surface HA, NA, and M2 protein as well as the internal nonglycosylated proteins of influenza M, NP, and PB2 proteins, have been isolated (Biddison et al., 1981; Fleischer et al., 1985). Cell-mediated immunity plays a role in recovery from influenza infection and may also prevent influenza-associated complications, but it does not seem to contribute significantly in preventing infection.

The level of memory CTLs to influenza does not correlate with susceptibility to infection or illness following experimental influenza infection, but it does correlate with an increased rate of clearance of the virus from the respiratory tract. There is a limited amount of data on human CTL responses to influenza available in the literature, but information from influenza infections using the murine model shows that a very strong T-helper response, is induced (McMichael et al., 1986). The CTL response has been shown to be cross-reactive between influenza A strains (Fleischer et al., 1985; Gerhard and Mozdanowska, 2001; Nguyen et al., 2001) and is very important in minimizing the spread of virus in the respiratory system (Fleischer et al., 1985; McMichael et al., 1986; Gerhard and Mozdanowska, 2001).

VACCINES

Vaccination induces a good degree of protection (60–90% efficacy) and is well tolerated by the recipient (Parkman et al., 1977; Couch and Kasel, 1983; La Montagne et al., 1983; Couch et al., 1984, 1986, 1996; Maassab and DeBorde, 1985; Kaiser et al., 1999; Simonsen et al., 1998b; Couch, 2000; Bridges et al., 2000; Halperin et al., 2002). For those at risk of complications from influenza, annual vaccination is recommended due to the antigenic changes in circulating strains. The current trivalent IV (TIV) and LAV are both safe and efficacious for healthy adults, elderly, and children (Barker and Mullooly, 1980; Couch and Kasel, 1983; Couch et al., 1984, 1986; Maassab and DeBorde, 1985; Belshe et al., 1998; Kaiser et al., 1999; Simonsen et al., 1998b; Couch, 2000; CDC, 2000; Bridges et al., 2000; Halperin et al., 2002). Vaccine is available for all persons, including school age children, who run the risk of becoming ill with influenza or of transmitting influenza to others and all children aged 6 months–4 years (Couch and Kasel, 1983; Couch et al., 1984; Kaiser et al., 1999; Simonsen et al., 1998b; Couch, 2000; Bridges et al., 2000). Vaccination is also recommended for adults aged 50 years or older; individuals aged 6 months–18 years at increased risk for Reye's syndrome because of long-term treatment with aspirin; women who will be pregnant during the influenza season; persons with chronic pulmonary (including asthma), cardiovascular (excluding hypertension), renal, hepatic, hematological, or metabolic disorders (including diabetes); immunosuppressed persons; those with any condition that can compromise respiratory function (Couch and Kasel, 1983; Couch et al., 1984; Kaiser et al., 1999; Simonsen et al., 1998b; Couch, 2000; Bridges et al., 2000). Vaccine is recommended for residents of nursing homes and other chronic care facilities; health care personnel; healthy household contacts and caregivers of children younger than 5 years; and adults aged 50 years or older (especially contacts of infants younger than 6 months); and persons with medical conditions increasing their risk for severe complications from influenza (Couch and Kasel, 1983; Couch et al., 1984; Kaiser et al., 1999; Simonsen et al., 1998b; Couch, 2000; Bridges et al., 2000).

Currently available IV as well as LAV are prepared from virus grown in embryonated hen's eggs (Palese, 2006). Most influenza virus vaccines used in the United States and Europe consist of embryonated egg-grown and formaldehyde-inactivated preparations, which, after purification, are chemically disrupted with a nonionic detergent (e.g., Triton X-100). Split virus preparations show lower pyrogenicity than whole virus vaccines (Couch et al., 1996; Keitel et al., 1997; Palese, 2006). In general, single dose for adults contains the equivalent of 45μg HA (15μg HA for each of the three antigenic components). This dose is approximately the amount of purified virus obtained from the allantoic fluid of one infected embryonated egg.

Live-attenuated influenza virus vaccines for strains of type A and type B influenza were developed by serial passage in chick-embryo cells at 25°C until they became cold-adapted (Murphy et al., 1973; Palese, 2006). Vaccine strains are prepared by the reassortment of gene segments from a master strain and a putative epidemic strain, followed by selection for a strain with genes for HA and NA from the putative epidemic strain

and the remaining genes from the cold-adapted parent. The vaccine is given intranasally by spray and induces mild upper respiratory tract symptoms in about 10–15% of persons (Maassab and DeBorde, 1985; Couch et al., 1986; Belshe et al., 1998).

Table 27.2 shows a list of the influenza strains used in vaccines for the flu seasons from 1989–2008. Currently all vaccine stocks are produced in eggs, but not all new antigenic variants replicate well in this system as was seen in development of vaccine to protect against the A/Fujian virus in 2000. The US FDA rejected the use of the most appropriate H3N2 strain, A/Fujian/411/2002, and instead used the same strain as in the 2002 formulation (Palese, 2006). This decision was made primarily because the A/Fujian/411/2002 strain had first been isolated in Madin–Darby canine kidney (MDCK) cells rather than in embryonated eggs. Use of MDCK cells for virus isolation is not allowed by FDA's rules, which do not yet encompass advanced technologies or scientifically sound purification procedures based on limiting dilutions or cloning with DNA. Because no egg-culture suitable A/Fujian-like virus was available, the vaccine was made with the A/Panama/2007/99 virus as the H3 component (Palese, 2006). It is important to realize that even though this strain was not an optimal match for the A/Fujian epidemic virus, it provided some protection, particularly in adults.

The 2007–2008 influenza vaccine formulation contains an A/Solomon Islands/3/2006 (H1N1)-like virus; an A/Wisconsin/67/2005 (H3N2)-like virus; and a B/Malaysia/2506/2004-like virus. The three strains for the new influenza vaccine formulation were confirmed by the US FDAs Vaccines and Related Biological Products Advisory Committee in February 2007 and correspond with recommendations made by the WHO in February. The A/Solomon Islands/3/2006 virus replaced the previous A/New Caledonia/99 virus which had circulated between 2000 and 2007.

HISTORY

The first influenza vaccine developed was a monovalent preparation which means that the vaccine was formulated from a single strain of influenza virus. In the 1960s and 1970s the influenza vaccines were bivalent or composed of two strains. Since 1978 influenza vaccines have been trivalent with the inclusion of a strain of influenza B and two strains of

TABLE 27.2 Strains used in vaccines for the flu seasons shown—1989–2007

Season	H1N1	H3N2	Type B
89–90	A/Taiwan/86	A/Shanghai/87	B/Yamagata/88
90–91	A/Taiwan/86	A/Shanghai/89	B/Yamagata/88

influenza A. From the 1970s on the vaccine has been changed to parallel the changes in currently circulating strains of virus with occasional changes in one or all of the strains included in the vaccine preparation. Surveillance by the WHO influences the strain selection included in each year's vaccine preparation and production of vaccine occurs year round.

Influenza virus vaccines first developed in the 1940s consisted of partially purified preparations of influenza viruses grown in embryonated hen's eggs. Because of substantial contamination by egg-derived components, these killed (formaldehyde-treated) vaccines were highly pyrogenic and lacking in efficacy. A major breakthrough in vaccine manufacture was the development of the zonal ultracentrifuge in the 1960s (Gerin and Anderson, 1969). This technology, which originated from uses for military purposes, revolutionized the purification process and industrial production of many viruses for vaccines including influenza virus. It remains the basis for the manufacturing process of current influenza virus vaccines. Most prototype seed strains are provided to the manufacturers by government agencies, which create high-yielding strains through classical reassortment with a high-yielding laboratory strain, A/PR/8/34 (Palese, 2006).

Whole inactivated virus vaccines were the first influenza vaccines to be produced. The currently circulating strain of influenza was inoculated into embryonated eggs, harvested 2–3 days later and inactivated. Because of the high incidence of reactions seen in individuals given whole, inactivated virus vaccine, attempts were made to produce a vaccine which was less reactogenic but conserved immunogenicity. Split vaccines can be prepared from inactivated particles disrupted with detergents. These vaccines have been shown to induce fewer side effects and were found to be as immunogenic as whole virus vaccine. Subunit vaccines which contain only the HA and NA antigen can also be produced. Subunit vaccines are used in aqueous suspension or may be absorbed to carriers. Volunteers given subunit vaccines experienced fewer reactions than those given whole virus vaccines (La Montagne et al., 1983; Couch et al., 1996).

Recently licensed LAVs induce immunity that is similar to that provided from natural infection with induction of both humoral and cellular immunity. Normal methods for attenuation include use of repeated passages and temperature adaptation (Palese, 2006). Attenuated strains of virus can also be mixed with wild-type virus to produce reassortants that contain the RNA fragments which code for wild-type HA and NA, and all the other genetic material form the attenuated strain (Kilbourne, 1969). When given intranasally, attenuated vaccines produce few side effects (Couch et al., 1986; Margolis et al., 1990; Nichol et al., 1996).

CURRENT LICENSED VACCINES

Influenza vaccination is the primary method for preventing seasonal influenza and its complications. Vaccines need to be evaluated and, if necessary, updated to provide coverage for the circulating strains of influenza every year and, consequently, the vaccine must also be administered every year. Table 27.3 lists the vaccines currently licensed for use in the US Both IV and LAV formulations of the vaccine are available. Both LAV and IV contain strains of influenza viruses that are antigenically equivalent to the annually recommended strains: one influenza A (H3N2) virus, one A (H1N1) virus, and one B virus. Each year, one or more virus strains can potentially be changed on the basis of global surveillance for influenza viruses and the emergence and spread of new strains. Both vaccines are administered annually to provide optimal protection against influenza virus infection. Although both types of vaccines are effective, the vaccines differ in several aspects. Inactivated influenza vaccine contains killed viruses, and thus cannot produce signs or symptoms of influenza virus infection. In contrast, LAV contains live, attenuated viruses and, therefore, has a potential to produce mild signs or symptoms related to influenza virus infection. LAV is administered intranasally by sprayer, whereas inactivated influenza vaccine is administered intramuscularly by injection.

The US FDA announced the licensure of the first vaccine in the United States for humans against the avian influenza H5N1 virus in 2007. This inactivated influenza virus vaccine is indicated for immunization of persons 18 through 64 years of age who are at increased risk of exposure to the H5N1 influenza virus subtype contained in the vaccine. This vaccine was derived from the A/Vietnam/1203/2004 influenza virus (Table 27.3).

Thimerosal is a very effective preservative that has been used since the 1930s to prevent contamination in some multidose vials of vaccines (preservatives are not required for vaccines in single dose vials). Thimerosal contains approximately 49% ethyl mercury. There is no convincing evidence of harm caused by the low doses of thimerosal in vaccines, except for minor reactions like redness and swelling at the injection site. However, in July 1999 the Public Health Service (PHS) agencies, the American Academy of Pediatrics (AAP), and vaccine manufacturers agreed that thimerosal should be reduced or eliminated in vaccines as a precautionary measure.

TABLE 27.3 Currently licensed vaccines*

Vaccine	Manufacturer	Form of vaccine	Dosage	Thimerisol preservative	Age indication for administration
Fluzone® seasonal flu vaccine	Sanofi Pasteur Inc.	Inactivated: One dose required 15μg each of HA of two influenza A & one influenza B	Multidose vial	Present 0.01% or (25μg mercury/dose)	6 months and older
			Single dose: 0.25 ml syringe	None	6–35 months
			Single dose: 0.5 ml syringe or vial	None	36 months and older
Fluvirin® seasonal flu vaccine	Novartis Vaccine	Inactivated: One dose required 15μg each of HA of two influenza A & one influenza B	Multidose vial	Present 0.01% or (25μg mercury/dose)	4 years and older
			Single dose: Prefilled 0.5 ml syringe	Preservative free: (1 mcg or less mercury/0.5 ml dose)	4 years and older
Fluvarix® seasonal flu vaccine	Glaxo Smith Kline Biologicals	Inactivated: One dose required 15μg each of HA of two influenza A & one influenza B	Single dose: Prefilled 0.5 ml syringe	Preservative free (1 mcg or less mercury/0.5 ml dose)	18 years and older
FluMist® seasonal flu vaccine	MedImmune Vaccines, Inc.	Live Attenuated: One dose required 15μg each of HA of two influenza A & one influenza B	Single dose sprayer	None	Healthy immunocompetent persons 2–49 years
AFluria® seasonal flu vaccine	CSL Biotherapies	Inactivated: One dose required 15μg each of HA of two influenza A & one influenza B	Single dose	None	18 years and older
Flulaval® seasonal flu vaccine	ID Biomedical Corporation	Inactivated: One dose required 15μg each of HA of two influenza A & one influenza B	Multidose vial	Yes 0.01% or (25μg mercury/dose)	18 years and older
Influenza virus vaccine, H5N1 pandemic flu vaccine	Sanofi Pasteur Inc.	Inactivated: 90μg/ hemagglutinin (HA) of the influenza virus strain A/ Vietnam/1203/2004 (H5N1, clade 1) two doses required			18–64 years of age

*as of July 2007.

DURATION OF IMMUNITY

A critical aspect of influenza vaccine development is the demonstration that immunization is capable of inducing a protective immune response. In individuals who have been immunologically primed by exposure to related viruses by infection or by immunization, a single dose of 15μg HA per strain, is considered to give high levels of protective immunity in younger adults and to prevent severe consequences of infection in the elderly. Although vaccines are usually prepared from whole virus, split products or from purified subunits and occasionally from whole virions, the

immune responses to immunization in primed populations are considered equivalent for each type of vaccine. Secretory antibody induced by inactivated viral vaccines, is thought to persist for about a year, after having reached a peak level at about 4–6 weeks following immunization or infection (Kilbourne, 1969). Inactivated virus vaccine induced greater serum IgA, IgG, and IgM HA antibody responses than did live virus vaccine (Artenstein et al., 1964; Kilbourne, 1969; Rossen et al., 1970; Couch et al., 1984; Clements et al., 1986; Murphy and Clements, 1989; Kroon et al., 1994; Mazanec et al., 1995). Although vaccination with both types resulted in significantly increased levels of nasal-wash HA antibodies, there was a striking difference in the predominant isotype of local antibody induced by each type of vaccine (Waldman and Ganguly, 1975). Recipients of live virus vaccine developed IgA antibody more frequently whereas recipients of inactivated influenza vaccine developed IgG antibody more frequently (Artenstein et al., 1964; Rossen et al., 1970; Clements and Murphy, 1986; Clements et al., 1986; Murphy and Clements, 1989; Mazanec et al., 1995).

CONTRAINDICATION OF VACCINATION, INCLUDING SPECIAL RISK GROUPS

Current vaccine components are grown in embryonated chicken eggs and are rendered noninfectious. The vaccine is safe. Soreness at the site of injection is the most common complaint. Fever, malaise, and myalgia are infrequent (Margolis et al., 1990; ACIP, 1999). The vaccine is recommended to be given each year prior to the influenza season. Immediate—presumably allergic—reactions (e.g., hives, angioedema, allergic asthma, and systemic anaphylaxis) occur rarely after influenza vaccination (Couch et al., 1986; Margolis et al., 1990; Nichol et al., 1996). These reactions probably result from hypersensitivity to certain vaccine components; the majority of reactions probably are caused by residual egg protein. Although current influenza vaccines contain only a limited quantity of egg protein, this protein can induce immediate hypersensitivity reactions among persons who have severe egg allergy (Wright et al., 1977; Couch et al., 1986; Margolis et al., 1990; Nichol et al., 1996; James et al., 1998). Influenza vaccine should, therefore, not be administered to anyone with a history of hypersensitivity to any vaccine component, including eggs, egg products, or thimerosal.

The vaccine should not be administered to individuals who have a prior history of Guillain–Barré syndrome (Schonberger et al., 1979; Hurwitz et al., 1981; Kaplan et al., 1982). People who have severely weakened immune systems or people who are in contact with others with severely weakened immune systems should not be given live vaccine formulations. The estimated risk of becoming infected with the current vaccine virus formulation after close contact with a person vaccinated with the nasal-spray LAV is low (0.6–2.4%) (Maassab and DeBorde, 1985; Couch et al., 1986; Belshe et al., 1998). Because the viruses are weakened, infection is unlikely to result in influenza illness symptoms. Immune compromised individuals should not be given the AV since it contains live although attenuated virus.

ADVERSE EVENTS

There are risks associated with all vaccines including current influenza vaccine formulations. The most common local and systemic adverse reactions to vaccine include soreness at the vaccination site that can last up to 2 days, pain, and swelling, fever, malaise, and myalgia (Margolis et al., 1990; ACIP, 1999). Other adverse reactions may occur. The most frequent side effects of the killed vaccine after IM injection are pain, redness, and swelling at the injection site lasting 1–2 days, and systemic side effects such as headache, fever, malaise, and myalgia in about 5% of people receiving vaccines (Margolis et al., 1990; Nichol et al., 1996). These side effects are largely due to a local immune response, with interferon production leading to systemic effects. Local side effects are more common with whole virus vaccines than subunit or split vaccines, and also more common with intradermal vaccination than intramuscular (IM) vaccination.

The inactivated vaccine does not contain live virus, and cannot cause influenza infection. Live-attenuated virus vaccines do contain live virus; however, side effects are rare, with a runny nose, congestion, sore throat, and headache being the most commonly reported symptoms, with occasional abdominal pain, vomiting, and myalgia (Couch et al., 1986). They are not recommended for children less than 2 years.

Inactivated influenza virus vaccine was associated with the occurrence of the Guillain–Barré syndrome during the program of immunization against swine influenza in 1976 (Schonberger et al., 1979; Hurwitz et al., 1981; Kaplan et al., 1982). However, studies in subsequent years did not confirm such a relationship. A similar relation was reported again recently, but the calculated risk was only one additional case of Guillain–Barré syndrome per million people

vaccinated, a risk lower than that of severe influenza in all age groups and particularly among people at high risk for complications (Schonberger et al., 1979; Hurwitz et al., 1981; Kaplan et al., 1982). Concern about the Guillain–Barré syndrome should not deter people from receiving an inactivated influenza virus vaccine.

PRECLINICAL, PHASE I, PHASE II, AND PHASE III TRIALS

The current egg-based technology for producing influenza vaccine was created in the 1950s. This current process of production of reassortant virus stocks followed by repeated passaging of the strain in embryonated hen's eggs to allow for egg adaptation and growth enhancement is time-consuming. A number of novel methods of production of vaccine virus are currently in process and include cell-culture based culture or production of recombinant viral proteins. Table 27.4 lists a number of vaccine formulations that are currently in preclinical or phase I–III trials in the US. Many of the candidate vaccines listed in Table 27.4 were formulated using methods that do not rely on embryonated hen's egg culture and hold great promise for the development of future influenza vaccines.

RATIONALE OF SECOND/THIRD/NEW GENERATION VACCINES

Use of Cell Lines to Produce Vaccine

Cell culture-derived influenza vaccines are currently in development as an option to egg-based production, which uses embryonated hen's egg as the standard method for production (Patriarca, 2007). There are a number of problems associated with this process, which include a dependency on the timely availability of embryonated hen's eggs as well as the selection of specific changes in the viral proteins due to egg culture (Robertson et al., 1985; Katz et al., 1987; Harmon et al., 1988; Katz and Webster, 1989; Robertson, 1993; Hardy et al., 1995; Ito et al., 1997; Patriarca, 2007; Reisinger et al., 2007) The H5 avian influenza virus strains responsible for recent epizoonotic outbreaks in Asia are lethal to chicken embryos (Palese, 2006; Patriarca, 2007). Also, due to the high pathogenicity of avian influenza virus strains, the conventional production of avian influenza virus vaccines would require the use of biosafety level 3 containment facilities for virus production. Vaccine development and production using the standard egg-based method often takes several months following the identification of new potential strains using current egg-based culture methods and typically require reassortment with a high-yield strain. Therefore, a culture method that can rapidly produce new influenza virus for vaccine production is needed as a priority for seasonal and especially for pandemic influenza preparedness.

The tissue culture process is easily expanded for large scale production of virus using large bioreactor systems to produce human influenza antigens, avian influenza antigens, or other animal influenza antigens as necessary (Patriarca, 2007). Several tissue culture cell types are being used to produce virus stocks for vaccine trials. These include MDCK (Ito et al., 1997; Patriarca, 2007), Vero cells, PER.C6 (patented human cell line) and an avian embryonic stem cell-derived cell line, EBx (a cell line is derived from chicken embryo cells, treated with a chemical mutagen to render the cell line immortal) (Patriarca, 2007). For production of cell-culture derived vaccines, live influenza virus is used to infect cells in culture. Once the viral infection has propagated through the cells, the live virus is harvested and inactivated in much the same way as in conventional egg-based influenza vaccines.

Several important regulatory issues will need to be addressed before a switch to cell culture-based production systems can occur. These include proof that the vaccine product is free of cell-derived contaminants as well as testing for any other contaminating viruses. Tissue culture-based influenza A vaccines have currently been approved for use throughout the European Union. Large scale safety and immunogenicity studies have been conducted in Europe, and trials of safety and immunogenicity are currently taking place in the United States as well. These studies show that the cell-culture based vaccine is of comparable safety and immunogenicity as compared to egg culture-based vaccines (Harmon et al., 1988).

Recombinant DNA-Based Approaches

The influenza A virus (Fig. 27.1) has ten gene products: HA and NA on the surface; the M2 ion channel and a variety of intraviral proteins; the M1 matrix proteins; and various RNA packaging proteins that make up the virion. HA and NA, which are on the surface of the virus, are available for attack by the immune system, but they are subject to immune pressures and antigenic drift (mutations) in their genetic material over time. HA protein has been synthesized by a variety of recombinant DNA (rDNA)-based approaches for vaccine development (Subbarao and Katz, 2004). HA or other influenza proteins can be made alone, can

be co-expressed with other proteins to boost immunogenicity (Prel et al., 2007; Treanor et al., 2007), or HA and NA can be expressed together with the matrix protein that underlies the membrane to make a virus-like particle (VLP) (Galarza et al., 2005a, 2005b; Ionescu et al., 2006; Pushko et al., 2007; Bright et al., 2007; Quan et al., 2007). Recombinant HA produced in a baculovirus system (insect tissue culture expression of HA followed by purification of the HA) has been successfully formulated into trivalent vaccine, and this trivalent

vaccine has demonstrated safety and efficacy in clinical trials in the United States (Treanor et al., 2007).

VLPs mimic the three-dimensional structure of a virus but do not contain genetic material, so they cannot replicate or cause infection. As VLPs maintain functional properties of both influenza surface proteins (HA and NA), they have been shown to activate multiple arms of the immune system to generate a broadly protective immune response (Galarza et al., 2005a, 2005b; Ionescu et al., 2006; Pushko et al., 2007; Bright et al., 2007; Quan et al., 2007). VLPs apparently have a high propensity for being taken up by the immune system; an effective dose of a VLP vaccine in a mouse model is about one-tenth the dose necessary for HA itself (Pushko et al., 2007; Bright et al., 2007; Quan et al., 2007). The potential advantage here is the reduction in the amount of vaccine necessary to elicit an effective immune response.

Antigens other than HA are also good candidates for the production of influenza vaccines. The NA protein, although one possible candidate, is susceptible to antigenic drift and immune pressure, and because of this does not offer an advantage over HA as a surface target. NA is also not a strong neutralizing antigen and blocking the enzymatic activity with antibody may confer some benefit. Conserved influenza antigens are the NS1 protein (a nonstructural nuclear protein), M1 (the matrix protein), NP, and M2 (which is the ion channel). In the context of the influenza virus, the M2 ion channel protein is particularly important at this time for the production of a "universal vaccine." The ion channel is important in virus replication, and during the uncoating of the virus a pH change must take place before the viral genome is released for the purpose of replication (Lamb et al., 1985; Neirynck et al., 1999). The M2e peptide appears to be relatively conserved and is a relatively stable target that in theory should not change year after year (Holsinger and Lamb, 1991; Pinto et al., 1992; Black et al., 1993; Neirynck et al., 1999). Different methods of making the influenza M2e based vaccine are in development and these include: (1) hooking four copies of the 24 amino acid M2 protein to flagellin produced in *Escherichia coli*; and (2) hooking a copy of M2e to Pam3Cys (e.g., tripalmitoyl cysteine, a synthetic adjuvant linked to M2e, the antigenic protein) to make Pam3Cys.M2e (Lamb et al., 1985). The flagellin fusion is thought to be a better method, since the M2e 24 amino acid peptide alone does not illicit an immune response.

Another option being developed is to use M2e fused at the N-terminus of the hepatitis B core protein (HBc) subunit or inserted in the immunodominant loop as a vaccine (Neirynck et al., 1999). Evidence indicates that these types of "universal" influenza A vaccines are promising and a number of candidate vaccines based on this methodology are currently being tested in human clinical trials.

DNA Vaccines

DNA vaccines are expressed in situ after DNA vaccination and these vaccines induce immune responses in the form of both humoral and CMI responses, including CTL (Fynan et al., 1993a; Deck et al., 1997; Kodihalli et al., 1999, 2000; Drape et al., 2006). DNA vaccines are comprised simply of *E. coli*-derived plasmid DNA, are not infectious, do not replicate, and encode only the proteins of interest without production of bacterial proteins. The functional components of the plasmid include a strong promoter system (such as the immediate early promoter of cytomegalovirus), a convenient cloning site for insertion of a gene of interest, a polyadenylation termination sequence, a prokaryotic origin of replication for production in *E. coli*, and a selectable marker (e.g., ampicillin resistance gene) to facilitate selection of bacterial cells containing the plasmid. Some of the earliest work on DNA vaccines was conducted using influenza as a model system. These studies at least in animals including nonhuman primates, demonstrated production of hemagglutination inhibiting (HI) antibodies and CTL. The potency of DNA vaccines encoding influenza virus antigens in many of these animal studies was demonstrated by the low amounts of DNA required to induce immunity, using either IM injection of the vaccine or by use of the gene gun (Fynan et al., 1993b). Combined immunization with DNA encoding HA (which can generate neutralizing antibodies) and DNA encoding NP and M1 (which can induce broad T-cell responses) may provide a greater breadth of protection than can be obtained with conventional inactivated influenza vaccines and may be useful in humans against influenza (Fynan et al., 1993a; Kodihalli et al., 1999). The first human trial of a DNA vaccine designed to prevent H5N1 avian influenza infection began on December 21, 2006. The vaccine was delivered with a particle-mediated epidermal delivery (PMED) needle-free injection system, which delivers DNA to the epidermal layer of the skin where it enters the cells of the immune network, creating immunity and facilitating both treatment and prevention of disease (Fynan et al., 1993b).

Adjuvants

Adjuvants are agents or drugs that have few or no antigenic effects or properties but may have the

potential to increase the efficacy or potency of vaccines or other drugs when given at the same time (see Chapter 9). Some of the most common adjuvants used in vaccine preparations are aluminum salts and monophosphoryl lipid (MPL)/QS21 cocktails. The response to potential pandemic flu vaccines has been shown to be much improved by the addition of MF59 (Nicholson et al., 2001; Stephenson et al., 2003; Atmar et al., 2006; Bresson et al., 2006; Baldo et al., 2007). MF59 also allows significant dose sparing, which is essential to increase the pandemic vaccine production capacity. Unfortunately, traditional adjuvants, such as Alum, do not appear to be potent for pandemic influenza vaccines. Although poorly understood scientifically, the successful development of adjuvants is important because they can greatly increase the efficacy of existing vaccine supplies. Most of the current IV and LAV virus vaccines do not contain an adjuvant. To stretch the available supply, antigen-sparing adjuvant approaches should be considered and many new approaches are under development.

Alternative Delivery of Antigens

Vaccines can be delivered in ways other than by direct IM injection. Any method can be used to introduce the vaccine directly to dendritic cells (the cells that carry antigen to the lymph nodes) located in the intradermal compartment of the skin, whence they will be effectively taken into the immune system. Thus, vaccines can be delivered through the skin using patches, microabrasion, or microtines coated with antigen. They can also be delivered through the intranasal system; Flu-Mist® administers a LAV by spray into the intranasal compartment to create local mucosal immunity.

PRECLINICAL DEVELOPMENT INCLUDING RELEVANT ANIMAL MODELS

There are a number of animal models presently available for the study of the pathogenesis of influenza. Influenza A virus will infect a number of Old World and New World primates (Kalter et al., 1969; London et al., 1972; Berendt and Hall, 1977). The gibbon and baboon develop clinical illness with nasal application of the virus, and the squirrel, cynomolgus and rhesus monkeys develop illness when the virus is inoculated intratracheally (Berendt, 1974; Berendt and Hall, 1977). Primate models have a number of disadvantages, including a lack of commercial availability of the reagents necessary to characterize the host response in detail. Mammals such as horses and pigs that are natural hosts for influenza have also been used experimentally. However, their large size and the limited availability of reagents available also preclude their use as good models in the laboratory.

Small-animal models that have been used to study influenza virus pathogenesis include the ferret, in which human influenza virus was originally isolated (Marois et al., 1971; Smith and Sweet, 1988; Herlocher et al., 2001, 2004; Yen et al., 2005; Lipatov et al., 2006; Govorkova et al., 2007; Belser et al., 2007). Adult ferrets become ill after infection with influenza A viruses, exhibiting fever, lethargy, and weight loss (Marois et al., 1971; Smith and Sweet, 1988; Herlocher et al., 2001, 2004; Yen et al., 2005; Lipatov et al., 2006; Govorkova et al., 2007; Belser et al., 2007). The ferret model has been used in recent studies of H5N1 viruses (Lipatov et al., 2006; Govorkova et al., 2007), the transmission of influenza and the development of resistance to antiviral therapy (Herlocher et al., 2001; Yen et al., 2005). Unfortunately, as is seen for other models, ferrets are outbred and again reagents are not readily available for evaluating the correlates of protective immunity. In contrast, laboratory strains of mice are inbred and there is an abundance of reagents to characterize both innate and adaptive immune responses. However, mice are not naturally infected with influenza viruses, and therefore most studies are performed using strains that have been adapted by extensive serial passage to replicate efficiently in this mammal (Hernandez et al., 2003; Evseenko et al., 2007; Joseph et al., 2007).

POSTEXPOSURE IMMUNE IMMUNOPROPHYLAXIS

Little information related to immunoprophylaxis for influenza infection is currently available. Limited trials of human monoclonal or polyclonal antibodies in animals have yielded promising results but large scale trials of passive antibody use for influenza have not yet been done (Krieg, 1999; Hanson et al., 2006). The ability of some nucleic acid-based drugs to elicit broad-spectrum antiviral immunity is of particular interest in the development of products that have the potential for prevention and treatment of influenza infection. Immunomodulating products that enhance innate and/or cellular immunity and provide some level of antiviral resistance may offer the potential of protection against a number of seasonal and avian strains of influenza viruses, regardless of genetic mutations, reassortments, recombinations, zoonotic origin, or development

of drug-resistance. Nucleic acid-based drugs currently in development that can stimulate the host's immune responses against viral infections include CpG containing oligonucleotides and dsRNA, such as poly ICLC (Levy et al., 1975; Wong et al., 1995). These drugs are Toll-like receptor (TLR) agonists, and are in various stages of clinical development. Liposomal poly ICLC provided protection against both seasonal and avian influenza viruses in experimental studies in animals (Wong et al., 1999). Mounting evidence in animal studies suggest synthetic dsRNA, such as poly ICLC can elicit effective and protective antiviral immune responses to influenza infection. Antiviral immune responses induced by these drugs have been shown to confer complete protection in mice against multiple challenge doses of influenza A viruses, including influenza A/PR/8/34 (H1N1) and A/Aichi (H3N2) strains (Wong et al., 1999). The observation that liposomal poly ICLC has been shown to be effective against various subtypes of influenza A viruses (H1N1, H3N2) may well suggest it is particularly well suited to deal with constantly evolving viruses, such as the influenza A viruses (Wong et al., 1999, 2005).

PROSPECTS FOR THE FUTURE

Influenza remains a serious disease despite the availability of good antivirals as well as IV and LAV vaccines, which are effective for most recipients. Current vaccines are safe and efficacious but there are problems with the current methodologies for vaccine production which can delay manufacture of sufficient vaccine stock viruses in pandemic situations. The human devastation caused by past influenza pandemics as well as recent concerns with avian influenza are a reminder that the threat of a future pandemic is real and that new approaches for vaccine production are necessary to meet the needs of the future.

KEY ISSUES

- Current vaccines are produced by growing virus in chicken egg–embryo culture. Problems associated with adequacy of egg supply, biological safety, killing of chick embryos by virulent avian strains and appropriateness of virus stocks used for inoculation make egg–embryo culture problematic and suggest that the development of nonegg-based culture systems should be a priority for future of influenza vaccine development.
- Development of better methods of selection and production of viral antigens using reverse genetics for both seasonal and pandemic strains of virus are needed if we are to produce adequate virus for the development of vaccines which reduce morbidity and mortality and improve influenza virus protection.
- Advances in vaccine research which show great promise for the future include evaluation of pure subunit vaccines, development of new adjuvants, development of DNA vaccines, enhancing methods for mucosal immunization, and the use of immunomodulators for enhancing immune responses.
- Development of better methods of selection and production of viral antigens for both seasonal and pandemic strains of virus are needed if we are to produce adequate virus to reduce morbidity and mortality and improve influenza virus protection in the future.

Japanese Encephalitis

Ichiro Kurane
Department of Virology, National Institute of Infectious Diseases, Tokyo, Japan

OUTLINE

ABSTRACT

Japanese encephalitis (JE) is the most important viral encephalitis in Asia. JE occurs in annual epidemics or endemically in many Asian countries. Nearly 3 billion people, approximately 60% of the world's population, are at risk from JE virus infection. JE virus is maintained in nature between vector mosquitoes and vertebrate animals, especially pigs. Pigs also play a role as an amplifier for JE virus. Humans are infected by the bite of infected mosquitoes. Neutralizing antibody provides the best evidence that protective immunity has been established, and the biological assay of neutralization shows correlation with protection. Vaccination is the most effective measure of prevention of JE in humans. Vaccine coverage must be maintained indefinitely in all individuals who are potentially exposed to the virus. However, the vaccines are not available to all the populations at risk in the world.

Four types of JE vaccines are currently used in the world: three types of inactivated vaccines and one type of live-attenuated vaccine. Mouse brain-derived inactivated JE vaccine is produced from infected mouse brains by inactivation and extensive purification of the virus. This type of vaccine is produced with Nakayama or Beijing-1 strain, and that produced with Nakayama strain has been used as the international JE vaccine. Primary hamster kidney (PHK) cell-derived inactivated JE vaccine and Vero cell-derived inactivated JE vaccine have been used in China. Live-attenuated JE vaccine derived from PHK cells also have been used in China and some other countries. Furthermore, additional Vero cell-derived inactivated vaccines and chimeric vaccines are under development, and phase II and III clinical trials are being undertaken in humans. Multiple types of JE vaccines will be available in the near future. The governments of the countries where JE is endemic or epidemic will need to determine which types of vaccine will be used in respective countries.

INTRODUCTION

Japanese encephalitis (JE) virus is the most important cause of viral encephalitis in Asia (Monath and Tsai, 2002). Nearly 3 billion people, approximately 60% of the world's population, are at risk from JE virus infection. In the last 20 years, JE virus transmission has intensified in certain countries. Further, the disease has extended its geographical range to previously unaffected areas of Asia and northern Australia. JE is a vaccine-preventable disease. All the populations at risk of JE virus infection in JE-endemic or -epidemic countries should be immunized with JE vaccine.

JE VIRUS

Genome and Structure

JE virus belongs to the family Flaviviridae (genus *Flavivirus*). The genome of JE virus is a single and plus-stranded RNA, nearly 11 kb in length (Sumiyoshi et al., 1987). The JE virus genome encodes an open reading frame flanked by about 100- and 600-nucleotideuntranslated regions at the 5′- and 3′-ends, respectively. The uninterrupted open reading frame codes for three structural proteins—the capsid (C), preM [which is the precursor to the membrane (M) protein], and the envelope (E) protein—and seven nonstructural proteins: NS1, NS2A, NS2B, NS3, NS4A, NS4B, and NS5 (Kimura-Kuroda et al., 1990). JE virion has a spherical shape about 40–50 nm in diameter. The nucleocapsid is about 30 nm in diameter and covered by the envelope. The envelope contains the E and M proteins. The E protein is glycosylated and responsible for attachment to still unidentified cellular receptors and fusion with cell membrane. The E protein contains the main epitopes recognized by neutralizing antibodies. It is believed that the E protein plays the most important role in induction of protective immunity (Kimura-Kuroda et al., 1990; Konishi et al., 1999). JE virus is grouped into the JE-serocomplex group in flaviviruses. JE virus demonstrates a high level of cross-reactivity with West Nile virus, St. Louis encephalitis virus, and Murray Valley encephalitis virus.

Ecology and Transmission

JE virus is maintained in nature between vector mosquitoes and vertebrate animals, especially pigs (Monath and Tsai, 2002). The principal vector of JE virus is culex mosquitoes, mainly *Culex tritaeniorhynchus* in Asia (Rosen, 1986). Wild birds probably play a role in the maintenance of JE virus in nature and in carrying the virus to new regions.

Humans are infected by the bite of infected mosquitoes. Pigs play a role as an amplifier for JE virus. Infectivity titers of JE virus reach high levels in pigs. Many mosquitoes are infected with the virus by biting infected pigs. The infected mosquitoes then transmit JE virus to humans. However, humans do not transmit virus to biting mosquitoes because of low titers of viremia; thus, humans are considered to be dead-end hosts.

JAPANESE ENCEPHALITIS

Clinical Symptoms

JE virus infection can be asymptomatic or symptomatic, demonstrating clinical illness of encephalitis, meningitis, or febrile illness in humans. One to three in 1000 infected humans develop clinical illness. JE is an inflammatory disease of the central nervous system, which consists of cerebrum, cerebellum, and spinal cord.

The incubation period of JE is 5–15 days. The illness starts with fever and headache. Other early

symptoms include vomiting, diarrhea, and muscle aches. Meningeal irritation becomes apparent on the second day, and then cerebral symptoms, including altered consciousness ranging from apathy to coma, rapidly develop. The case fatality rate is about 20–30%. Approximately 30–50% of the surviving patients have neuropsychiatric sequelae. Complete recovery occurs in only one-third of the patients.

Pathogenesis

The pathogenesis of JE is not completely understood. JE virus is transmitted to humans by mosquito bite. It first multiplies in the local lymph nodes or other organs and then enters blood vessels, causing viremia. The virus reaches neuronal cells in the central nervous system by crossing the blood-brain barrier. It is generally believed that in most JE virus infections, the virus does not enter the central nervous system, which is protected by the blood-brain barrier, but results in inapparent infection.

Laboratory Tests

Clinical diagnosis is a prerequisite for early and proper treatment. Laboratory tests are essential for confirmatory diagnosis of JE. Virus isolation from blood or cerebrospinal fluid of patients can be successful at a very early stage of the illness but is usually very difficult. Recently, the IgM-capture ELISA has been widely used for detection of specific IgM (Martin et al., 2000). Hemagglutination inhibition (HI) test is still used for serodiagnosis in many laboratories.

EPIDEMIOLOGY

Global Distribution of JE

Approximately 20,000 JE cases with 6000 deaths are reported annually in the world. The actual number, however, is estimated to be a few-fold greater. A surveillance standard has been published, but implementation of a surveillance system specifically for JE is incomplete in many Asian countries, as encephalitis is not differentiated by etiology.

JE occurs in annual epidemics or endemically in many Asian countries, including Japan, Korea, Taiwan, China, Vietnam, Thailand, Malaysia, Myanmar, India, Nepal, and Sri Lanka (Vaughn and Hoke, 1992; Basnyat et al., 2001). The endemic regions are surrounded by Japan, China, and Korea in the north, Indonesia and Australia in the south, India and Pakistan in the west, and the Philippines and Guam in the east (Fig. 28.1). Nearly 3 billion people, approximately 60% of the world's population, are believed to be at risk of JE virus infection. The first JE patient in Papua New Guinea was reported in 1995 and then again in 1997 (Mackenzie, 1999; Hanson et al., 2004; Rubin and Baird, 2004). In Australia, three JE patients were first reported in Badu Island in the Torres Strait

FIGURE 28.1 The areas where Japanese encephalitis is naturally found.

in 1995 (Hanna et al., 1996). In 1998, patients were again reported in Badu Island and, for the first time, in Cape York Peninsula in the Australian Subcontinent (Hanna et al., 1999). Thus, JE is no more a disease restricted to Asia only but is also found in Oceania.

Seasonal Prevalence

JE virus transmission season differs among endemic regions. It is mainly due to numbers and activities of vector mosquitoes. The climate, especially temperature and rainfall, affects the number and activity of vector mosquitoes. The changes in agricultural procedures, including rice cultivation, also affect the mosquito density and eventually the size and frequency of the transmission cycle of JE virus. Levels of immunity among pig population also influence the transmission cycle.

There is a year-round transmission of JE virus in tropical countries (Monath and Tsai, 2002). In the Southeast Asian countries, JE virus transmission mainly occurs between May and December and throughout the year in limited sites. However, the transmission pattern in the temperate zone (e.g., Japan, Korea, and northern China) is rather well defined (Monath and Tsai, 2002). The epidemic season in these areas usually starts in May or June and ends in September or October.

CONTROL OF JE

Protective Immunity against JE Virus

Protective immunity against JE virus has been long studied using mouse models. It is accepted that neutralizing antibodies play a key role in the protection. Passive transfer of neutralizing antibodies before virus inoculation protected mice from lethal challenge (Oya, 1988; Kimura-Kuroda and Yasui, 1988). Thus, preexisting neutralizing antibodies are important for protection of the infection. There was a linear relationship between the levels of neutralizing antibodies and the titers of challenge viruses that were resisted by mice. It was also demonstrated that when antibody was passively transferred after infection, partial protection was observed. Although complement-mediated cell lysis and antibody-dependent cell-mediated cytotoxicity were attributed to the protective activity, the mechanism of protection by anti-NS1 antibodies is not completely understood. The role of cytotoxic T cells (CTLs) in the recovery from JE virus infection has not been well established. However, it has been reported that passive transfer of virus-specific CTLs also protects mice from lethal challenge by JE virus (Murali-Krishna et al., 1998).

Control of JE in Nature

Considering the transmission cycle of JE virus to humans, there are several ways that are theoretically effective for preventing JE virus infection of humans. The control of mosquitoes and the vaccination of pigs are effective in certain circumstances; however, these measures are not practical as a means of preventing human illness. At this point, vaccination of humans is the most effective measure of prevention of JE in humans. This has been demonstrated epidemiologically in Japan, Korean and Taiwan in East Asia. Humans are incidental hosts; thus, coverage must be maintained indefinitely in all the people who are potentially exposed to the virus.

JE VACCINES

Effect of JE Vaccine on JE Epidemics

The total number of reported JE cases has been recently decreased, according to a report of the World Health Organization (WHO). China accounted for the largest number of JE cases in the world. In the last few decades, however, China achieved a significant reduction in the number of JE cases, mainly because of a nationwide implementation of JE vaccination (Yu, 1995). In Japan, the annual JE case number is less than 10 since the 1990s. Similar trends are observed in Korea and Taiwan.

The age distribution of JE patients varies in countries. In countries where JE virus is hyperendemic, half of the patients are children under 4 years of age, and most of the patients are children under 10 years of age (Gajanana et al., 1995). However, in Japan, Korea, and Taiwan, where mass JE vaccination has been extensively implemented, JE occurs among adult populations rather than children, the majority of the patients being at over 50 years of age (Matsunaga et al., 1999; Petersen and Marfin, 2005). As stated above, most of the JE patients are children, and the children at risk should receive safe and efficacious JE vaccine to acquire protective immunity. However, this goal has not been achieved in most of the countries in JE-endemic and -epidemic regions of the world, as JE vaccines are not distributed to all at risk. Insufficient doses of vaccines are produced, and some of the currently available vaccines are still expensive for use in developing countries.

Currently Produced JE Vaccines (Table 28.1)

Four types of JE vaccines are currently used in the world: three types of inactivated vaccines and one

TABLE 28.1 Currently produced JE vaccines

Type of vaccine	Organs or cells	Virus strains	Countries
Inactivated	Mouse brain	Beijing-1	Japan, Thailand
	Mouse brain	Nakayama	Korea, Taiwan, Vietnam, India, Japan (for export only)
	PHK cells	P3	China
	Vero cells	P3	China
Live attenuated	PHK cells	SA 14-14-2	China

Note: PHK: primary hamster kidney

type of live-attenuated vaccine (Halstead and Tsai, 2004). These are mouse brain-derived inactivated JE vaccine, primary hamster kidney (PHK) cell-derived inactivated JE vaccine, Vero cell-derived inactivated JE vaccine, and live-attenuated JE vaccine derived from PHK cells.

Inactivated JE Vaccine

Mouse Brain-Derived Inactivated JE Vaccine Nakayama and Beijing-1 strains are used as production strains. The vaccine is produced from infected mouse brains by inactivation and extensive purification of the virus. Mouse brain-derived inactivated JE vaccine produced with Nakayama strain was first licensed in Japan in 1954 and has been used as the international JE vaccine. This type of vaccine is currently produced in Japan, Korea, Taiwan, Thailand, India, and Vietnam. The strain for vaccine production was changed to Beijing-1 strain in Japan in 1989. Beijing-1 strain is used as the virus seed in Japan and Thailand, and Nakayama strain in Korea, Vietnam, and India. The efficacy of mouse brain-derived inactivated JE vaccine was evaluated in two field trials. In a study in Taiwan in 1966, the efficacy of the Nakayama vaccine was 80% after two immunizations (Hsu et al., 1971) while other studies in Thailand demonstrated that the efficacies of monovalent Nakayama vaccine and Nakayama and Beijing-1 bivalent vaccines were both 91% (Hoke et al., 1988).

PHK Cell-Derived Inactivated JE Vaccine The vaccine is produced from JE virus propagated in PHK by inactivation and purification (Halstead and Tsai, 2004). PHK cell-derived inactivated JE vaccine has been produced exclusively in China using P3 strain since 1968. Approximately 70 million doses are distributed annually in China, and this vaccine had been the principal JE vaccine in China until the live-attenuated vaccine was produced. Regional trials in China showed protection against JE with efficacies of 85–87%.

Vero Cell-Derived Inactivated JE Vaccine The vaccine is produced from JE virus propagated in Vero cells by inactivation and purification. Vero cell-derived inactivated JE vaccine using P3 strain has been licensed in China since 1998. Approximately 10 million doses have been distributed in China up to 2006. Regional trials in China showed protection against JE with efficacies of over 90%.

Live-Attenuated JE Vaccine

Live-Attenuated JE Vaccine Derived from PHK Cells A PHK cell-derived, live-attenuated JE vaccine was developed using the SA 14-14-2 strain and licensed in 1988 in China (Tsai, 2000). The efficacy of the vaccine has been reported more than 99% (Bista et al., 2001). It has been reported that more than 100 million children received the SA 14-14-2 vaccine with no serious adverse events. Two-dose immunization 1 week apart is recommended as a routine immunization, although single-dose immunization showed a comparable efficacy. The vaccine has also been licensed in Korea (Sohn et al., 1999), Nepal, and India.

Adverse Events

Adverse events due to the mouse brain-derived inactivated JE vaccine have been studied. Local reactions at the injection sites and fevers occur in approximately 10% of vaccinated children after vaccination with mouse brain-derived inactivated JE vaccine in Japan. In addition, severe allergic symptoms have been reported recently (Plesner et al., 2000; Marfin et al., 2005). The incidence of systemic reactions characterized by generalized urticaria, respiratory symptoms, and cardiovascular symptoms have been noted. Some showed serum IgE against gelatin included as a stabilizer; however, many have remained obscure in etiology (Sakaguchi and Inouye, 1998).

Since JE vaccine used infected mouse brain as a source, concerns existed regarding the possible incidence of severe adverse reaction in nervous systems of vaccinees. Severe neurological disorders, including acute disseminated encephalomyelitis (ADEM), were reported in relation to JE vaccination (Fukuda et al., 1997). The incidence rate is about one–two in 1,000,000 doses in Japan, but the etiological relationship has not been confirmed in most of these cases. Adverse events

TABLE 28.2 JE vaccines under development

Type of vaccine	Organs or cells	Virus strains	Countries
Inactivated	Vero cells	Beijing-1	Japan
	Vero cells	SA 14-14-2	Austria
Live (chimeric vaccine)	Vero cells	SA 14-14-2	U.S.A.

of other types of JE vaccines have not been extensively analyzed or reported.

JE VACCINES UNDER DEVELOPMENT

These are summarized in Table 28.2.

Inactivated Vaccines

Vero Cell-Derived Inactivated JE Vaccine

Mouse brain-derived inactivated JE vaccine has been considered as the internationally accepted vaccine for a long period of time. The contribution of this vaccine to the prevention of JE in the past is well appreciated, but the fact that the vaccine is produced from infected mouse brain raises some concerns. It has been expected that the production of inactivated JE vaccines will eventually be shifted from infected animal brains to cell culture.

New Vero cell-derived inactivated JE vaccines have been developed using Beijing-1 and SA 14-14-2 strains as seed viruses in Japan and Europe, respectively (Sugawara et al., 2002). These candidate vaccines demonstrated high levels of immunogenicity and safety in phase I and II studies, and phase III clinical trials are being performed. On the other hand, the changes of the source of JE virus from mouse brain to cell culture will require new quality control measures to be implemented.

Live Vaccine

Chimeric JE Vaccine

Chambers et al. (1997) developed a chimera virus by replacing preM and E genes of yellow fever virus 17D strain with those of JE virus SA 14-14-2 strain. This chimera virus induced JE virus-specific antibodies in the vaccinees. The chimera vaccine proved efficacious in yellow fever-immune individuals. The vaccinees showed viremia for 4–7 days after inoculation, and some developed fever and malaise as those who had received yellow fever 17D vaccination. The yellow fever–JE chimeric vaccine is expected to be as potent as yellow fever vaccine in the duration of specific antibody for years, even after a single injection (Monath et al., 2002). Currently, the phase II studies have been completed for the development program of the yellow fever–JE chimeric vaccine.

EVALUATION OF JE VACCINE

Vaccine Potency

Neutralizing antibody provides the best evidence that protective immunity has been established, and the biological assay of neutralization shows correlation with protection (Hombach et al., 2005). A linear titer-protection relationship exists, and data from efficacy trials corroborate the role of neutralizing antibody in protection. Moreover, neutralizing antibody-mediated protection has been demonstrated for homotypic and heterotypic JE strains. It is accepted that a reasonable threshold antibody level for protection is 1:10 dilution of serum in a 50% plaque reduction neutralization test (PRNT). Roles of immunological memory and cellular immunity in the protection have also been considered, but details are not known.

Assessment of Protective Potency of New Vaccine

The potency of the vaccine should be determined by titration of neutralizing antibody induced in immunized mice by the PRNT. Mice are usually immunized twice via the intraperitoneal route. Neutralization antibody titers should be calculated as a 50% PRNT, which represents the neutralizing potency most reliably. The candidate vaccine needs to be tested in parallel with a reference vaccine (standard). The challenge JE virus strain should be homologous to the vaccine strain.

Evaluation in Clinical Studies

The new vaccine should assure the protection against JE infection. As stated above, a neutralizing antibody titer of not less than 1:10 dilution is considered to be the level that assures protective immunity. In clinical studies, two endpoints are considered (Hombach et al., 2005). The first endpoint is the seroconversion rate using a 1:10 dilution of serum. The second endpoint is geometric mean titers (GMT) of induced neutralizing antibodies. The comparison of protective efficacy between the tested and control

vaccines in the field study is theoretically possible; however, such a trial will require an enormous number of volunteers to obtain statistically significant data and is extremely difficult.

Further, in the current situation where JE vaccines are actually used, it is unethical to perform double-blind phase III studies including a placebo group. Thus, head-to-head comparison in neutralizing antibody responses between a new candidate vaccine and the currently licensed mouse brain-derived vaccines is the test protocol to be considered. When a new candidate vaccine is produced with a strain different from that used for currently licensed vaccine(s), selection of the challenge virus strains in neutralization assays will be a key issue. It has been reported that neutralizing antibody titers are usually higher against homologous strains than against heterologous strains. In particular, the titers are lower against those belonging to other virus genotypes.

Thus, the question will be: which strains of JE virus will be used as a challenge virus in neutralization assay? The possible strains are: (i) the new vaccine-producing strain(s), (ii) the current vaccine strain, and (iii) a third strain that is antigenically (and genetically) between the new vaccine strain and the current vaccine strain. There is no agreement yet on which approach will be followed. The selection of the third neutral strain is scientifically quite difficult. Therefore, the use of the strains homologous to the respective vaccine-producing strains is likely to be most reasonable.

FURTHER STUDIES

International References

JE vaccine reference is important to assure the potency of the vaccines, that is, levels of induced neutralizing antibodies to JE virus. However, there is no international vaccine reference at this point, although the reference vaccines have been prepared with Nakayama and Beijing-1 strains for domestic use in Japan. Currently, the countries that produce JE vaccines use Japanese vaccine references or prepare their own references based on the Japanese reference. At present, there is a trial of preparing a regional JE reference among Southeast Asian countries. Thus, designation of international reference will be the first step for the harmonization of the quality control of JE vaccine in the world.

It is expected that the vaccine reference will possess a potency similar to that used in field phase III trials and demonstrated sufficient potencies. Further, the vaccine reference is expected to be prepared for each respective strain of JE vaccine. This suggests that development of new reference vaccine(s) will be required because vaccine development using new strains of JE virus is being pursued.

Effect of Other Flaviviruses

It is known that there is an immunological cross-reaction among flaviviruses. The regions where JE virus is endemic are overlapped with areas where other flaviviruses are endemic; especially dengue viruses. If vaccinees are immune to other flaviviruses, the induction of neutralizing antibodies to JE virus will be modulated. Thus, the vaccinees' immune status to JE virus should be carefully screened in clinical trials. In studies to evaluate JE vaccine potency for the induction of JE virus neutralizing antibodies, the immune status of the candidates to other flaviviruses as well as JE virus must be carefully screened.

Cross-Reactive Protection against JE Virus in Heterologous Genotypes

JE virus strains are grouped into five genotypes, based on the nucleotide sequence of the E gene (Solomon et al., 2003). However, JE virus strains comprise only one serotype (Tsarev et al., 2000). Current JE vaccines are produced using Beijing-1 or Nakayama strains (mouse brain-derived inactivated JE vaccine), Beijing P3 (PHK cell-derived inactivated JE and Vero cell-derived inactivated JE vaccines in China), and SA14-14-2 (live attenuated vaccine in China). New Vero cell-derived inactivated JE vaccines under development use Beijing-1 and SA 14-14-2 strains. All these strains belong to genotype 3. In neutralizing antibody titrations of the sera obtained from JE vaccine-immunized mice, titers against homologous virus strains are generally higher than those against heterologous JE strains within the same genotype. The neutralizing antibody titers are further lower against the strains belonging to other genotypes. This raises a question whether the level of protective immunity against heterologous strains may not be as high as against homologous strains. The protective efficacy of 91% determined from clinical trials in Thailand may have been higher if JE virus strains very closely related to the prevalent strains in the region had been used as a production strain. Thus, selection of strains for vaccine production is another issue to be carefully addressed in the future.

In terms of using neutralizing antibody levels as a correlate of protection, it should be further confirmed whether JE vaccine produced using genotype 3 JE

virus strains induce similar levels of protective immunity against all the genotypes of JE virus in humans. It should be, however, noted that it is generally accepted that JE vaccines produced with genotype 3 strains induce protective immunity to JE virus in other genotypes as well as those in the same genotype.

KEY ISSUES

- Four types of JE vaccines are currently used in the world. Furthermore, additional Vero cell-derived inactivated vaccine and a new chimeric vaccine are under development.
- Multiple types of JE vaccines will be available in the near future.
- The governments of the countries where JE is endemic or epidemic will need to determine which types of vaccine to be used.
- There are still many questions to be addressed on JE vaccines, and further studies are still needed to develop third-generation JE vaccines.
- Although JE is a vaccine-preventable disease, availability of the vaccine is a practical issue.
- The vaccines should be distributed and available to all the populations at risk.

OUTLINE

ABSTRACT

Argentine hemorrhagic fever (AHF) is a rodent-borne viral hemorrhagic fever endemic to north-central Argentina. The etiologic agent, Junin virus, has caused significant morbidity and mortality since its recognition approximately 50 years ago. Junin is a Clade B arenavirus, and possesses many of the biological and physicochemical characteristics for potential use as a biological weapon. Consequently, the virus is regarded as a major (CDC Category A) biothreat agent.

Numerous attempts were made during the 1950s, 1960s, and 1970s by Argentine investigators to develop inactivated and live vaccines; for a variety of reasons, all ultimately proved unsuitable. In 1981, a collaborative venture involving the Argentine government, the U.S. Department of Defense, the United Nations Development Program, and the Pan American Health Organization was initiated to develop an AHF vaccine. This program resulted in the creation of Candid #1, a live-attenuated Junin vaccine initially produced at the Salk Institute in Swiftwater, PA. Candid #1 was proven safe and effective in a series of clinical trials conducted in both the United States and Argentina. In the wake of technology transfer, Candid #1 was manufactured and licensed for use in Argentina. The vaccine has had substantial impact in reducing the incidence of AHF, and is currently incorporated into the Argentine National Vaccine Program. Candid #1 remains the only vaccine proven effective against a disease caused by an arenavirus.

INTRODUCTION AND HISTORY

Argentine hemorrhagic fever (AHF) is a severe, rodent-borne zoonosis endemic to the fertile grasslands, or "humid pampas," of north-central Argentina (Fig. 29.1). AHF was first recognized as a clinical entity during the 1950s, following reports of a hemorrhagic fever syndrome among farmers and agricultural workers (Arribalzaga, 1955; Alvarez Ambrosetti et al., 1959; Rugiero et al., 1959b). Many epidemiologic features of AHF (e.g., its seasonality, demographics, and patterns of spread) were noted in the initial report of the disease (Arribalzaga, 1955; Sabattini and Maiztegui, 1970). Virus recovered in 1958 from patients with various clinical manifestations (Parodi et al., 1958; Pirosky et al., 1959a) was confirmed as the cause of AHF via volunteer human inoculation (Pirosky et al., 1959a, 1959b; Rugiero et al., 1959a). Although this agent, subsequently called Junin virus, was recovered consistently from the organs and body fluids of several rodent species, the drylands vesper mouse, *Calomys musculinus*, was ultimately established as its principal natural reservoir (Mills et al., 1991; Sabattini et al., 1967, 1977; Sabattini and Gonzales, 1967).

FIGURE 29.1 Geographic distribution of Junin virus in nature.

ETIOLOGIC AGENT

Junin virus is a member of the Tacaribe complex of New World arenaviruses (Mettler et al., 1963). Phylogenetic reconstruction of New World arenaviruses based on N gene sequences has allowed grouping into three lineages (Clades A, B, and C). Junin shares membership in Clade B with three other agents causing hemorrhagic fever in the Americas: Machupo, Guanarito, and Sabia viruses (causative agents of Bolivian hemorrhagic fever, Venezuelan hemorrhagic fever, and hemorrhagic fever in Brazil, respectively), suggesting radiation of this highly pathogenic phenotype from a common ancestor (Bowen et al., 1996).

Junin is an enveloped virus containing two single-stranded RNA molecules. Virions are pleomorphic; particles varying in diameter from about 40 to 200 nm, with evenly spaced glycoprotein spikes protruding 7–10 nm from the surface (Buchmeier et al., 2006). Electron-dense structures representing host-cell ribosomes are frequently seen within the viral envelope. The genome consists of two RNA segments, termed L (7.2 kb) and S (3.4 kb), that serve as ambisense templates for mRNA synthesis (Meyer et al., 2002). The L RNA segment encodes the viral RNA-dependent RNA polymerase (L protein), and a small zinc-binding (Z) matrix protein that plays a regulatory role in virus replication. The S RNA segment contains genes for the nucleocapsid protein (NP) and the viral glycoprotein precursor (GP-C). The NP is the principal structural protein of the viral nucleocapsid, and complexes with genomic RNA. Translation of GP-C sequences yields the GP-C precursor protein and a small signal peptide (SP) important in targeting the nascent polypeptide to the rough endoplasmic reticulum for glycosylation. The GP-C is processed by a cellular enzyme (subtilase SKI-1/S1P) to produce the two mature surface glycoproteins GP-1 (40–46 kDa) and GP-2 (35 kDa) (Buchmeier et al., 2006; York et al., 2004). The GP-1 and GP-2 associate noncovalently with myristoylated SP to form the mature glycoprotein complex, visible as the spikes on the virion surface (York et al., 2004). GP-1 is situated at the top of the spike, and functions as the virion attachment protein mediating binding with cell surface receptors. GP-2 forms the stalk of the spike; it promotes the acid-dependent fusion of viral and cellular membranes within internalized endosomes that is essential to viral entry (Buchmeier et al., 2006; Kunz et al., 2002). The role of the small residue SP associated with the complex is unclear, but it appears to be required for efficient pH-dependent membrane fusion (York et al., 2004). Serum neutralizing antibodies are directed primarily against the viral glycoprotein (Sanchez et al., 1989).

Host-cell receptors are important to virus pathogenicity and tropism. It has been shown that α-dystroglycan serves as the major cellular receptor for Old World and Clade C New World arenaviruses, but not Clade A and B viruses (Spiropoulou et al., 2002). Recently, transferin receptor-1 (TfR1) was identified as a cellular binding site for Clade B arenaviruses (including Junin). The behavior and expression of this receptor on macrophages, activated lymphocytes, and endothelial cells are important to viral replication and disease pathogenesis (Radoshitzky et al., 2007).

PROTECTIVE IMMUNE RESPONSE

It is likely that both cellular and humoral immunity are involved in protection from AHF. The use of immune plasma therapy and the relationship between therapeutic efficacy and neutralizing antibody content have established the importance of neutralizing antibody in recovery from disease (Enria et al., 1984, 1986; Maiztegui et al., 1979). That neutralizing antibody is similarly critical to protection is strongly inferred. In a study demonstrating efficacy of the Candid #1 live-attenuated Junin virus vaccine (see below), the vast majority (91.1%) demonstrated seroconversion (Maiztegui et al., 1998). Junin virus-specific IgG subclass patterns were similar between patients convalescing from AHF and subjects receiving Candid #1 vaccine, suggesting an important role for IgG_1 in recovery and protection (del Carmen Saavedra et al., 2003). Patterns of neutralizing antibodies observed among nonhuman primates receiving the Candid #1 vaccine and subsequently surviving challenge with virulent wild-type Junin virus indicate that humoral immunity plays a significant role in protection (McKee et al., 1992). While human AHF immune plasma protected guinea pigs from experimental Junin infection, the $F(ab')_2$ fraction alone did not (Kenyon et al., 1990). Although evidence strongly supports a pivotal role for elimination of virus by neutralizing antibody, observations in model systems argue for an important role of antibody in elimination of virus-infected cells as well. In particular, resistance to Junin infection develops in conjunction with appearance of virus-specific antibody-dependent cellular cytotoxicity (ADCC), and anti-Junin virus antibodies can sensitize cells to complement-mediated lysis, (Kenyon and Peters, 1989; Peters et al., 1987).

A role for cellular immunity in protection has also been inferred, but the evidence is less clear. In some Candid #1-vaccinated individuals who do not develop measurable antibody, Junin virus-specific lymphoproliferative responses have been observed

(Maiztegui et al., 1998). Rarely, experimental animals may be protected from virulent Junin virus challenge in the absence of detectable neutralizing antibody (McKee et al., 1992). Vaccination of guinea pigs with recombinant vaccinia virus expressing Junin glycoproteins protected against disease, but not necessarily infection, in the face of low or undetectable levels of neutralizing antibody (Lopez et al., 2000). Therefore, it is likely that a balanced immune response, involving humoral, cellular, and perhaps other, as yet undefined, factors, is involved in protection from serious illness and death from AHF.

EPIDEMIOLOGY

When AHF was initially recognized, the endemic area comprised about 16,000 km^2 within rural portions of Buenos Aires province, where the population at risk was estimated to be 270,000 persons (Maiztegui, 1975). Over the ensuing years, however, a progressive expansion of the disease to the north, east, and west has been documented (Maiztegui et al., 1986; Maiztegui and Sabattini, 1977). By end of the 20th century, the endemic zone occupied portions of four provinces (Buenos Aires, Cordoba, Santa Fe, and La Pampa), encompassing an area more than 9 times that originally described, and placing approximately 5,000,000 persons at risk (Garcia et al., 2000) (Fig. 29.2).

As the AHF-endemic area has expanded, temporal and geographic patterns have emerged. Throughout the endemic area, Junin virus infection in both rodents and humans tends to be focal in distribution. The incidence of human disease (AHF) has been observed to be highest during the first 5–10 years following it recognition in newly affected areas, with subsequent decline with the passage of time. However, pockets of disease have reemerged in some of these historically active areas. The basis for these spatial and temporal patterns is undefined, but subtle changes in reservoir rodent genetics and susceptibility to infection, the dynamics of virus reintroduction, and other factors are likely involved.

In recent years, the geographic expansion of the endemic area appears to have slowed (Enria and Barrera Oro, 2002). Whether this signals an approach to the ultimate extent of spread of this disease is unknown; the natural distribution of *C. musculinus* remains larger than the disease-endemic area, and, when sought, virus can be recovered from rodents outside the disease-endemic zone (Mills et al., 1991; Mills and Childs, 1998).

Prior to the availability of a preventive vaccine, between 100 and 800 cases of AHF were diagnosed each year in the AHF endo-epidemic area (Arribalzaga, 1955; Maiztegui, 1975). Cases occurred year-round in all age groups and both genders, but most occurred in 15–60-year-old male agricultural workers during a March–June epidemic season coinciding with the annual grain harvests and higher rodent population densities. Beginning in 1992, in conjunction with selective vaccination of high-risk adults using the Candid #1 live-attenuated Junin virus vaccine, a dramatic decrease in AHF incidence along with a shift in case demographics toward women, children under 15 years of age, and individuals without rural contact has been observed (Enria and Barrera Oro, 2002; Enria et al., 1999).

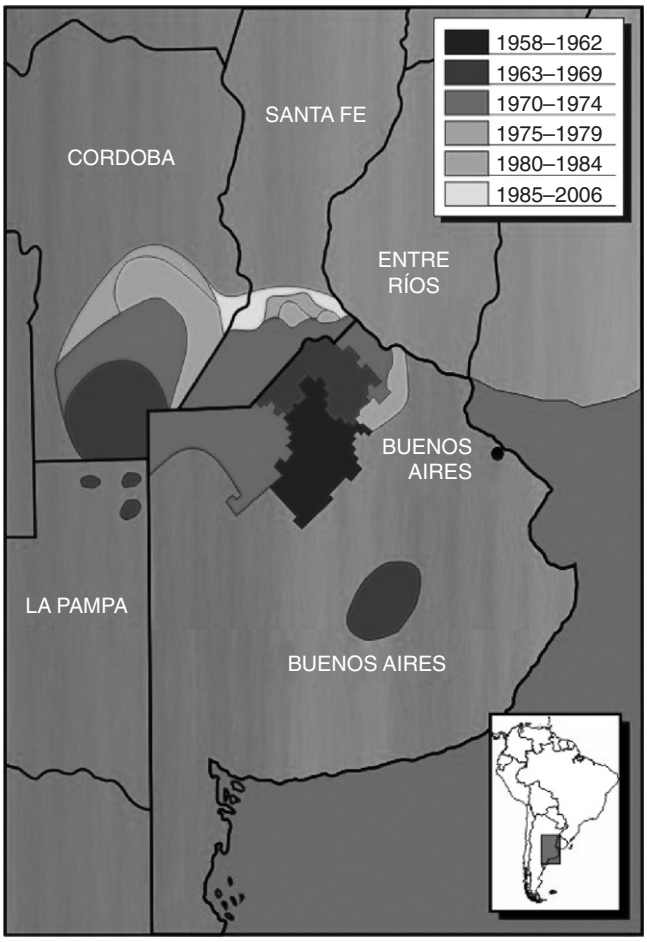

FIGURE 29.2 Progressive expansion of AHF region of endemnicity.

An association between AHF and indigenous rodents was made shortly after the disease was recognized (Pirosky et al., 1959a). Subsequently, the epidemiology of AHF and distribution of Junin infections among humans were found to be linked closely to the ecology and patterns of infection in these rodents (Mills and Childs, 1998).

C. musculinus has been established as the principal reservoir for Junin virus (Mills et al., 1991; Sabattini et al., 1977; Carballal et al., 1986). This species has

comprised the vast majority of virus and/or antigen-positive rodent captures in the endemic area, and persistent viremia as well as salivary shedding have been documented in naturally and laboratory-infected animals. However, the virus has also been recovered from organs and body fluids of other rodent species inhabiting the central Argentine pampas, including *Calomys laucha* and *Akodon azarae*, and, less frequently *Mus musculus*, *Bolomys obscurus*, and *Oligoryzomys flavescens* (Mills et al., 1991; Sabattini et al., 1967, 1977; Sabattini and Gonzales, 1967).

The dynamics of Junin infection in rodent reservoir species is complex. The virus traditionally has been thought to establish asymptomatic, persistent infections, and to be maintained in nature by a balance between horizontal and vertical transmission (Vitullo and Merani, 1990). Carrier males may infect virus-negative females, producing vertically infected offspring of both genders (Buchmeier et al., 2006). However, chronically infected females infected as newborns are generally sterile as adults, presumably limiting their role in producing chronically viremic offspring (Vitullo and Merani, 1988), and Junin infections acquired vertically have been observed to result in growth retardation, decreased survivorship, and impaired reproductive ability (Vitullo et al., 1987). Field observations implicate horizontal transmission as the predominant mode of Junin virus spread among *C. musculinus* (Mills et al., 1992). Under experimental conditions, about half of *C. musculinus* infected as adults become chronic carriers with persistent viremia, while the remainder develop antibody and clear the infection (Vitullo and Merani, 1990).

Shedding of Junin in secreta and excreta by chronically infected *C. musculinus* underlies acquisition of the virus by humans. It is thought that infection occurs incidentally, through exposure to aerosols and/or fomites during the course of routine occupational (e.g., farming) or other activities that intrude on the natural habitat of infected rodents (Maiztegui, 1975). *C. musculinus* is an opportunistic species, widely distributed across the pampas. Although numerically prevalent in farm fields, particularly during the harvest season, this rodent appears to have a preference for linear habitats such as roadsides and fencerows (Mills et al., 1992). Thus, although transmission of Junin virus to humans may occur to laborers or others working in fields, contact along roadsides before or after entering the fields (e.g., as the individual walks or drives into roadside vegetation; or rests, eats, or engages in other activities along fences or roadways) may represent a greater risk of exposure to the virus (Mills et al., 1992). This feature of habitat preference could also explain disease acquisition among nontraditional demographic groups.

BIOTHREAT AGENT POTENTIAL

There is no direct evidence that Junin virus has ever been weaponized or used intentionally to infect unsuspecting persons. It was extensively studied, however, by scientists working in the well-documented offensive biological weapons programs of the former Soviet Union (Alibek, 1999). Junin possesses multiple epidemiological, clinical, and physiochemical characteristics that make it highly suitable for use in this capacity. The virus is stable and highly infectious by aerosol (inhalation of infectious aerosols and/or fomites being principle mode of acquisition of AHF in nature), is relatively readily accessible, causes significant morbidity and mortality among those infected, appears on the basis of animal studies to be infectious at low doses, and, despite having limited potential for casual person-to-person spread, is capable of instilling fear and panic in at-risk populations. In conjunction with other pathogenic arenaviruses (e.g., Lassa, Machupo) it is grouped with other viral hemorrhagic fever agents by the U.S. Centers for Disease Control and Prevention as a Category A (highest threat level) pathogen (Centers for Disease Control and Prevention, 2000); as such, it is a focus of priority resource allocation for countermeasure development.

CLINICAL DISEASE

Details of the evolution of the AHF clinical syndrome derive from field observations as well as two meticulously chronicled human volunteer inoculations (Pirosky et al., 1959a; Rugiero et al., 1959a). Human infection with Junin virus usually results in symptomatic illness, although subclinical infections have been reported (Maiztegui, 1975). The onset of disease is insidious. Following an incubation period of 1–2 weeks after natural exposure (precisely 39.25 h in one volunteer receiving a total of 3.47×10^6 suckling mouse IC LD_{50} by sequential intramuscular and subcutaneous injections), malaise, myalgia, anorexia, and fever gradually develop. Within 3–4 days, severe prostration accompanied by back pain, headache, dizziness, and gastrointestinal disturbances appear. On physical examination, facial flushing and edema, conjunctival injection, and petechiae on the palate and axillary surfaces are observed. The gums frequently appear congested, and bleeding is commonly seen, particularly among those with poor dentition. Hemorrhage along the gingival margins is a characteristic finding. Cardiovascular effects include electrocardiographic abnormalities, moderate bradycardia, and orthostatic

hypotension. Neurological changes are commonly seen, the most frequent of which are tremors of the tongue and hands, diminished deep tendon reflexes, lethargy, and cutaneous hyperaesthesia; meningeal signs are generally not evident (Maiztegui, 1975; Mills and McKee, 2000).

The acute febrile period generally lasts for 8–10 days, and most patients then go on to improve and recover. Convalescence is typically prolonged, but sequelae are uncommon (Maiztegui, 1975; Mills and McKee, 2000). In up to a third of cases, however, progression to a more serious form of disease occurs. In these patients, evolution along one of three lines is seen: a predominantly hemorrhagic syndrome with diffuse ecchymoses, bleeding from venipuncture sites, and oozing from mucous membranes; a progressive neurologic deterioration characterized by delirium, coma, and convulsions; or a mixed hemorrhagic-neurologic syndrome with features common to each, and accompanied by shock (Maiztegui, 1975; Mills and McKee, 2000). Case-fatality rates may approach 30% among untreated patients with severe disease, with death generally occurring during the second week of illness (Enria and Barrera Oro, 2002). Pregnant women, particularly in the third trimester, are at increased risk for death from AHF, and fetal mortality is high (Briggiler et al., 1990). Among survivors of severe AHF, convalescence may be protracted, 1–3 months or more, with weight loss, fatigue, autonomic instability, and hair loss commonly seen.

During the acute phase of AHF, leucopenia (total white blood cell count $<4000/mm^3$) and thrombocytopenia (platelet count $<100{,}000/mm^3$) are almost always evident. In a retrospective case-control study, these two parameters in combination had a sensitivity of 100% and specificity of 71% for the disease (Harrison et al., 1999). Proteinuria and oliguria are frequently observed, although anuria (except in terminal cases) is rare (Maiztegui, 1975). Hyaline casts, inclusion-containing cells, and red blood cells may be seen in urinary sediment. Abnormalities in routine clotting studies may be seen in severely affected cases. Serum aspartate aminotransferase and alanine aminotransferase values are generally normal or only slightly elevated; hyperglycemia and glycosuria have been occasionally seen (Maiztegui, 1975; Mills and McKee, 2000).

TREATMENT

Supportive care, with attention to hydration, osmotic shifts, and electrolyte alterations, is the cornerstone of management for viral hemorrhagic fevers, including AHF (Buchmeier et al., 2006; Centers for Disease Control and Prevention, 1995). Measures to minimize microvascular trauma (e.g., avoidance of travel, gentle sedation, minimizing use of intramuscular injections and drugs that affect clotting [such as aspirin]) should be implemented. Interventions to counter specific pathologic conditions (e.g., bleeding diathesis) should be applied according to clinical judgment. Management of shock can be challenging, due to the increased vascular permeability seen with the disease. Person-to-person spread of Junin virus is uncommon, but has been documented in sexual partners (Briggiler et al., 1987).

Administration of immune plasma obtained from convalescent AHF patients has significantly improved outcome in patients with this disease. When administered within 8 days of onset of illness, mortality was reduced from 20–30% to 1–2% (Maiztegui et al., 1979). Therapeutic efficacy correlates with the content of neutralizing antibody contained in plasma; at least 3000 therapeutic units (Σ[neutralizing antibody titer $\times$ plasma volume]/body weight [kg]), generally equivalent to 2–3 convalescent plasma units, is the optimal dosage (Enria et al., 1984, 1986). About 10% of treated survivors will develop a curious late neurologic syndrome characterized by fever, headache, tremors, and ataxia (Maiztegui et al., 1979). The cause of this condition that develops 4–6 weeks after receipt of plasma therapy is unknown, but it is typically benign and self-limited.

PATHOGENESIS

In many respects, AHF is a classical viral hemorrhagic fever, presenting nonspecifically as a febrile illness, manifesting clinical signs and symptoms of vascular injury and dysregulation, and with relatively unimpressive gross pathology. Much of our understanding of AHF pathogenesis has been informed by studies of Junin and related arenaviruses in experimental animal systems, particularly guinea pigs (Guerrero et al., 1977; Oubina et al., 1984; Weissenbacher et al., 1975b) and nonhuman primates (Gonzales et al., 1983; Green et al., 1987; McKee et al., 1985, 1987; Weissenbacher et al., 1979). Studies of blood and tissues samples from humans with the disease have also yielded valuable insights into the mechanisms underlying the physiologic and pathologic changes observed.

Junin viral replication is thought to occur at the initial site of infection, generally the lungs (Buchmeier et al., 2006). Although pneumonic infiltrates are not evident early, it is felt that local pulmonary infection and spread to regional (usually hilar) lymphatics

occurs, with subsequent dissemination to other parenchymal tissues. As infection progresses, a wide variety of other organs may become affected, notably vascular endothelium, myocardium, kidneys, and the central nervous system. The gross pathological changes to these tissues tend to be nonspecific and often relatively unimpressive (Maiztegui, 1975). Destruction of splenic white pulp and the cortical areas of lymph nodes may be prominent, but frank necrosis is otherwise infrequent (Buchmeier et al., 2006; Gonzalez et al., 1980).

The genesis of bleeding abnormalities common to patients with AHF is beginning to be elucidated. Although the cause of quantitative alterations observed in platelet and white blood cell counts of patients with AHF is poorly understood, bone marrow hypoplasia and decreased erythropoietin levels are likely related (Marta et al., 2000). There is evidence for low-level but persistent coagulation and fibrinolytic system activation (Heller et al., 1995). In conjunction with thrombocytopenia, platelet function appears to be compromised; a circulating inhibitor of platelet aggregation, and platelet activation inhibitors (nitric oxide [NO] and prostacyclin [PGI_2]) have been described (Gomez et al., 2003, Cummins et al., 1990). Although total serum complement activity, as well as levels of some complement proteins (specifically, C2, C3, and C5) may be decreased, immune complex formation seems not to be important to disease pathogenesis (de Bracco et al., 1978).

Tropism of Junin virus for macrophages and endothelium, and subsequent release of immune mediators from these cells are believed to be central to AHF pathogenesis. Macrophages and activated lymphocytes, both of which express the recently characterized New World hemorrhagic fever arenavirus receptor, TfR1, to high levels, appear to be the principal targets of the virus (Radoshitzky et al., 2007). This receptor is also highly expressed on endothelial cells. Patients with AHF demonstrate high circulating levels of interferon-α and tumor necrosis factor (TNF)-α correlating with disease severity (Heller et al., 1992; Levis et al., 1984, 1985). Elevated levels of interleukins (IL) 6, 8, and 10 are also seen, and correlations have been observed between levels of TNF-α and levels of both IL-8 and IL-10, and between IL-8 and elastase α1 antitrypsin complex (E-α1AT) (a marker of neutrophil lysosomal degranulation) (Marta et al., 1999). Therefore, in addition to direct effects of viral infection on endothelium and immune cells, mediators released from, and/or acting on, these cells are likely stimuli for endothelial cell dysfunction, coagulation defects, and neutrophil activation.

A possible role for virus-specific factors in the varying clinical syndromes observed in patients with severe AHF is unresolved. Patterns of infection seen in humans (hemorrhagic, neurologic, or mixed) and, in some cases, virulence, were replicated when patient isolates were inoculated experimentally into rhesus macaques (McKee et al., 1985, 1987; Peters et al., 1987). However, fidelity of disease patterns with clinical isolates was not seen to the same degree in guinea pigs (Kenyon et al., 1986). Moreover, sequence analysis of GP-1 and GP-2 genes from seven Junin virus isolates recovered from patients with varying presentations failed to yield a genetic marker corresponding to clinical syndrome (Garcia et al., 2000).

VACCINES

History

Shortly after the isolation of Junin virus in 1958, Argentine scientists began the quest to develop a vaccine against AHF. Efforts were made to develop both inactivated and live-attenuated vaccines, and involved both homologous (Junin) and heterologous (Tacaribe) viruses (Barrera Oro and McKee, 1991).

Initial attempts to produce a killed virus vaccine focused on formalin-inactivation of Junin grown in mouse brain. These products were reported to induce neutralizing antibodies in mice and guinea pigs, and to protect against challenge in these animals with virulent Junin virus strains (Barrera Oro et al., 1967; Pirosky et al., 1959a). One formalin-inactivated mouse brain Junin vaccine was assessed for efficacy in humans (Agnese, 1999), then administered to more than 15,000 inhabitants of the AHF-endemic area between 1959 and 1962; however, no formal evaluation of immunogenicity or efficacy was undertaken (Mettler, 1969). Later, a formalin-inactivated Junin vaccine was produced in cell culture. While this candidate immunogen-induced neutralizing antibodies in laboratory animals, it was unsuccessful in protecting against challenge with virulent strains of Junin virus (Videla et al., 1989).

Alternative inactivation strategies included photoinactivation of Junin virus following exposure to neutral red dye, ultraviolet radiation, heating, and acetone (de Martinez Segovia et al., 1980; Parodi et al., 1965; Carballal et al., 1985; D'Aiutolo et al., 1979). Guinea pigs immunized with mouse brain pools of two different Junin virus strains inactivated using neutral red and ultraviolet light were challenged with a virulent Junin virus strain; 50% of the animals were reported to survive the challenge. This vaccine was subsequently assessed in 11 human volunteers, but was successful in eliciting complement fixing antibodies in only 2 previously immune individuals (de Guerrero et al., 1977).

Attempts to produce a viral subunit vaccine were made as well. One such candidate, a purified G38 capsular glycoprotein emulsified in Freund's complete adjuvant, induced specific neutralizing antibodies in rabbits, and protected guinea pigs from challenge with virulent Junin virus strains (Cresta et al., 1980). However, further evaluation of this product was not undertaken.

In the wake of a fortuitous observation that the prototype XJ strain of Junin virus lost virulence for guinea pigs after approximately 40 serial passages in newborn mouse brain (Casals, 1965; Mettler et al., 1963), enthusiasm for developing a live-attenuated vaccine ensued. A virus pool was created at the U.S. National Institutes of Health by passing a plaque-purified isolate from mouse brain passage 14 of XJ strain virus into newborn hamster brain. This strain, designated XJ Clone 3, was further passed in continuous cell culture and newborn mouse brain by Argentine scientists for use as a vaccine (Barrera Oro and McKee, 1991; Rugiero et al., 1981). The XJ Clone 3 vaccine proved attenuated for, and immunogenic in, guinea pigs (De Guerrero et al., 1969), and, beginning in 1968, human clinical trials with this product were initiated (Rugiero et al., 1969; Weissenbacher et al., 1969). By 1970, a total of 636 persons of both sexes were vaccinated. Although clinical reactions were recorded in about 75% of intensively followed individuals, most signs and symptoms were of relatively mild-to-moderate severity, and immunogenicity, measured by neutralizing antibodies, was reported to be 96% (Rugiero et al., 1974). The persistence of the immune response was established in 90% of a sample of vaccinees studied between 7 and 9 years after inoculation (Rugiero et al., 1981). In 1971, however, an expert panel from the National Academy of Medicine of Argentina, recommended that vaccination with XJ Clone 3 be suspended due to the absence of sound documentation of viral passage history, and disclosure of passages in heteroploid cell lines and mouse-brain substrate (Weissenbacher et al., 1987). Further characterization of this product led to the demonstration of long-term viral persistence, neurotropism, and neurovirulence in guinea pigs and nonhuman primates. Similar problems plagued additional attempts to develop attenuated viruses from prototype XJ strain Junin virus (Barrera Oro and McKee, 1991).

The realization that laboratory animals infected with Tacaribe, a New World arenavirus related serologically and chemically to Junin, developed neutralizing antibodies cross-reactive against Junin virus (Parodi and Coto, 1964; Tauraso and Shelokov, 1965; Weissenbacher et al., 1975a) prompted its examination as a potential heterologous vaccine. While immunization of guinea pigs and nonhuman primates with Tacaribe virus evoked persistent antibodies against Junin, and cross protection against Junin virus challenge could be demonstrated (Coto et al., 1980; Damonte et al., 1981; Samoilovich et al., 1988, 1984; Weissenbacher et al., 1982, 1987; Weissenbacher and Damonte, 1983), further development has not been pursued.

Current Licensed Vaccines

Discussions held in 1976 during the First International Seminar on Arenaviral Hemorrhagic Fevers (Eddy and Barrera Oro, 1977) prompted formation of an international collaboration to develop a safe and effective vaccine against AHF. This project, which was initiated in 1979, brought together experts in vaccine development representing the governments of Argentina and the United States under the auspices of the United Nations Development Program and the Pan American Health Organization (PAHO). Utilizing high-containment laboratories at the United States Army Medical Research Institute of Infectious Diseases (USAMRIID) at Fort Detrick, Maryland, a program was established under the direction of Dr. Julio G. Barrera Oro from Argentina's Malbran Institute to produce an experimental Junin vaccine to be tested in human volunteers under the supervision of U.S., Argentine, and PAHO regulatory agencies. The initiative culminated in the production of Candid #1, a live-attenuated Junin vaccine derived from a well-documented descendent of prototype XJ strain Junin virus that was passaged and "cloned" in certified diploid mammalian cells (Barrera Oro and McKee, 1991).

Candid #1 ($XJGP_2\ MB_{44}\ FRhL_{19}$), was derived from the 44th mouse brain passage (XJ#44) of XJ strain Junin virus. It was determined to be at least as attenuated as the previous Argentine live vaccine candidate (XJ Clone 3) in guinea pigs, and was assay-negative for murine viruses. Later studies of nucleotide and amino acid sequences of L and Z genes from Candid #1 and its progenitors demonstrated 12-point mutations in the L protein unique to the vaccine strain, suggesting a molecular basis for the attenuation phenotype (Goñi et al., 2006). Preclinical studies at USAMRIID demonstrated the safety, immunogenicity, and protective efficacy of Candid #1 in guinea pigs and rhesus macaques; the median protective dose of the vaccine was less than 34 plaque-forming units (pfu) for guinea pigs, and less than 16 pfu for rhesus macaques (Barrera Oro and Eddy, 1982; Barrera Oro et al., 1985; Kenyon et al., 1989; McKee et al., 1992).

Additionally, the vaccine protected guinea pigs and rhesus macaques against Machupo virus, the etiologic agent of Bolivian Hemorrhagic Fever; a dose of 3 pfu was sufficient to protect rhesus from challenge with a virulent strain of Machupo (Barrera Oro and Eddy, 1982; Barrera Oro et al., 1988; Jahrling et al., 1988; Lupton et al., 1988).

Using lots of vaccine produced in the United States at the Salk Institute in Swiftwater, PA, clinical studies with Candid #1 were initiated in 1985. A series of phase I and II clinical trials performed in both the U.S. and Argentina demonstrated the safety and immunogenicity of the vaccine in more than 200 human volunteers: none of the vaccinated subjects developed significant clinical, hematological, biochemical, or urinary abnormalities, and >91% of vaccinees developed specific neutralizing antibodies (Barrera Oro et al., 1987; MacDonald et al., 1988, 1987; Maiztegui et al., 1988; Maiztegui and McKee, 1989). Between 1988 and 1990, a prospective, double-blind, placebo-controlled phase III efficacy trial was performed in 6500 human volunteers living and/or working in a high-risk region of Santa Fe Province, Argentina. No significant adverse events attributable to the vaccine were recorded, and 91.1% of vaccinees developed Junin-specific neutralizing antibodies. Vaccine efficacy during the 2–3 year follow-up proved excellent; 95% for protection against AHF (95% CI: 82–99%), and 84% for protection against infection with any clinical symptoms (95% CI: 60–94%) (Maiztegui et al., 1998).

Between 1994 and 2003, the remaining limited quantities of vaccine produced at the Salk Institute were used to vaccinate (under protocols approved by Argentine regulatory authorities) more than 240,000 highly at-risk individuals 15 years of age and older in the AHF-endemic zone. No significant adverse events attributable to Candid #1 were reported, and Junin virus-specific neutralizing antibodies were detected in 88.5–95.7% of recipients studied. Moreover, neutralizing antibodies at titers ≥1:10 were shown to persist for more than 10 years in >90% of vaccinees. With the gradual introduction of Candid #1, the annual incidence of AHF has fallen dramatically (Fig. 29.3). The estimated effectiveness of Candid #1 vaccine for protection against AHF for the period 1992–1999 was 98.1% (95% CI: 96.6–99%) (Enria and Barrera Oro, 2002, Enria et al., 1999).

Following completion of phase III efficacy trials, efforts to transfer the technology for producing Candid #1 from the U.S. to Argentina were undertaken. The Ministry of Health of Argentina determined that vaccine production could best be accomplished at a nascent facility colocated with the Instituto Nacional de Enfermedades Virales Humans (INEVH) in Pergamino.

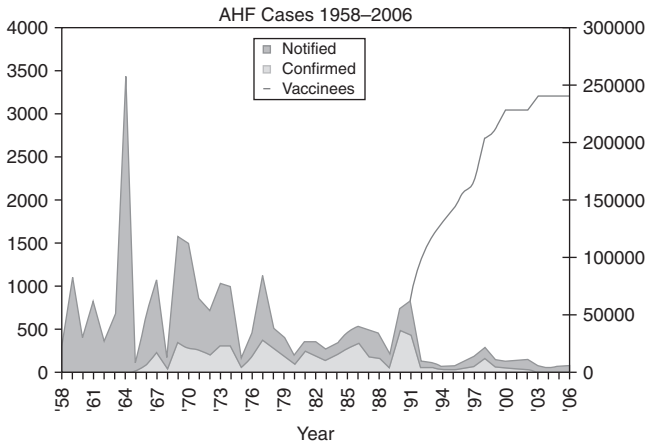

FIGURE 29.3 Incidence of AHF in relation to introduction of Candid #1 Junin vaccine in Argentina. "Notified" indicates cases of human disease clinically compatible with AHF, and reported as suspected AHF, to authorities; "Confirmed" indicates AHF cases confirmed virologically and/or serologically. Source: Argentine National Program for AHF Control, Pergamino, Argentina (Enria, personal communication).

A program for training INEVH personnel in good manufacturing practices (GMP) and quality control practices at the Salk Institute in Pennsylvania (the location where vaccine for use in all clinical trials had been manufactured) was established, and efforts commenced to manufacture Candid #1 in Argentina (Ambrosio et al., 2006). The INEVH facility was certified in 2001 by the Argentine regulatory authority (ANMAT) for production of attenuated viral vaccines.

During 2005–2006, a bridging study to establish the equivalence of Candid #1 vaccine produced in the U.S. with that produced in Argentina was conducted in 946 human subjects. During a 3-month period of active follow-up, no severe adverse events linked to the vaccination were recorded. Vaccine immunogenicity, measured by titration of neutralizing antibodies against Junin virus, was more than 95% (Enria et al., in press). In 2006, Candid #1 vaccine was licensed by the regulatory agency of Argentina (ANMAT, Disposicion No. 4812, August 29, 2006).

Vaccine Administration, Contraindications, and Precautions

Candid #1 is administered as a single intramuscular injection. Requirements for booster immunization have not been determined.

Contraindications for receipt of Candid #1 are similar to those for receipt of live-attenuated vaccines in general, and include the existence of malignancy, chronic, or uncontrolled illnesses that could affect the

immune response, as well as the concurrent use of immunosuppressive therapies. Deferral of vaccination should be considered for those with acute febrile illnesses.

Specific contraindications include:

- Congenital or acquired immune deficit.
- Pregnancy: the effects that this vaccine could produce during pregnancy are unknown, and for this reason unpredictable.
- Lactation.
- Allergies to vaccine components.

Candid #1 should not be administered concurrently with other vaccines, as there is no data on possible interactions. Candid #1 has not been evaluated in children less than 15 years of age.

Manufacturing and Licensure

Candid #1 is manufactured exclusively at the Instituto Nacional de Enfermedades Virales Humanas "Dr. J.I. Maiztegui," ANLIS, Ministerio de Salud de la Nación. Monteagudo 2510 (2700) Pergamino, Pcia. de Buenos Aires, Argentina. The vaccine is licensed for use only in Argentina.

Vaccine Indications

Candid #1 is indicated for the prevention of AHF. In Argentina, Candid #1 is included in the National Immunization Agenda (Program). The vaccine is approved for use in adults and children 15 years of age and older that are living and/or working in the endemic area for AHF; in general, recipients derive from the provinces of Santa Fe, Córdoba, Buenos Aires, and La Pampa. The total population at risk for AHF in the Argentine endemic area is estimated currently to be approximately 5,000,000 persons.

Candid #1 is an orphan vaccine (Lang and Wood, 1999). It is destined to be used in a restricted area of Argentina, where AHF is endemic. It may also be used by investigators around the world working with Junin virus. Preclinical data suggest that Candid #1 might be useful for the protection against Bolivian hemorrhagic fever (Barrera Oro et al., 1988; Jahrling et al., 1988; Lupton et al., 1988); however, no clinical trails to address this indication have been performed.

Duration of Immunity

Persistence of neutralizing antibodies against Junin virus have been demonstrated for more than 10 years following receipt of a single dose of Candid #1 vaccine (Enria and Barrera Oro, 2002). Neutralizing antibodies directed against Junin virus are considered a surrogate marker for efficacy (Enria et al., in press).

Adverse Events Associated with Vaccination

Local reactions following receipt of Candid #1 vaccine include mild pain, discomfort, itching, erythema, and induration at the inoculation site. Systemic adverse events that have been reported in temporal association (within 3 weeks) with vaccination include headache, lassitude, myalgias, fever, nausea and/or vomiting, retroocular pain, dizziness, low-back pain, and exanthema. Mild leucopenia (<4000 white blood cells/mm^3) and thrombocytopenia (<150,000 platelets/mm^3) have also been reported. All events reported have been mild and have disappeared either spontaneously or with symptomatic treatment (Enria et al., in press).

As Candid #1 is a live-attenuated Junin virus vaccine, the possibility exists that a recipient could develop signs and symptoms of AHF. If a diagnosis of AHF is made, administration of AHF immune plasma should be considered within the first week from onset of symptoms.

Vaccines in Development

There are currently no efforts underway to develop a next-generation vaccine for AHF. However, technologies and molecular engineering methodologies applied to developing and/or producing vaccines for other pathogenic arenaviruses could prove useful in future efforts to control or eliminate AHF (Auperin et al., 1988; Clegg and Lloyd, 1987; Morrison et al., 1989; Fisher-Hoch et al., 1989; Lopez et al., 2000; Rico-Hesse, 1999; Bredenbeek et al., 2006; Giacalone et al., 2007; Pushko et al., 2001).

Postexposure Immunoprophylaxis

There is no recognized role for Candid #1 vaccine in prophylaxis after exposure to Junin virus. Plasma obtained from AHF survivors that contains anti-Junin neutralizing antibody is effective in treating individuals with AHF if administered within 8 days of disease onset (Enria et al., 1984, 1986a; Maiztegui et al., 1979). Therefore, it is reasonable to consider immunoprophylaxis following high-risk exposure to Junin virus (e.g., needlestick) with immune plasma (Peters and Shelokov, 1990).

PROSPECTS FOR THE FUTURE

AHF is an endemic disease for which effective control can be anticipated. Therapy to reduce the case-fatality rate is proven and available, and Candid #1 vaccine has been demonstrated to reduce the incidence of the illness. However, as in other zoonotic diseases with a nonhuman reservoir, viral eradication is not likely. For this reason, even with good vaccine coverage, isolated cases and small outbreaks of AHF can be expected to continue.

KEY ISSUES

- AHF a rodent-borne zoonosis endemic to north-central Argentina, is a major public health problem.
- The etiologic agent of AHF, Junin virus, is a CDC Category A biothreat agent.
- Candid #1, a safe and effective live-attenuated Junin virus vaccine, is licensed in Argentina for prevention of AHF.
- Introduction of Candid #1 into Argentina's National Immunization Program has resulted in a significant reduction in AHF incidence.
- Candid #1 is currently the only vaccine proven effective against an arenavirus.

OUTLINE

ABSTRACT

Measles is a highly contagious disease characterized by a prodromal illness of fever, cough, coryza, and conjunctivitis followed by the appearance of a generalized maculopapular rash. Measles virus is a nonsegmented, single-stranded, negative-sense RNA virus and a member of the *Morbillivirus* genus in the family of Paramyxoviridae. Although RNA viruses have high mutation rates, measles virus is an antigenically monotypic virus and the surface proteins responsible for inducing protective immunity have retained their antigenic structure. The public health significance is that measles vaccines developed decades ago from a single measles virus strain remain protective worldwide. Prior to the development and widespread use of measles vaccine, 30 million cases of measles were estimated to occur each year, resulting in more than 1 million deaths. Several live, attenuated measles vaccines are available, either as single-antigen vaccines or in combination with rubella and mumps vaccines (MR and MMR vaccines). Most of the currently used measles vaccines were derived from the Edmonston strain of measles virus that was isolated by Enders and Peebles in 1954.

Measles vaccines are recommended for all susceptible children and adults for whom the vaccine is not contraindicated. Despite progress in reducing measles mortality, measles remains a major cause of vaccine-preventable death and an important cause of morbidity and mortality in children, particularly sub-Saharan Africa and in Asia. The ideal measles vaccine would be inexpensive, safe, heat-stable, immunogenic in neonates or very young infants, and administered as a single dose without needle or syringe. A number of vaccine candidates with some of these characteristics are undergoing preclinical studies, including DNA vaccines and various viral and bacterial vectored vaccines. The high infectivity of measles virus is a characteristic suitable to a biothreat agent. However, increasingly high levels of measles vaccination coverage throughout the world as part of accelerated measles control efforts would protect many from the deliberate use of measles virus as a biothreat agent. Genetic engineering of a measles virus strain that was not neutralized by antibodies induced by the current attenuated measles vaccines would likely have reduced infectivity, as suggested by the fact that wild-type measles viruses have not mutated to alter their neutralizing epitopes. Measles virus meets many of the biological criteria for disease eradication. Measles virus has no nonhuman reservoir, can be accurately diagnosed, and measles vaccination is a highly effective intervention. Where measles virus differs from smallpox and polio viruses is that it is more highly infectious, necessitating higher levels of population immunity to interrupt transmission. It remains unclear whether the threat from bioterrorism precludes stopping measles vaccination after eradication, but provision of a second opportunity for measles vaccination likely could be stopped following eradication.

INTRODUCTION

Measles is a highly contagious disease characterized by a prodromal illness of fever, cough, coryza, and conjunctivitis followed by the appearance of a generalized maculopapular rash. Deaths from measles are due largely to an increased susceptibility to secondary bacterial and viral infections, attributed to a prolonged state of immune suppression. Despite the development of an effective attenuated vaccine, measles remains a leading vaccine-preventable cause of childhood mortality worldwide, particularly sub-Saharan Africa and in Asia, and continues to cause outbreaks in communities with low vaccination coverage rates in industrialized nations.

HISTORY OF MEASLES

Measles is one of the most important infectious diseases of humans and has caused millions of deaths

FIGURE 30.1 Countries reporting measles cases (indigenous or imported) in 2005–2006

since its emergence thousands of years ago. Measles virus most closely resembles rinderpest virus, a pathogen of cattle, and likely evolved as a zoonotic infection in communities where cattle and humans lived in close proximity. Measles virus is believed to have become established in human populations about 5000–10,000 years ago when human populations achieved sufficient size in Middle Eastern river valley civilizations to maintain virus transmission.

Abu Becr, an Arab physician also known as Rhazes, is generally credited with distinguishing smallpox from measles in the 9th century. He dated the first description of measles to the 6th century. However, epidemics identified as measles were not recorded until the 11th and 12th centuries, and measles was first mentioned as a childhood disease in 1224. The name "morbilli" was derived from the Italian meaning "little diseases" to distinguish it from plague, "il morbo." Sanvages in 1763 defined morbilli as measles, but called it rubeola, leading to confusion with rubella.

Introduction of measles into previously unexposed populations has been associated with high mortality. One quarter of the population on the Fiji Islands died after the introduction of measles virus in 1875. Millions died as a result of European exploration of the New World, largely due to the introduction of diseases such as smallpox and measles into native Amerindian populations. The high mortality from these diseases facilitated European conquest of the Americas (McNeill, 1976).

Many of the basic principles of measles epidemiology and infection were elucidated by Peter Panum, a Danish physician who was sent to the Faroe Islands in 1846 during a large measles epidemic (Panum, 1938). Panum deduced the highly contagious nature of the disease, the 14-day incubation period, the lifelong immunity following infection, and postulated a respiratory route of transmission. Measles virus first was isolated from the blood of David Edmonston and others by Enders and Peebles (1954). The development of vaccines against measles soon followed.

MEASLES VIRUS

Measles virus is a spherical, nonsegmented, single-stranded, negative-sense RNA virus and a member of the *Morbillivirus* genus in the family of Paramyxoviridae. Other members of the *Morbillivirus* genus are rinderpest virus and canine distemper virus. Although RNA viruses have high mutation rates, measles virus is an antigenically monotypic virus, meaning that the surface proteins responsible for inducing protective immunity have retained their antigenic structure. The public health significance is that measles vaccines developed decades ago from a single measles virus strain remain protective worldwide. Measles virus is killed by ultraviolet light and heat. Attenuated measles vaccine viruses retain these characteristics, necessitating a cold chain for transportation and storage.

The measles virus RNA genome consists of approximately 16,000 nucleotides and is enclosed in a lipid-containing envelope derived from the host cell. The genome encodes eight proteins, two of which (V and C) are nonstructural proteins and are transcribed from the phosphoprotein (P) gene. Of the six structural proteins, P, large protein (L), and nucleoprotein (N) form the nucleocapsid housing the viral RNA. The hemagglutinin protein (H), fusion protein (F), and matrix protein (M), together with lipids from the host cell membrane, form the viral envelope.

The H protein interacts with F to mediate fusion of the viral envelope with the host cell membrane (Malvoisin and Wild, 1993). The primary function of the H protein is to bind to the host cellular receptors for measles virus. The two identified receptors are CD46 and CD150 (SLAM). CD46 is a complement regulatory molecule expressed on all nucleated cells in humans. SLAM, an acronym for signaling lymphocyte activation molecule, is expressed on activated T and B lymphocytes and antigen-presenting cells. The binding sites on H for these receptors overlap and strains of measles virus differ in the efficiency with which each is used. Wild-type measles virus binds to cells primarily through the cellular receptor SLAM whereas most vaccine strains bind to CD46; however, most measles virus strains can use both CD46 and SLAM as receptors during acute infection (Schneider et al., 2002). Additional, as yet unidentified receptors for measles virus exist on human endothelial and epithelial cells (Andres et al., 2003).

Other measles virus proteins are involved in viral replication. The P protein regulates transcription, replication, and the efficiency with which the N assembles into nucleocapsids (Spehner et al., 1997). The M protein links ribonucleoproteins with envelope proteins during virion assembly. The functions of V and C proteins have not been clearly defined, but both appear to contribute to the virulence of measles virus by regulating transcription and sensitivity to the antiviral effects of interferon (IFN) α/β (Valsamakis et al., 1998; Patterson et al., 2000).

Variability within the genome is sufficient to allow for molecular epidemiologic investigation. Genetic characterization of wild-type measles viruses is based on sequence analysis of the genes encoding the

N and H proteins. One of the most variable regions of the measles virus genome is the 450-nucleotide sequence at the carboxy-terminal of the N protein, with up to 12% variability between wild-type viruses. The World Health Organization (WHO) recognizes 8 clades of measles virus (designated A through H) and 23 genotypes (World Health Organization, 2006). New genotypes likely will be identified with enhanced surveillance and molecular characterization. As measles control efforts intensify, molecular surveillance of circulating measles virus strains can be used to document interruption of measles virus transmission and to identify the source and transmission pathways of measles virus outbreaks (Rota and Bellini, 2003). Molecular epidemiologic tools also would be important in documenting deliberate bioterrorist introductions of wild-type or genetically modified measles virus strains.

IMMUNE RESPONSES TO MEASLES VIRUS

Host immune responses to measles virus are essential for viral clearance, clinical recovery, and the establishment of long-term immunity. The early nonspecific (innate) immune responses that occur during the prodromal phase of the illness include activation of natural killer (NK) cells and production of IFN-α and β. These innate immune responses contribute to the control of measles virus replication before the onset of more specific adaptive immune responses. The protective efficacy of antibodies to measles virus is illustrated by the immunity conferred to infants from passively acquired maternal antibodies and the protection of exposed, susceptible individuals following administration of antimeasles virus immune globulin (Black and Yannet, 1960). The first measles virus-specific antibodies produced after infection are of the IgM subtype, followed by a switch to predominantly IgG3 and then to IgG1 and IgG4 isotypes (Isa et al., 2002). IgA antibodies to measles virus are found in mucosal secretions. The most abundant and rapidly produced antibodies are against N, and the absence of antibodies to N is the best indicator of seronegativity to measles virus. Antibodies to H and F proteins contribute to virus neutralization and are sufficient to provide protection against measles virus infection.

Evidence for the importance of cellular immunity to measles virus is demonstrated by the ability of children with agammaglobulinemia to fully recover from measles, whereas children with severe defects in T-lymphocyte function often develop severe or fatal disease (Good and Zak, 1956). Monkeys depleted of $CD8^+$ T-lymphocytes and challenged with wild-type measles virus had a more extensive rash, higher measles virus loads, and longer duration of viremia than control animals, further confirming the importance of cellular immunity in measles virus clearance (Permar et al., 2003). $CD4^+$ T-lymphocytes also are activated in response to measles virus infection and secrete cytokines capable of modulating the humoral and cellular immune responses. Plasma cytokine profiles show increased levels of IFN-γ during the acute phase, followed by a shift to high levels of interleukin (IL)-4 and IL-10 during convalescence (Moss et al., 2002). The initial predominant Th1 response (characterized by IFN-γ) is presumed to be essential for viral clearance, while the later Th2 response (characterized by IL-4) promotes the development of measles virus-specific antibodies.

The duration of protective immunity following wild-type measles virus infection is generally thought to be lifelong. The immunologic mechanisms involved in sustaining high levels of neutralizing antibody to measles virus are not completely understood, although general principles of immunologic memory probably govern this process. Immunologic memory to measles virus includes both continued production of measles virus-specific IgG antibodies and the circulation of measles virus-specific $CD4^+$ and $CD8^+$ T-lymphocytes (Ovsyannikova et al., 2003). Although immune protection is assessed by measurement of antimeasles virus antibodies, long lasting cellular immune responses almost certainly play an important role in protection from infection and disease.

Young infants in the first months of life are protected against measles by maternally acquired IgG antibodies. An active transport mechanism in the placenta is responsible for the transfer of IgG antibodies from the maternal circulation to the fetus starting at about 28 weeks gestation and continuing until birth (Crowe, 2001). Three factors determine the degree and duration of protection in the newborn: (1) the level of maternal antimeasles antibodies; (2) the efficiency of placental transfer; and (3) the rate of catabolism in the child. Although providing passive immunity to young infants, maternally acquired antibodies can interfere with the immune responses to the attenuated measles vaccine by inhibiting replication of vaccine virus. In general, maternally acquired antibodies are no longer present in the majority of children by 9 months of age, the time of routine measles vaccination in many countries. Women with vaccine-induced immunity tend to have lower antimeasles virus antibody titers than women with naturally acquired immunity, and their children may be susceptible to measles at an earlier age.

EPIDEMIOLOGY

Prior to the development and widespread use of measles vaccine, 30 million cases of measles were estimated to occur each year, resulting in more than 1 million deaths. Despite progress in reducing measles mortality, measles remains the most frequent cause of vaccine-preventable death and an important cause of morbidity and mortality in children, particularly in sub-Saharan Africa and in Asia (Henao-Restrepo et al., 2003).

The disease burden due to measles decreased over the past several decades due to a number of factors. Measles mortality declined in developed countries in association with economic development, improved nutritional status and supportive care, particularly antibiotic therapy for secondary bacterial pneumonia. Remarkable progress in reducing measles incidence and mortality has been, and continues to be, made in resource-poor countries as a consequence of increasing measles vaccine coverage, provision of a second opportunity for measles vaccination through supplementary immunization activities, and efforts by the WHO, the United Nations Children's Fund (UNICEF) and their partners to target 45 countries for accelerated and sustained measles mortality reduction. Specifically, this targeted strategy aims to achieve >90% measles vaccination coverage in every district of the 45 countries and to ensure that all children receive a second opportunity for measles immunization (World Health Organization, 2001). Provision of vitamin A through polio and measles vaccination campaigns has contributed further to the reduction in measles mortality (World Health Organization, 2005).

In 2003, the World Health Assembly endorsed a resolution urging member countries to reduce the number of deaths attributed to measles by 50% by the end of 2005 compared with 1999 estimates. Overall global measles mortality in 2005 was estimated to be 345,000 deaths (uncertainty bounds 247,000 and 458,000 deaths) (Wolfson et al., 2007). This estimate represents a 60% decrease from 1999, when the global number of measles deaths was estimated to be 873,000 (uncertainty bounds 634,000 and 1,140,000 deaths). The largest decrease in measles mortality was in Africa, contributing 72% of the global reduction in measles mortality.

Measles incidence has a typical temporal pattern characterized by annual, seasonal epidemics superimposed upon longer epidemic cycles of 2–5 years or more. In temperate climates, annual measles outbreaks typically occur in the late winter and early spring. These annual outbreaks are likely the result of social networks facilitating transmission (e.g., congregation of children at school) and environmental factors favoring the viability and transmission of measles virus (Fine and Clarkson, 1982). Measles cases continue to occur during the interepidemic period in densely populated communities but at low incidence. The longer cycles occurring every several years result from the accumulation of susceptible persons over successive birth cohorts and the subsequent decline in the number of susceptibles following an outbreak. In the absence of a vaccination program these longer epidemic cycles tend to occur every 2–4 years. Measles vaccination programs that achieve coverage rates in excess of 80% extend the interepidemic period to 4–8 years by reducing the number of susceptible individuals.

Humans are the only reservoir for measles virus, a characteristic important for the potential eradication of measles. Nonhuman primates may be infected with measles virus and develop an illness similar to measles in humans, with rash, coryza, and conjunctivitis. However, populations of wild monkeys are not of sufficient size to maintain measles virus transmission.

Measles virus is transmitted primarily by respiratory droplets small enough to traverse several feet but too large to remain suspended in the air for long periods of time. The symptoms induced during the prodrome, particularly sneezing and coughing, enhance transmission. Measles virus also may be transmitted by the airborne route, suspended on small particles for a prolonged time. Direct contact with infected secretions can transmit measles virus, but the virus does not survive long on fomites as it is quickly killed by heat and ultraviolet radiation. The average incubation period for measles, the time from infection to clinical disease, is approximately 10 days to the onset of fever and 14 days to the onset of rash (range 7–18 days). The incubation period may be shorter in infants and following a large inoculum of virus, and longer in adults. During this seemingly quiescent period, the virus is rapidly replicating and infecting target tissues.

Measles virus is one of the most highly contagious infectious agents and outbreaks can occur in populations in which less than 10% of persons are susceptible. Chains of transmission commonly occur among household contacts, school children, and health care workers. Generally, persons with measles are infectious for several days before and after the onset of rash, when titers of measles virus in the blood and body fluids are highest. As with many other acute viral infections (SARS-coronavirus being an exception), the fact that measles virus is contagious prior to the onset of recognizable disease hinders the effectiveness of quarantine measures. Measles virus can be isolated in tissue culture from the urine as late as 1 week after rash onset. Detection of measles virus in body

fluids by a variety of means, including identification of multinucleated giant cells in nasal secretions or the use of reverse transcriptase-polymerase chain reaction (RT-PCR), suggests the potential for a prolonged infectious period in persons immunocompromised by severe malnutrition or human immunodeficiency virus type 1 (HIV-1) infection (Dossetor et al., 1977; Permar et al., 2001; Riddell et al., 2007). However, whether detection of measles virus by these methods indicates prolonged contagiousness is unclear.

In densely populated urban settings with low vaccination coverage rates, measles is a disease of young children. The cumulative distribution can reach 50% by 1 year of age, with a significant proportion of children acquiring measles virus infection before 9 months, the age of routine vaccination. As measles vaccine coverage increases, or population density decreases, the age distribution shifts toward older children. In such situations, measles cases predominate in school-age children. Infants and younger children, although susceptible if not protected by immunization, are not exposed to measles virus at a rate sufficient to cause a large disease burden in this age group. As vaccination coverage increases further, the age distribution of cases may be shifted into adolescence and young adulthood, as seen in measles outbreaks in the United States, Brazil, and Australia (Hutchins et al., 1996; de Quadros et al., 1998; Lambert et al., 2000), necessitating targeted measles vaccination programs for these older age groups.

The high infectivity of measles virus is a characteristic suitable to a biothreat agent. However, increasingly high levels of measles vaccination coverage throughout the world as part of accelerated measles control efforts would protect many from the deliberate use of measles virus as a biothreat agent. Genetic engineering of a measles virus strain that was not neutralized by antibodies induced by the current attenuated measles vaccines would likely have reduced infectivity, as suggested by the fact that wild-type measles viruses have not mutated to alter their neutralizing epitopes.

CLINICAL DISEASE

Clinically apparent measles begins with a prodrome characterized by fever, cough, coryza, and conjunctivitis. Koplik's spots, small white lesions on the buccal mucosa inside the mouth, may be visible during the prodrome and allow the astute clinician to diagnose measles prior to the onset of rash. The prodromal symptoms intensify several days before the onset of rash. The characteristic erythematous and maculopapular rash appears first on the face and behind the ears, and then spreads in a centrifugal fashion to the trunk and extremities. The rash lasts for 3–4 days and fades in the same manner as it appeared.

In uncomplicated measles, clinical recovery begins soon after appearance of the rash. Complications occur in up to 40% of measles cases, and the risk of complication is increased by extremes of age, malnutrition, and vitamin A deficiency (Morley, 1969). Complications of measles have been described in almost every organ system. The respiratory tract is a frequent site of complication, with pneumonia accounting for most measles-associated deaths (Duke and Mgone, 2003). Pneumonia is caused by secondary viral or bacterial infections, or by measles virus itself. Pathologically, measles virus infection of the lung is characterized by multinucleated giant cells, formed when measles virus proteins on the cell surface allow cells to fuse. Other respiratory complications include laryngotracheobronchitis and otitis media. Mouth ulcers, or stomatitis, may hinder children from eating or drinking. Many children with measles develop diarrhea, which further contributes to malnutrition. Keratoconjunctivitis is common after measles, particularly in children with vitamin A deficiency, and was a frequent cause of blindness.

Because the rash of measles is a consequence of the cellular immune response, persons with impaired cellular immunity, such as those with the acquired immunodeficiency syndrome (AIDS), may not develop the characteristic measles rash. These persons have a high case fatality and may develop a giant cell pneumonitis due to measles virus (Moss et al., 1999). T-lymphocyte defects due to causes other than HIV-1 infection, such as cancer chemotherapy, are also associated with increased severity of measles.

Rare but serious complications of measles involve the central nervous system. Postmeasles encephalomyelitis complicates approximately 1 in 1000 cases, mainly older children and adults. Encephalomyelitis occurs within 2 weeks of the onset of rash and is characterized by fever, seizures, and a variety of neurological abnormalities. The finding of periventricular demyelination, the induction of immune responses to myelin basic protein, and the absence of measles virus in the brain suggest that postmeasles encephalomyelitis is an autoimmune disorder triggered by measles virus infection. Other central nervous system complications that occur months to years after acute infection are measles inclusion body encephalitis (MIBE) and subacute sclerosing panencephalitis (SSPE). In contrast to postmeasles encephalomyelitis, MIBE and SSPE are caused by persistent measles virus infection. MIBE is a rare but fatal complication that affects

individuals with defective cellular immunity and typically occurs months after infection. SSPE is a slowly progressive disease characterized by seizures, progressive deterioration of cognitive and motor functions followed by death that occurs 5–15 years after measles virus infection, most often in persons infected with measles virus before 2 years of age.

There are conflicting and inconclusive data suggesting that measles virus infection causes or contributes to the development of chronic diseases, including multiple sclerosis, Paget's disease, inflammatory bowel disease, and otosclerosis (Perry and Halsey, 2004). However, no causal association has been established between measles and these conditions.

The characteristic clinical features of measles are of sufficient sensitivity and specificity to have high predictive value in regions where measles is endemic. However, laboratory diagnosis is necessary where measles virus transmission rates are low or in immunocompromised persons who may not have the characteristic clinical manifestations. Infection with rubella, parvovirus B19, human herpes virus 6, and dengue viruses may mimic measles. Detection of IgM antibodies to measles virus by enzyme immunoassay (EIA) is the standard method of diagnosing acute measles (Bellini and Helfand, 2003). Alternatively, seroconversion using IgG-specific EIA, hemagglutinin inhibition, complement fixation, or virus neutralization assays can be used to diagnose acute measles based on testing serum or plasma obtained during the acute and convalescent phases.

Measles virus can be isolated in tissue culture from white blood cells, respiratory tract secretions, and urine, although the ability to isolate measles virus diminishes quickly after rash onset. Amplification and detection of measles virus RNA by RT-PCR from blood, urine, and nasal discharge is highly sensitive in detecting measles virus RNA and allows sequencing of the measles virus genome for molecular epidemiologic studies.

TREATMENT

No specific antiviral drug is used routinely to treat measles virus infection, although the broad antiviral agent ribavirin has been used to treat immunocompromised persons or persons with SSPE, alone or in combination with IFN-α or intravenous immunoglobulin (Forni et al., 1994; Solomon et al., 2002). The major components of case management include provision of vitamin A, prompt treatment of secondary bacterial infections, and nutritional support. Several placebo-controlled trials have demonstrated marked reductions in morbidity and mortality in hospitalized children with measles treated with vitamin A. The WHO recommends administration of two daily doses of 200,000 IU of vitamin A to all children with measles 12 months of age or older. Lower doses (100,000 IU) are recommended for children less than 12 months of age. Overall, this regimen resulted in a 64% reduction in the risk of mortality (RR = 0.36, 95% CI 0.14–0.82) (D'Souza and D'Souza, 2002). Pneumonia-specific mortality is reduced, and the impact is greatest in children less than 2 years of age (D'Souza and D'Souza, 2002).

Secondary bacterial infections are a major cause of morbidity and mortality following measles (Duke and Mgone, 2003), and effective case management involves prompt treatment with antibiotics. Various strategies have been used to guide antibiotic therapy in children with measles. Antibiotics are indicated for children with measles who have clinical evidence of bacterial infection, including pneumonia, otitis media, skin infection, eye infection, and severe mouth ulcers. *Streptococcus pneumoniae* and *Haemophilus influenza* type b are the most common causes of bacterial pneumonia following measles, and antibiotic therapy should be directed against these pathogens. Whether all children with measles, or all hospitalized children with measles, should be given prophylactic antibiotics remains controversial. Limited evidence suggests that antibiotics administered as prophylaxis to all children presenting with measles may reduce the incidence of pneumonia but not mortality (Duke and Mgone, 2003). The potential benefits of antibiotic prophylaxis need to be weighed against the risks of accelerating antibiotic resistance.

Vitamin A has been widely distributed through polio and measles supplemental immunization activities as well as through routine child health services. Pooled analysis of community-based studies of vitamin A supplementation of apparently healthy children resulted in a 39% reduction in measles-associated mortality (Villamor and Fawzi, 2000). Thus, vitamin A is not only effective in reducing mortality when used to treat hospitalized children with measles but community-based supplementation programs also can result in measles mortality reduction.

PATHOGENESIS

Respiratory droplets from infected persons serve as vehicles of transmission by carrying infectious virus to epithelial cells of the respiratory tract of susceptible hosts. During the 10–14 day incubation period between infection and the onset of clinical signs and symptoms, measles virus replicates and

spreads within the infected host. Initial viral replication occurs in epithelial cells at the portal of entry in the upper respiratory tract and the virus then spreads to local lymphatic tissue. Replication in local lymph nodes is followed by viremia (the presence of virus in the blood) and the dissemination of measles virus to many organs, including lymph nodes, skin, kidney, gastrointestinal tract and liver, where the virus replicates in epithelial and endothelial cells as well as monocytes and macrophages.

Although measles virus infection is clinically inapparent during the incubation period, the virus is actively replicating and the host immune responses are developing. Evidence of these processes can be detected. During the incubation period, the number of circulating lymphocytes is reduced (lymphopenia) (Auwaerter et al., 1999). Measles virus can be isolated from the nasopharynx and blood during the later part of the incubation period and during the several days prior to the onset of rash when levels of viremia are highest. The prodrome ends with the appearance of the measles rash. The rash results from measles virus-specific cellular immune responses and marks the beginning of viral clearance from blood and tissue. Histologic examination of the rash reveals infected capillary endothelial cells and a mononuclear cell infiltrate (Kimura et al., 1975). Clearance of infectious virus from the blood and other tissues occurs within the first week after the appearance of the rash, although measles virus RNA can be detected in body fluids of some children for at least several months using a RT-PCR-based assay (Permar et al., 2001; Riddell et al., 2007).

The intense immune responses induced by measles virus infection are paradoxically associated with depressed responses to unrelated (nonmeasles virus) antigens, lasting for several weeks to months beyond resolution of the acute illness. This state of immune suppression enhances susceptibility to secondary bacterial and viral infections causing pneumonia and diarrhea, and is responsible for much measles-related morbidity and mortality (Beckford et al., 1985; Greenberg et al., 1991). Delayed-type hypersensitivity (DTH) responses to recall antigens, such as tuberculin, are suppressed (Tamashiro et al., 1987) and cellular and humoral responses to new antigens are impaired following measles virus infection (Coovadia et al., 1978). Reactivation of tuberculosis and remission of autoimmune diseases have been described after measles and are attributed to this state of immune suppression.

Abnormalities of both the innate and adaptive immune responses have been described following measles virus infection. Transient lymphopenia with a reduction in $CD4^+$ and $CD8^+$ T-lymphocytes occurs in children following measles virus infection. Functional abnormalities of immune cells have also been detected, including decreased lymphocyte proliferative responses (Hirsch et al., 1984). Dendritic cells, major antigen-presenting cells, mature poorly, lose the ability to stimulate proliferative responses in lymphocytes, and undergo cell death when infected with measles virus in vitro (Servet-Delprat et al., 2000). The dominant Th2 response in children recovering from measles can inhibit Th1 responses and increase susceptibility to intracellular pathogens (Griffin et al., 1985; Griffin and Ward, 1993). The production of IL-12, important for the generation of Th1-type immune response, decreases following binding of the CD46 receptor (Karp et al., 1996) and is low for several weeks in children with measles (Atabani et al., 2001). This diminished ability to produce IL-12 could further result in a limited Th1 immune response to other pathogens. Furthermore, engagement of CD46 and CD3 on monocytes induces production of high levels of IL-10 and transforming growth factor (TGF)-β, an immunomodulatory and immunosuppressive cytokine profile characteristic of regulatory T cells (Kemper et al., 2003). The role of these cytokines in the immune suppression following measles is supported by in vivo evidence of elevated levels of IL-10 in the plasma of children after measles virus infection (Moss et al., 2002).

MEASLES VACCINES

History of Measles Vaccines

Attenuation of measles virus was achieved primarily by serial passage in chick embryo cells. The first attenuated measles vaccine licensed in the United States was Edmonston B. This vaccine was immunogenic and widely used between 1963 and 1975, but was frequently associated with fever and rash. The Schwarz and Moraten (more attenuated) strains were derived from the original Edmonston strain but further attenuated through additional passage in chick embryo fibroblasts. Despite differences in their passage history, these vaccine strains have identical genomic sequences (Parks et al., 2001). The Moraten vaccine (Merck) is the only measles vaccine used in the United States, whereas the Schwarz vaccine is used in many countries throughout the world. Other attenuated measles vaccines have been produced from locally derived wild-type strains, particularly in Russia, China, and Japan. One vaccine strain, the Edmonston-Zagreb vaccine, was also passaged in human diploid cells after attenuation in chick embryo fibroblasts, which may account for its increased immunogenicity and reactogenicity. Measles vaccines

are relatively heat stable in the lyophilized (dry) form, but rapidly lose potency when exposed to heat after reconstitution.

In the 1960s, a formalin-inactivated, alum-precipitated measles vaccine (FIMV) was licensed and administered to children in the United States. Three doses of inactivated vaccine elicited a protective antibody response but antibody titers waned within months (Carter et al., 1962). Up to 60% of immunized children exposed to measles developed atypical measles, characterized by high fever, pneumonitis, and a petechial rash on the extremities (Fulginiti et al., 1967; Nader et al., 1968), leading to withdrawal of the FIMV in 1967. In a rhesus macaque model, atypical measles was shown to be associated with immune complex deposition in affected tissues and a systemic and pulmonary eosinophilia (Polack et al., 1999). The antibody response consisted of high levels of complement fixing antibodies with low avidity for measles virus, characteristics that may have promoted exaggerated immune complex formation and disease.

Seroconversion rates with attenuated measles vaccines in young infants are low because of immunologic immaturity and the interference of transplacentally acquired maternal antibodies with replication of vaccine virus (Gans et al., 1998). To protect young infants against measles, high-titer preparations containing 10–100 times the standard dose of vaccine virus were evaluated in several countries. Seroconversion rates in 4–6 month old infants immunized with high-titer measles vaccine were comparable to those of 9–15 month old children vaccinated with standard-titer measles vaccine, and the protective antibody response persisted for over 2 years. However, high-titer measles vaccine resulted in a poorly understood increase in mortality in immunized girls 1–2 years after vaccination compared to girls immunized with standard-titer vaccine at 9 months of age (Holt et al., 1993; Aaby et al., 1996). The increased mortality was attributable to infections commonly associated with measles, such as diarrhea and pneumonia. Although these studies were carried out in countries with different levels of socioeconomic development, excess mortality was observed only in countries with poor socioeconomic conditions and frequent malnutrition (Senegal, Haiti, and Guinea Bissau). The basis for the increased mortality in girls is not understood.

Current Licensed Measles Vaccines

Several live, attenuated measles vaccines are available worldwide, either as single-antigen vaccines or in combination with rubella and mumps vaccines (MR and MMR vaccines). Recently, a combined measles-mumps-rubella-varicella vaccine was licensed by the United States Food and Drug Administration (ProQuad, Merck and Co., Inc.). Licensed combination vaccines do not reduce the immunogenicity of the measles component. Most of the currently used measles vaccines were derived from the Edmonston strain of measles virus that was isolated by Enders and Peebles in 1954. These vaccines have undergone different passage histories in cell culture, but nucleotide sequence analysis shows less than 0.6% genetic differences between the vaccine strains. Vaccines in widespread use that were derived from the Edmonston measles virus stain include the Schwarz, Edmonston-Zagreb, and Moraten strains. Vaccines derived from other measles virus strains include CAM-70, Leningrad-16, and Shanghai 191.

The live, attenuated measles vaccines are typically cultured in primary chick embryo or human diploid (e.g., Edmonston-Zagreb) cells for several days. The supernatant fluid is harvested and frozen. Vaccine stocks are quality and safety tested before they are lyophilized. Measles vaccines may contain sorbitol or gelatin as stabilizers and the antibiotic neomycin, but do not contain thimerosal. Traces of the reverse transcriptase of an avian retrovirus can be found in vaccines cultured in chick embryo fibroblasts but there is no evidence that this is harmful to vaccine recipients. Prior to use, the vaccine must be reconstituted in sterile diluent. Measles vaccines lose about half of their potency after reconstitution if stored at 20°C for 1 h, and lose almost all potency if stored at 37°C for 1 h.

Measles vaccines are recommended for all susceptible children and adults for whom the vaccine is not contraindicated (Table 30.1). Adolescents and young adults may constitute a susceptible population,

TABLE 30.1 Recommendations for measles vaccination

Recommendations of the Advisory Committee on Immunization Practices for the United States
- A two-dose schedule with MMR vaccine is recommended.
- The first dose is recommended at 12–15 months of age.
- The second dose is recommended at 4–6 years of age.
- Adults at increased risk should receive special consideration for measles vaccination, including international travelers, students attending colleges and other post-high school educational institutions, and persons who work at health care facilities.
- Measles vaccine is not indicated for persons with severe hypersensitivity (anaphylaxis) to neomycin or gelatin, or who are severely immunocompromised.

Recommendations of the World Health Organization
- Measles vaccine should be administered at 9 months of age.
- A second opportunity for measles vaccination should be provided through mass measles vaccination campaigns.
- HIV-infected children should receive measles vaccine at 6 and 9 months of age, unless severely immunocompromised, because of their increased risk of severe measles.

including university students, health care workers, and military recruits. A single dose of measles vaccine provides lifelong immunity in the majority of vaccine recipients. However, a second opportunity for measles vaccination provides protection to those with primary vaccine failure and a chance to reach unvaccinated children. The second opportunity may be delivered through routine health services at school entry or through supplementary immunization activities such as national immunization days.

Measles vaccines are usually injected subcutaneously but can be administered intramuscularly. Each 0.5 mL dose of vaccine contains at least 1000 infective units of measles vaccine virus. The optimal age of measles vaccination is determined by consideration of the age-dependent increase in seroconversion rates following measles vaccination and the average age of infection. In regions of intense measles virus transmission, the average age of infection is low and the optimal strategy is to vaccinate against measles as young as possible. However, both maternally acquired antibodies and immunologic immaturity reduce the protective efficacy of measles vaccination in early infancy (Gans et al., 1998). In many parts of the world, 9 months is considered the optimal age of measles vaccination (Halsey, 1983), and is the age recommended by the Expanded Program on Immunization (EPI). Most countries following the EPI schedule administer measles vaccine alone, although more countries are introducing combined measles and rubella vaccines as rubella control programs expand. Under some circumstances, provision of an early dose of measles vaccine at 6 months of age (e.g., in outbreaks or to HIV-infected children) is appropriate. In regions that have achieved measles control or elimination, where the risk of measles in infants is low, the age of measles vaccination is increased to ensure that a higher proportion of children develop protective immunity. For example, in the United States the first dose of measles vaccine is administered at 12–15 months of age, as the combined MMR vaccine.

Measles vaccine induces both humoral and cellular immune responses. Antibodies first appear between 12 and 15 days after vaccination and peak at 21–28 days. IgM antibodies appear transiently in blood, IgA antibodies are predominant in mucosal secretions, and IgG antibodies persist in blood for years. Vaccination also induces measles virus-specific T-lymphocytes (Ovsyannikova et al., 2003; Wong-Chew et al., 2004). Although both humoral and cellular responses can be induced by measles vaccine, they are of lower magnitude and shorter duration compared to those following wild-type measles virus infection (Ward et al., 1995).

The proportion of children who develop protective antibody titers following measles vaccination depends on the presence of inhibitory maternal antibodies and the immunologic maturity of the vaccine recipient, as well as the dose and strain of vaccine virus. Frequently cited figures are that approximately 85% of children develop protective antibody titers when given measles vaccine at 9 months of age and 90–95% respond when vaccinated at 12 months of age (Cutts et al., 1995). Concurrent acute infections may interfere with the immune response to measles vaccine, although this is probably uncommon (Scott et al., 1999). Polymorphisms in human immune response genes also influence immune responses to measles vaccine (Ovsyannikova et al., 2004).

The duration of immunity following measles vaccination is more variable and shorter than following wild-type measles virus infection, with an estimated 5% of children developing secondary vaccine failure at 10–15 years after vaccination (Anders et al., 1996). Immunologic boosting from repeated exposure to measles virus may play a role in maintaining protective antibody levels in communities with measles virus transmission (Whittle et al., 1999).

The WHO encourages measles vaccination of all susceptible children and adults. Because measles can be more severe in HIV-infected persons and the risk of serious adverse events appears to be small, the WHO recommends that asymptomatic HIV-infected persons, and even those who are symptomatic but not severely immunocompromised, receive measles vaccine. The American Academy of Pediatrics recommends that severely immunocompromised children and adults, defined by low $CD4^+$ T-lymphocyte cell counts or percentage, should not receive measles vaccine because of the potential risk of vaccine-related pneumonitis. Measles vaccine is contraindicated in persons with a history of anaphylactic reaction to neomycin, gelatin, or other vaccine components.

Fever occurs in approximately 5–15% of recipients 6–12 days following measles vaccination, and a rash occurs in approximately 5% of recipients. These signs and symptoms are a consequence of the host immune response to replicating measles vaccine virus, but do not result in serious morbidity or mortality. Rarely, thrombocytopenia may occur.

Although assumed to be rare, the risk of disease caused by attenuated measles vaccine virus in HIV-infected persons is unknown. The only documented case of disease induced by vaccine virus in an HIV-infected person was in a 20-year-old man who died 15 months after receiving his second dose of measles vaccine (Angel et al., 1998). He had a very low $CD4^+$ T-lymphocyte cell count but no HIV-related symptoms at the time of

vaccination. Ten months later he developed giant cell pneumonitis and measles vaccine virus was identified in his lung. Fatal, disseminated infection with measles vaccine virus has been reported rarely in persons with other impairments of immune function (Monafo et al., 1994), and MIBE due to vaccine virus was reported in a child with an uncharacterized immune deficiency (Bitnun et al., 1999).

Much public attention has focused on a purported association between MMR vaccine and autism following publication of a report in 1998 hypothesizing that MMR vaccine may cause a syndrome of autism and intestinal inflammation (Wakefield et al., 1998). The events that followed, and the public concern over the safety of MMR vaccine, led to diminished vaccine coverage in the United Kingdom and provide important lessons in the misinterpretation of epidemiologic evidence and the communication of scientific results to the public (Offit and Coffin, 2003). The publication that incited the concern was a case series describing 12 children with a regressive developmental disorder and chronic enterocolitis. Nine of the children had autism. Onset of the developmental delay was associated by the parents with MMR vaccination in eight children. This simple temporal association was misinterpreted and misrepresented as a possible causal relationship, first by the lead author of the study and then by the media and public. Subsequently, several comprehensive reviews and additional epidemiological studies rejected evidence of a causal relationship between MMR vaccination and autism (DeStefano and Thompson, 2004). One of the most conclusive studies was a large retrospective cohort study of over half a million Danish children that found the relative risk of MMR vaccine for autistic disorder to be 0.92 (95% confidence interval, 0.68–1.24) (Madsen et al., 2002).

Measles Vaccines in Development

Aerosol administration of measles vaccine was first evaluated in the early 1960s in several countries, including the former Soviet Union and the United States. More recent studies in South Africa (Dilraj et al., 2000) and Mexico (Bennett et al., 2002) have shown that aerosol administration of measles vaccine is highly effective in boosting antibody titers, although the primary immune response to aerosol measles vaccine is lower than following subcutaneous administration (Wong-Chew et al., 2004). Administration of measles vaccine by aerosol has the potential to greatly facilitate measles vaccination during mass campaigns, and the WHO plans to test and bring to licensure an aerosol measles vaccine by 2009.

The ideal measles vaccine would be inexpensive, safe, heat-stable, immunogenic in neonates or very young infants, and administered as a single dose without needle or syringe. The age at vaccination should coincide with the EPI schedule to maximize compliance and share resources. Finally, a new vaccine should not elicit atypical measles upon exposure of immunized individuals to wild-type measles virus and should not be associated with prolonged immunosuppression, adversely affecting immune responses to subsequent infections.

A number of vaccine candidates with some of these characteristics are undergoing preclinical studies (Table 30.2). Naked cDNA vaccines are thermostable, inexpensive, and could theoretically elicit antibody responses in the presence of passively acquired maternal antibody. DNA vaccines encoding either or both the measles H and F proteins are safe, immunogenic, and protective against measles challenge in naïve, juvenile rhesus macaques (Polack et al., 2000). A different

construct, containing H, F, and N genes and an IL-2 molecular adjuvant, provided protection to infant macaques in the presence of neutralizing antibody (Premenko-Lanier et al., 2003, 2004). Alternative techniques for administering measles DNA, such as alphavirus (Pan et al., 2005), parainfluenza virus (Skiadopoulos et al., 2001), or enteric bacterial (Pasetti et al., 2003) vectors, also are under investigation. Immune responses to intranasal administration of measles virus vaccines is enhanced by the use of adjuvants (Chabot et al., 2005). Novel oral immunization strategies have been developed using plant-based expression of the measles virus H protein in tobacco (Webster et al., 2005). These vaccines induced humoral immune responses following both primary immunization and as a booster dose after a DNA prime. In addition, attenuated recombinant measles virus vaccines have been used as vectors for the delivery of genes from other pathogens (Tangy and Naim, 2005).

POSTEXPOSURE IMMUNOPROPHYLAXIS

Immune globulin can be given intramuscularly to susceptible persons within 6 days of exposure to prevent or lessen the severity of disease. Postexposure immunoprophylaxis is indicated for those at high risk of severe disease, including susceptible household contacts between 6 months and 1 year of age, pregnant women, and immunocompromised persons. Where resources are not limited, HIV-infected children, or those exposed to HIV but whose infection status is unknown, should receive postexposure immunoprophylaxis. Persons who are not immunocompromised and who have received at least one dose of measles vaccine at 12 months of age or older should not receive postexposure immunoprophylaxis. If given with 72 h of exposure, measles vaccine may provide protection against disease.

PROSPECTS FOR THE FUTURE

The possibility of measles eradication has been discussed for almost 40 years (Sencer et al., 1967). Serious consideration of measles eradication began in the late 1960s as smallpox eradication was nearing completion and the effective, long-term immunity induced by measles vaccine became apparent. Measles virus meets many of the biologic criteria for disease eradication (Moss and Griffin, 2006). Measles virus has no nonhuman reservoir; infection can be accurately diagnosed, and measles vaccination is a highly effective intervention. Although measles virus displays sufficient genetic variability to conduct molecular epidemiologic analyses, the antigenic epitopes against which protective antibodies develop have remained stable. Measles virus differs from smallpox and polio viruses, however, in that it is more highly infectious, necessitating much higher levels of population immunity to interrupt transmission.

Potential barriers to measles eradication include: (1) lack of political will; (2) difficulties of measles control in densely populated urban environments; (3) the HIV epidemic; (4) waning immunity and the potential transmission from subclinical cases; (5) transmission among susceptible adults; (6) the risk of unsafe injections; and (7) unfounded fears of disease due to measles vaccine (Orenstein et al., 2000). Whether the threat from bioterrorism precludes stopping measles vaccination after eradication is a topic of debate, but, at the least, a single-dose rather than a two-dose measles vaccination strategy could be adopted (Meissner et al., 2004). The elimination of endemic measles virus transmission in large geographic areas, such as the Americas, suggests that global eradication is feasible with current vaccination strategies (de Quadros, 2004). Many believe this to be a realistic and morally imperative goal, but, as polio eradication efforts have shown, the endgame may be full of challenges.

KEY ISSUES

- Measles is highly contagious viral infection.
- Great progress has been made in measles control and elimination through accelerated efforts, including increased routine vaccination coverage rates and supplementary immunization activities.
- Despite the reduction in measles cases and deaths, measles remains a leading cause of vaccine-preventable death worldwide.
- The high infectivity of measles virus is a characteristic suitable to a biothreat agent.
- Increasingly high levels of measles vaccination coverage throughout the world would protect many from the deliberate use of measles virus as a biothreat agent.
- Measles vaccine virus can be used as a vector to deliver genes derived from other pathogens.
- Genetic engineering of a measles virus strain that was not neutralized by antibodies induced by the current attenuated measles vaccines would likely have reduced infectivity, although this is not certain.

CHAPTER

31

Hendra and Nipah

Vincent Deubel[1] *and Fabian T. Wild*[2]
[1]Institut Pasteur of Shanghai, Chinese Academy of Sciences, Shanghai, China
[2]Inserm, U758, IFR128 BioSciences Lyon-Gerland, Lyon, France

OUTLINE

ABSTRACT

Among viruses that can be called "emerging viruses," Hendra and Nipah viruses, together with SARS coronavirus and avian influenza viruses, are on the top of those listed for the last 15 years. These two viruses were new genetically close-related viruses, clustering in a new genus *Henipavirus*, in the family *Paramyxoviridae*. They emerged in different animals and crossed the species barrier to infect humans, in Australia in 1994 and in Malaysia in 1998, causing different clinical outcomes with Nipah outbreaks reported later on in India and Bangladesh.

Then, both spread geographically showing pathological and epidemiological features similar to other endemic zoonotic viruses, each outbreak challenging public health services to control the disease. Very rapidly, scientists identified the reservoir hosts of the viruses by serology and by isolating viruses in *Pteropus* fruit bats. Due to the high mortality rate caused by henipaviruses in domestic animals and in humans, and their possible transmission by aerosol, they were immediately categorized to be handled in Biosafety Level-4 containment. Thus, only a few teams have been able to undertake research on the viruses, and many aspects of the virus life cycle, host responses to infection, pathogenesis, and prophylaxis still need to be solved. From the review presented in this chapter, it is obvious that these viruses represent potential agents for bioterrorism against which protection should be rapidly implemented.

INTRODUCTION

Based on unique genetic characteristics, two newly identified highly pathogenic agents, Hendra virus (HeV) and Nipah virus (NiV) have been classified in the genus *Henipavirus* in the family *Paramyxoviridae* (Wang et al., 2000; Mayo, 2002). These zoonotic viruses have caused fatal diseases in animals, HeV in horses, and NiV in pigs, and have crossed the species barrier to infect humans with mortality rates up to 75% (Eaton et al., 2007). They emerged from *Pteropus* fruit bats. They must be handled in Biosafety Level 4 containment. Due to the high pathogenicity of the viruses and cultural reasons, only few necropsy samples are available for pathogenesis studies. However, several animal models have been examined for further studies on vaccine and therapy development.

HISTORY OF THE DISEASE

HeV virus first occurred in 1994 in Brisbane, Australia, as the causative agent of a highly fatal disease of race horses. During the outbreak, 14 of 21 infected horses died of an acute respiratory disease, and one of two infected humans, the trainer, also died (Murray et al., 1995; Selvey et al., 1995). A second incident in which two horses and a farmer died came to light a year later, although infection actually occurred prior to the Brisbane outbreak. The farmer developed a mild meningitis illness after he participated to the necropsies of the two horses, but then recovered. Thirteen months later, he became ill and died from a severe encephalitis, which was found to be caused by HeV (O'Sullivan et al., 1997). In total, only four human cases of HeV infection have been recorded and two of them died (Murray et al., 1995; O'Sullivan et al., 1997). Retrospective analysis of equine specimens confirmed that they too had been infected with HeV indicating that the horses were the probable source of infection. Thus, the virus reactivated after a period of latency. Two more horses died of HeV infection in 1999 and 2004.

NiV, closely related to HeV, emerged in 1998 in Peninsular Malaysia, as a highly pathogenic infection of pigs and humans (Chua et al., 1999) (Fig. 31.1). It resulted in 265 human cases of whom 105 died, and a further 11 cases and 1 death among abattoir workers in Singapore (Paton et al., 1999) (Table 31.1). About 90% of human cases were among pig farmers or others associated with the transport or culling of pigs (Goh et al., 2000; Chua et al., 1999). Only 8% of patients reported no contact with pigs suggesting other sources of infection, such as infected dogs and cats (Parashar et al., 2000).

The disease in humans was predominantly encephalitic (Lee et al., 1999) whereas that in pigs was an acute respiratory disease with or without neurological signs (Mohd Nor et al., 2000). No human-to-human transmission was observed, but the disease in pigs was highly contagious. The majority of patients who survived acute NiV infection made a full recovery, but about 20% had residual neurological sequelae. The outbreak was controlled by the culling of over 1.1 million pigs and by implementing strict quarantine measures.

More recently, outbreaks of NiV infection have been reported from Bangladesh and India (Fig. 31.1). Five outbreaks have occurred in Bangladesh between 2001 and 2005 with a case fatality rate over 75% (Hsu et al., 2001; Eaton et al, 2007; Field et al., 2007; Harcourt et al., 2005; WHO, 2004, ICDDR, 2004b) (Table 31.1). The epidemics in Faridpur district showed specific features not observed during previous NiV epidemics with patients who developed acute respiratory distress syndrome. Human-to-human transmission was also reported during this epidemic (WHO, 2004). The incubation period of contaminated people through close contact with sick patients was from 6 to 11 days and 6 members of one family and community died after direct contact or subsequent contact with one index case (ICDDR, 2004b). Epidemiological investigations of the epidemic in Goalanda failed to establish any link with pigs, but rather suggested that contamination could have occurred by eating fruits spoiled by urine or saliva of fruit bats during the night or by drinking palm juice (Luby et al., 2006). One outbreak has been reported in Siliguri from West Bengal in

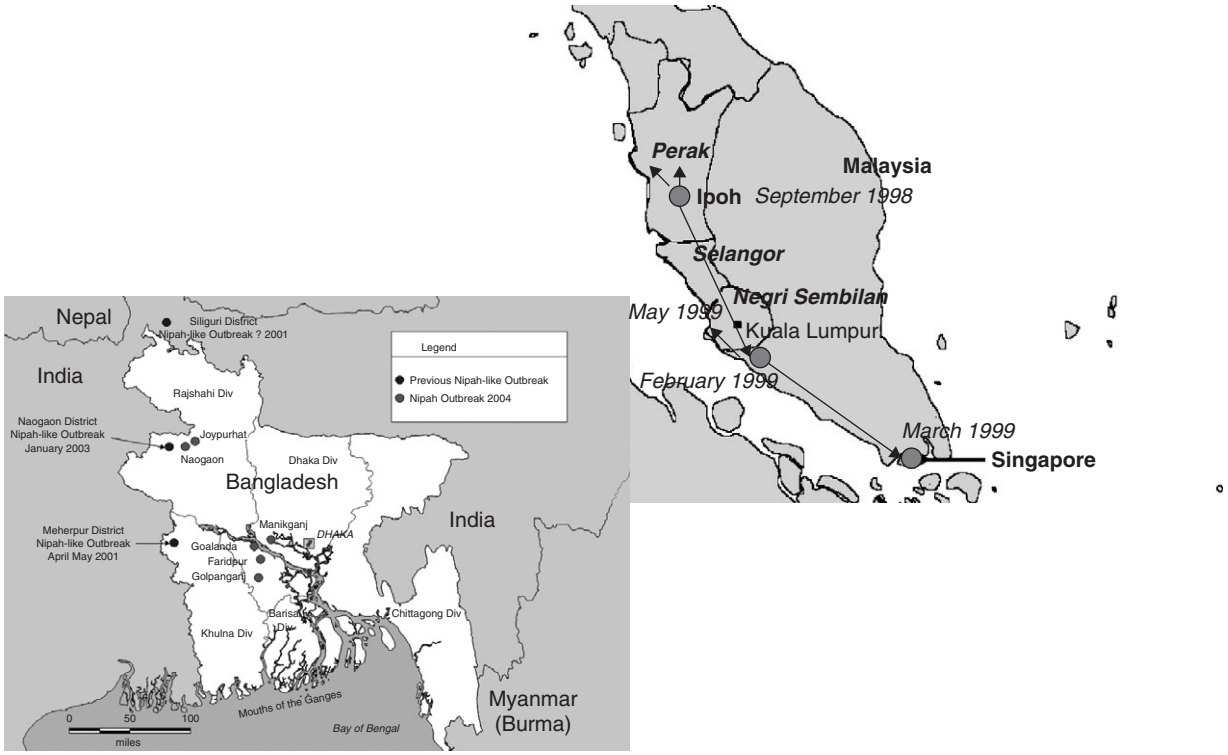

FIGURE 31.1 Geographic distribution of Nipah virus outbreaks, 1998–2005 (see Table 31.1).

TABLE 31.1 Nipah virus outbreaks, 1998–2005

Dates	Location	Number of cases	Number of deaths	CFR (%)
September–May 1998	Malaysia	265	105	40
March 1999	Singapore	11	1	9
February 2001	Siliguri, India	66	45	68
April–May 2001	Meherpur, Bangladesh	13	9	69
January 2003	Naogaon, Bangladesh	12	8	67
January 2004	Goalando, Bangladesh	29	22	76
April 2004	Faridpur, Bangladesh	36	27	75
January–March 2005	Tangail, Bangladesh	12	11	92

India (Harit et al., 2006). A new genetic variant was identified as responsible for the epidemics (Harcourt et al., 2005). These outbreaks have been characterized by very high fatality rates. In Tangail District, Bangladesh, from December 15, 2004, through January 31, 2005, 12 persons were infected with NiV and developed fever with new onset of seizures or altered mental status. Eleven (92%) died. The strain was genetically related to NiV but showed overall 91.2% nucleotide homology and >92% amino acid homology with the NiV strain isolated in Malaysia (Harcourt et al., 2005). An outbreak of febrile illness associated with central nervous system (CNS) defects was notified in the two first months of 2001 in Siliguri, West Bengal, India (Chadha et al., 2006). Retrospective serological analysis detected NiV-specific IgM and IgG antibodies in 9 of 18 patients and RT-PCR detected RNA from NiV in urine samples from 5 of them.

ETIOLOGIC AGENT

Virus Morphology

Henipaviruses are pleiomorphic with spherical or filamentous structures ranging from 40 to 2000 nm in size (Fig. 31.2A). Nucleocapsids are visible in electron microscopy with a diameter of about 18 nm (Hyatt

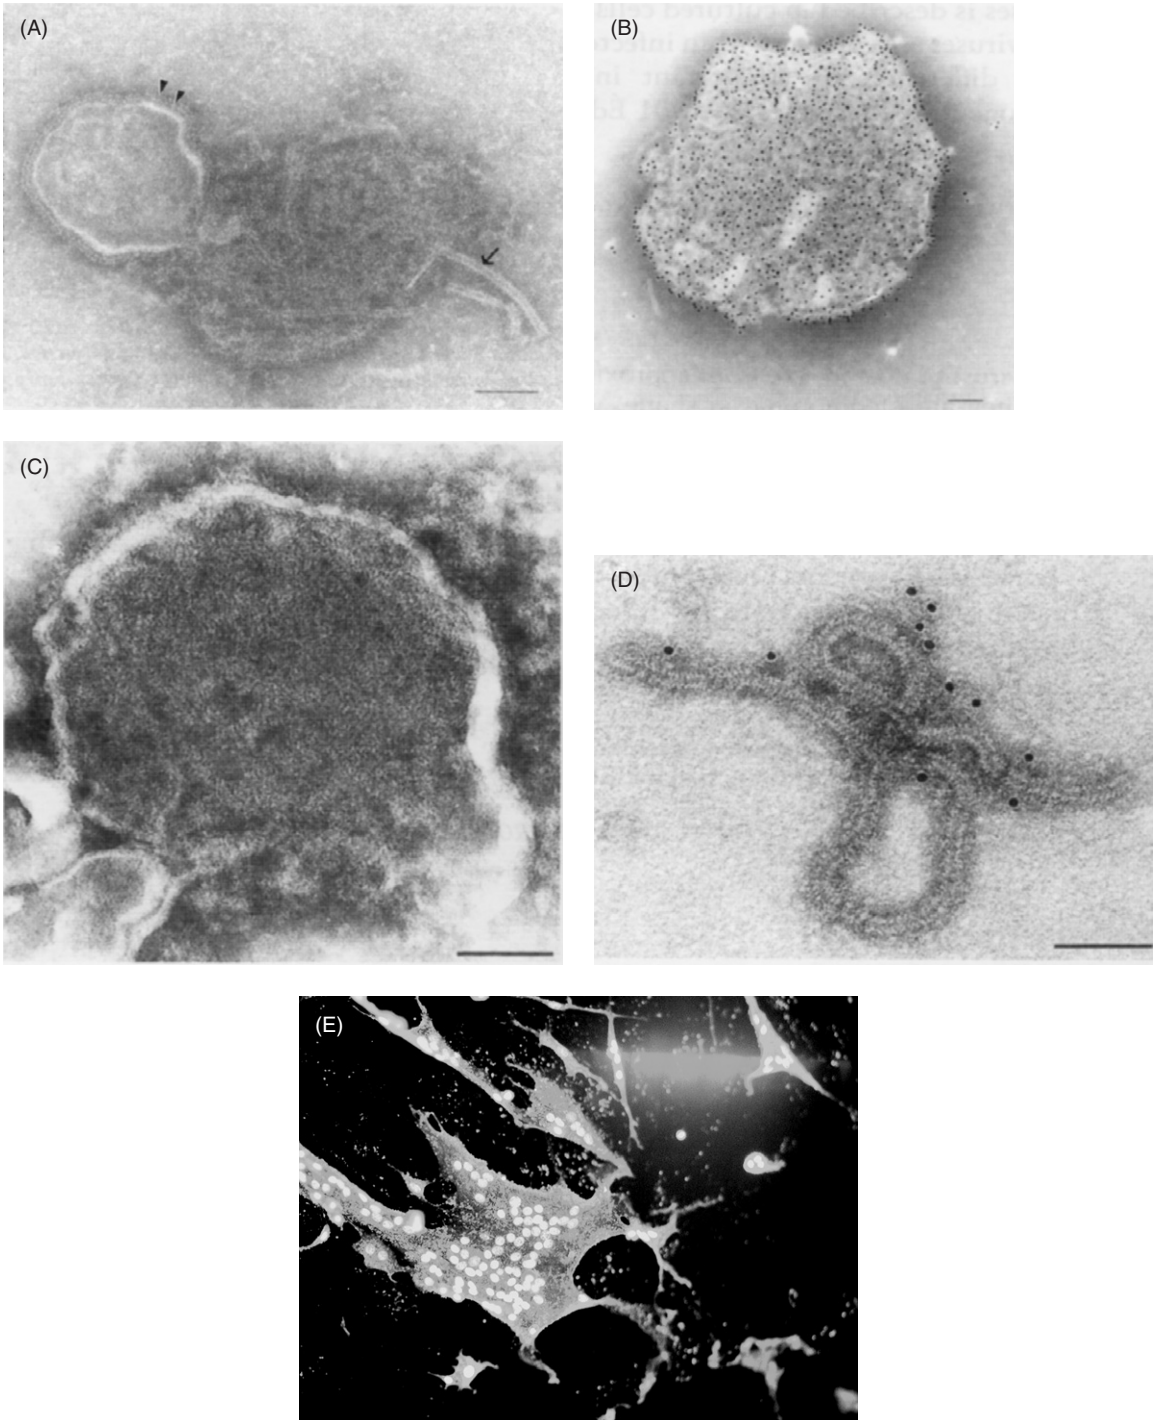

FIGURE 31.2 Microscopy of Nipah virus. (A–D) Electron microscopy showing enveloped virus (A–C) and nucleocapsids (D) (from Hyatt et al., 2001); (B) Syncytia of BHK-21 cells infected with Nipah virus (m.o.i. 0.025, 24 h postinfection) and immunostained with anti-Nipah antibodies and counterstained with Hoechst (original magnification: 20×) (see color plate section).

et al., 2001). Viruses form characteristic aggregation of nucleocapsids in the cytoplasm of infected cells (Goldsmith et al., 2003) (Fig. 31.2B). Infected cells form large syncitia (Fig. 31.2E) with nucleus disposed at the periphery (NiV) or more concentrated inside the cell (HeV). NiV form larger syncitia than HeV or Tioman virus, another paramyxovirus isolated from bats. Virus replication leads to virus release in the cell supernatant within 5–6 h with titers higher than 10^8 PFU/ml. Vero cells rapidly fuse, within 1–3 days, with

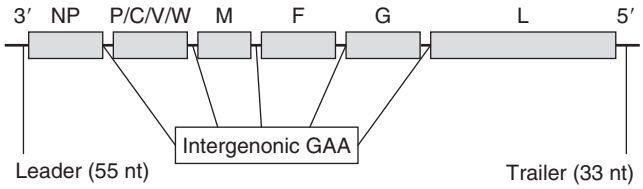

FIGURE 31.3 Structure of henipavirus genome.

a multiplicity of infection ranging from 1 to 0.001, respectively.

Virus Classification

The *Paramyxoviridae* family is subdivided based on the nature of the encoded genes and their organization within the genome. NiV and HeV are closely related to the morbilliviruses and respiroviruses coding for six proteins with similar functions. However, they differ from the respiroviruses in that they lack a functional neuraminidase. They can be further differentiated by the size of their genome, 18 kb, compared with 15.1–15.9 kb for other paramyxoviruses. They have now been classified in a separate genus, *Henipavirus*.

The genome of HeV is 18,234 nucleotides, while that of NiV isolated in the Malaysian epidemic in 1998 is 18,246 nucleotides (Harcourt et al., 2000, 2001; Wang et al., 2001; Chan et al., 2001), whereas that isolated in Bangladesh in 2004 contains an extra six nucleotides (Harcourt et al., 2005). Thus, the genome size follows the rule of six as was proposed from in vitro studies (Halpin et al., 2004). The 3′ leader (55 nucleotides) and the 5′ trailer (33 nucleotides) sequences function as promoters for the positive and negative strands, respectively. The 12-terminal 3′ and 5′ nucleotides are highly conserved and complementary (Wang et al., 2001). The organization of the different genes within the genome is shown in Fig. 31.3. The intergenic sequence GAA is the same as in morbilliviruses and respiroviruses.

Molecular Epidemiology

Several strains of HeV were isolated from horses, humans, and bats, in different epidemic locations in Australia (1994–1996) and NiV was isolated from pigs, humans, and bats in Malaysia, India, Bangladesh, and Cambodia (1999–2004). Full-length sequences of HeV and NiV genomes share up to 75% nucleotide sequence similarity but only 40–45% with other viruses in *Paramyxoviridae* family (Wang et al., 2000).

Partial sequence analysis of HeV showed high similarity between horse, human, and bat isolates over a 2-year period. However, full-length or partial sequencing of NiV has shown significant divergence, in particular between Malaysian/Cambodian and India/Bangladesh clusters which differed by about 5% in nucleotide sequence. Clusters shared more than 98% nucleotide sequence similarity (Reynes et al., 2005; Chua et al., 2002a; Harcourt et al., 2005; Chadha et al., 2006; Luby et al., 2006; Abubakar et al., 2004). Higher divergence was noticed in Bangladesh/India outbreaks, suggesting different introductions of the virus by different colonies of Pteroptera. No correlation between amino acid change and epidemic or virulence features has been identified up to now.

Antigens Encoded by Agent

The *nucleoprotein gene* codes for a protein of 532 amino acids having 92.1% homology between the two viruses. In keeping with other Paramyxoviruses, the variable region is at the –COOH terminus where 22 of the 42 amino acid differences between the N proteins of NiV and HeV are located in a 28-amino-acid portion.

The *P gene* is transcribed into an mRNA (2704 nucleotides) coding for a P protein of 707 (HeV) or 709 (NiV) amino acids. This protein is approximately 100 amino acids larger than the P protein of other paramyxoviruses (Lamb and Kolakofsky, 2001). The overall homology between NiV and HeV is 67.6%, but the amino- (137 amino acids) and carboxy- (321 amino acids) terminals contain approximately 80% identity. Like other paramyxoviruses, a second protein, C is translated from a different open reading frame (+23 or +26 nucleotides) to give a protein of 166 amino acids, which has 83.2% identity for NiV and HeV. Interestingly, HeV, but not NiV, has the potential to code for a second protein in the same frame as C, but this has so far not been identified in virus-infected cells. Similar to other paramyxoviruses, henipaviruses have found a mechanism of increasing their genetic potential. During transcription of the *P gene*, one or two G residues may be inserted at a specific editing site. This leads to the synthesis of a fusion-protein in which the N-terminal P protein contains 406 amino acids fused to (+1G) 55 (HeV) or 52 (NiV) amino acid C-terminal giving a V protein or (+2Gs) leading to a 47 amino acid C-terminal W protein (Fig. 31.4).

The *matrix (M) gene* codes for a protein of 352 amino acids with a homology of 89% between NiV and HeV, although 12 of the changes occur within the first 13 amino acids. In paramyxoviruses, the M protein

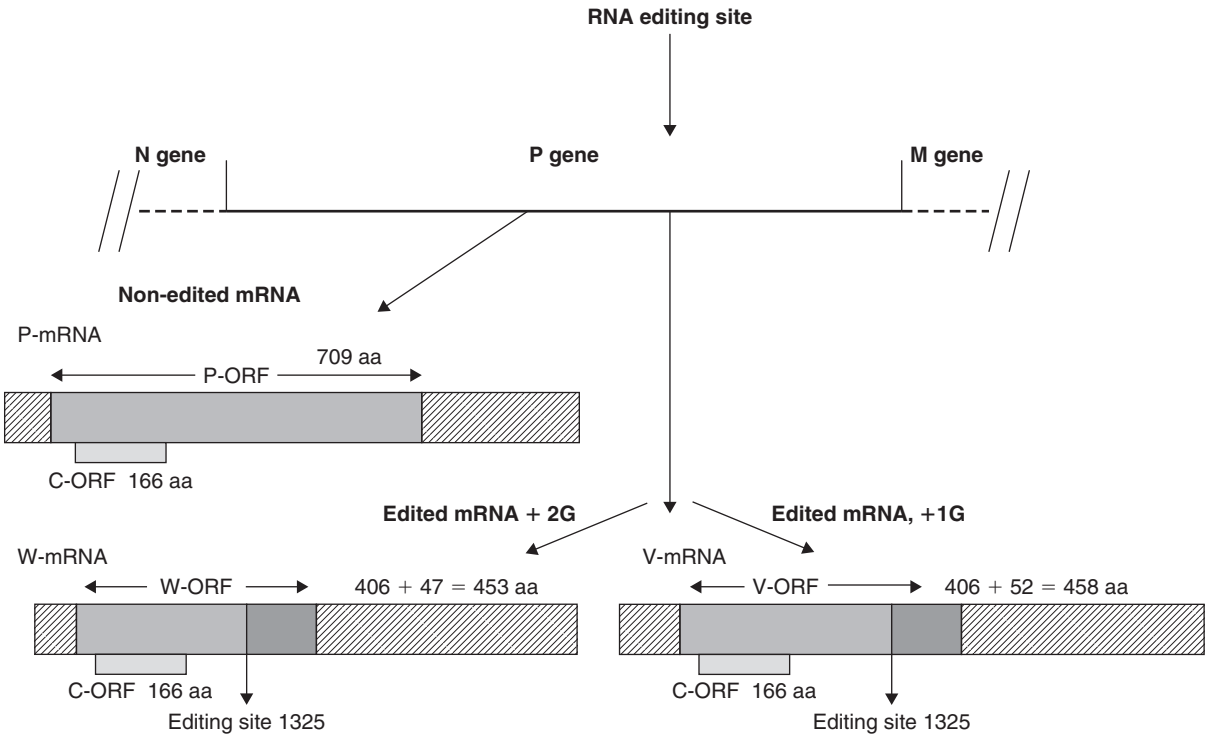

FIGURE 31.4 Translation strategy of the *P gene* of henipaviruses.

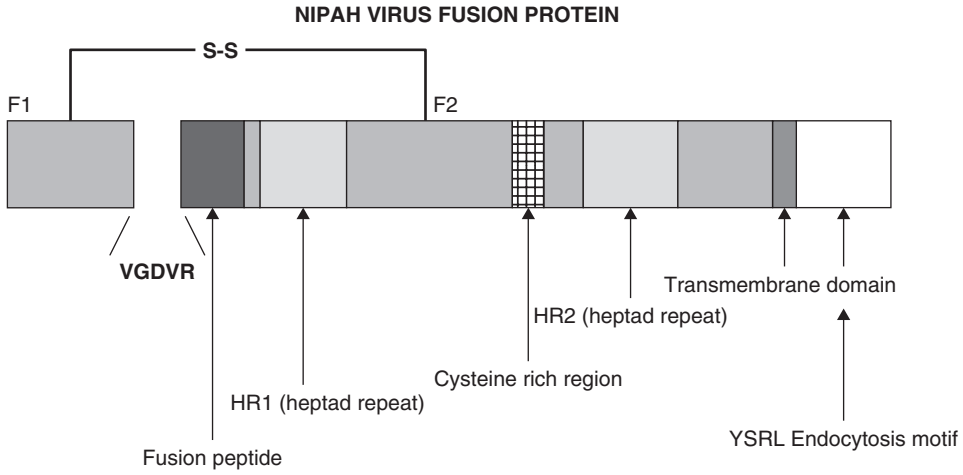

FIGURE 31.5 Henipavirus fusion F protein (see color plate section).

participates in the budding process. Expression of the NiV M protein is sufficient to produce budding virus-like particles that are physically and morphologically similar to NiV. A "late domain-like" sequence YMYL within the NiV M protein plays a role in this function. Deletion of this sequence causes the M to relocate to the nucleus (Ciancanelli and Basler, 2006).

The *fusion (F) gene* codes for a protein for both viruses which is 546 amino acids containing 88.1% homology (Ni/HeV). Similar to other paramyxoviruses, it is a type 1 transmembrane protein with a membrane-spanning region close to the carboxy-terminal, with two α-helical regions (HR1, HR2) involved in the fusion process and a cysteine-rich zone implicated in the interaction with the virus attachment protein (Fig. 31.5). The F protein is synthesized as an inactive precursor, F0, that is subsequently cleaved into two subunits F1 + F2 liberating at the amino terminus of F1 a hydrophobic peptide, which can interact with the host cell membrane. The cleavage site has a unique single basic residue (lysine

in HeV and arginine in NiV) and is not cleaved by the protease furin, as in other paramyxoviruses (Moll et al., 2004a; Craft and Dutch, 2005). It has been proposed that the inactive uncleaved form is transported to the surface and subsequently internalized within the endosomal compartment, where it is cleaved and recycled to the cell surface as a fusion-active protein (Pager et al., 2004; Diederich et al., 2005; Meulendyke et al. 2005). Endocytosis is normally mediated by tyrosine dileucine–dependent signals in the cytoplasmic tails of transmembrane proteins. Mutation of these motifs (YXXF) in the NiV F glycoprotein inhibited endocytosis and fusion (Diederich et al., 2005).

HeV mutated in the motif at position 525 (Y525A) reached the plasma membrane rapidly, but was subsequently endocytosed much slower compared to the wild-type version (Meulendyke et al., 2005). After endocytosis both wild-type and mutated versions were cleaved. Pager and Dutch (2005) have shown that the endosomal/lysosomal protease cathepsin L is involved in the proteolytic maturation of HeV F. Cathepsin L–specific inhibitors reduced cleavage and the purified enzyme could cleave F0 into the F1 + F2 subunits. The cleavage of HeV F was initially assumed to be after a monobasic residue in the GDVK/R sequence. However, mutation of the basic residue or the upstream amino acids failed to eliminate cleavage (Craft and Dutch, 2005; Moll et al., 2004a). The apparent lack of specificity for cleavage is in keeping with the cleavage properties of cathepsin L.

These studies suggest that the henipavirus F protein is transported to the plasma membrane in an uncleaved form (F0), where it is endocytosed and subsequently cleaved by cathepsin L before returning to the membrane. HeV virions were found to contain both uncleaved and cleaved forms of F (Michalski et al., 2000). This may imply that during infection the viruses may use either membrane fusion or endocytosis during virus entry.

There are six potential N-linked glycosylation sites (three in F1 and three in F2), but only two sites in the F2 subunit (N67 and N99) and two in F1 (N414 and N464) have been shown to be glycosylated. Mutation of the sites in the F2 moiety does not affect cleavage, transport, or fusion activity. In contrast, mutation of the F1 sites leads to a greater than 80% reduction of expression of F at the cell surface. N414 is particularly critical for the folding and transport of the protein (Moll et al., 2004a, 2004b; Carter et al., 2005).

The *G gene* codes for the host-cell attachment protein, which is a class 2, type transmembrane protein of 602 amino acids HeV or 600, NiV (83.3% homology). This membrane protein spans the membrane leading to a membrane-proximal stalk domain with a large C-terminal globular head. This latter domain contains the receptor-binding region and by analogy with the structures determined for other paramyxoviruses is organized into a six-blade β-sheet propeller structure. The henipavirus G protein shares structural features characteristic of viruses in the genus *Respirovirus*. The locations of all seven proposed disulfide bonds are conserved. The overall canonical folding pattern of six parallel sheets, which is conserved in viral, bacterial, and eukaryotic neuraminidases, is also retained in henipavirus G. Among the seven active site residues known to be important for neuraminidase activity (Langedijk et al., 1997) only one is present. Structural models of the G protein suggest that the sites of interaction on G with the cell receptor are on the globular head. Mapping studies using escape mutants of either NiV or HeV propose that there is a major discontinuous epitope, which commences near the shallow depression in the center of the top surface of the globular head and extends to the rim of the barrel-like structure on the top loops of β-sheet 5 (White et al., 2005; Guillaume et al., 2006a).

The G glycoprotein is expressed at the plasma membrane, but unlike the F glycoprotein there are no motifs in the cytoplasmic tail, which would aid endocytosis. However, it appears to be constitutively internalized with the bulk flow during membrane turnover (Vogt et al., 2005). In several Paramyxoviruses, the two glycoproteins have been shown to be noncovalently linked (Malvoisin and Wild, 1993). The NiV glycoproteins can be co-immunoprecipitated and mutational studies have established that the avidity of the interactions is inversely related to their fusogenic activity (Aguilar et al., 2006, 2007). The interaction of the two viral glycoproteins would be a means by which G could be co-endocytosed even though it does not contain the appropriate motif.

The *L gene* in both viruses codes for a protein of 2244 amino acids with 86.8% homology at the protein level. In the region predicted to contain the catalytic site, both viruses contain the sequence GDNE that varies from other sequenced nonsegmented negative strand viruses (GDNQ). Mutation of E→Q in NiV did not affect its efficiency (Magoffin et al., 2007).

VIRUS–CELL INTERACTIONS

The Host Cell Receptor

Studies on tissues from humans and infected animals have shown that henipaviruses infected a number of tissues including lungs, endothelial cells, and neurons (Hooper et al., 2001; Wong et al., 2002). In vitro, the viruses infect a wide range of cells of

different species. The lack of an active neuraminidase site makes it unlikely that sialic acid can act as a cellular receptor, especially as neuraminidase treatment of cells failed to effect virus infection (Eaton et al., 2004).

Two groups have identified a cellular protein, ephrin-B2, that permits the attachment and penetration of henipaviruses into host cells (Negrete et al., 2005; Bonaparte et al., 2005). Ephrin-B2 is a critical gene involved in embryonic development, and has established roles in vasculogenesis and axonal guidance. Ephrin genes are highly conserved and have been found in all animal species examined. Both ephrin-B2 and its cognate receptor EphB4 have tyrosine signaling and PDZ binding motifs in their cytoplasmic domains (Kullander and Klein, 2002). Forward signaling mediated by EphB4 facilitates anti-adhesive and repulsive behavior on contact with ephrin-B2 expressing cells, while ephrin-B2 "reverse" signaling facilitates adhesion upon contact with EphB4-expressing cells (Sakamoto et al., 2004). Bennett et al. (1995) identified ephrin-B2 mRNA in most human tissues examined with the exception of blood leukocytes and the pancreas. Cerretti et al. (1995) confirmed its expression in human adult lung and kidney. Ephrin-B2 persists in adult arteries where it extends into some of the smallest diameter microvessels. It is expressed in vascular smooth muscle of arteries, but not veins (Shin et al., 2001). The ephrin-B2 is expressed in neurons and is thought to act postsynaptically by modulating glutamate receptors (Grunwald et al., 2001; Henderson et al., 2001; Contractor et al., 2002) and thereby modulates Ca^{2+} influx into the postsynaptic cells. Thus, the expression of ephrin-B2 in different tissues is similar to the tropism observed for henipaviruses.

The crystal structure of the extracellular domain of mouse ephrin-B2 has been determined (Toth et al., 2001). It has a β-barrel globular domain composed of eight strands arranged in two sheets around a hydrophobic core. In the crystal structure, the ephrin-B2 ectodomains are associated as extensively interacting dimers, which is likely a functional form in vivo. There are two surface regions on the proposed structure, I—a small concave pocket of hydrophobic nature surrounded by charged amino acids, represents a site critical for Eph receptor binding, whereas a second area (II) is implicated in dimerization.

The interactive regions between ephrin-B2 and the henipavirus attachment protein have yet to be mapped. However, soluble NiV G protein with deletions in the globular head domains (372–393, 437–464, or 559–587) fails to interact with ephrin-B2 (Negrete et al., 2005). This would suggest that the conformational folding of the viral glycoprotein is important in its interaction with the receptor. Using soluble forms of NiV or HeV and ephrin-B2, it was shown that there was a high-affinity interaction, which could be specifically blocked with monoclonal antibodies, which neutralized both NiV and HeV.

In a search for alternative receptors for NiV, it was shown that soluble NiV-G could also bind to ephrin-B3, but not to any of the other ephrins. The binding affinity to cell surface B3 was lower than ephrin-B2, but was sufficient to permit viral entry of virus (Negrete et al., 2006). Competition studies with soluble ephrins B2 and B3 suggest that they interact with an overlapping site. Mutational analysis showed that the Leu-Trp residues in the solvent exposed G-H loop of ephrins B2 and B3 were critical determinants of NiV binding and entry. Replacement of the Tyr-Met residues in the homologous positions in ephrin-B1 with Leu-Trp conferred NiV receptor activity to ephrin-B1.

In contrast to ephrin-B2, ephrin-B3 does not appear to be expressed in the endothelium, but is found in the CNS in overlapping and distinct patterns with ephrin-B2 (Flenniken et al., 1996; Bergemann et al., 1998). Presumably in cells where both receptors are expressed, the virus would use ephrin-B2 due to its greater affinity. However, in regions such as the corpus callosum (Liebl et al., 2003) and the spinal cord (Yokoyama et al. 2001), ephrin-B3 is distinctly expressed and could be the major receptor.

The Fusion Process

In paramyxovirus infections, the virus and cell membranes undergo fusion during the initiation of virus entry into the cell and then during in late infection when the infected cell membranes interact with their neighboring uninfected cells. To initiate this phenomenon, the virus G attachment protein interacts with the cell receptor. The F protein, which is noncovalently linked to the G protein, dissociates and the hydrophobic region at the N-terminal of F1 is introduced into the cell membrane. The two α-helical regions (HR1, HR2) associate in the form of a six helical bundle (Xu et al., 2004a, 2004b), which in turn brings the viral and cell membranes together to fuse. The whole process can be analyzed by expressing the two virus glycoproteins (G and F) in cells that possess the appropriate host cell receptor. In the majority of the paramyxovirus systems, it has been shown that the two glycoproteins must be homologous, i.e., from the same virus. In the case of henipaviruses, heterologous pairs of F and G proteins from NiV and HeV can induce fusion (Bossart et al., 2001, 2002; Tamin et al., 2002). The proportion of the two viral glycoproteins at the cell membrane can influence fusion. Optimum fusion was observed when the G and F were expressed at the membrane in equal amounts. Further,

the HeV G protein levels are modulated by both a more rapid protein turnover and a slower protein trafficking than that for HeV F (Whitman and Dutch, 2007).

Mutational studies on the cytoplasmic tail region of NiV F showed that they could affect the avidities of the NiV–F and –G interactions. Mutations decreasing these interactions increased the fusion activity (Aguilar et al., 2007). Similar observations have been previously shown with measles virus glycoproteins (Plemper et al., 2002).

In the second stage of fusion, the two α-helical regions of the F glycoprotein associate to bring the viral and cell membranes together. It has been shown that for a number of the paramyxoviruses synthetic polypeptides corresponding to the HR2 region inhibit the association of the two α-helical regions and thus block fusion (Lambert et al., 1996; Wild and Buckland, 1997). Similar studies with henipaviruses have shown that peptides corresponding to the HR2 region also block fusion (Bossart et al., 2002). The peptides, which efficiently block fusion, are relatively long (42 mer) and show hydrophobic properties, which would limit their in vivo use. More recent studies have developed a second generation of peptides which are shorter (32 mer) and include a capped peptide via amidation and acetylation and two poly (ethylene glycol)-linked (PEGylated) peptides, one PEG moiety at the C-terminus and the other at the N-terminus. These peptides are highly soluble and inhibited fusion and virus infection at similar concentrations to the nonmodified peptides (Bossart et al., 2005b). From studies with other peptides it can be assumed that such modifications will increase their half-life in vivo.

The amino acid sequences in this region of the F protein are somewhat conserved among the paramyxoviruses, fusion inhibition by the HR2 peptides has generally been found to be virus specific. Peptides specific for NiV or HeV F proteins equally inhibited the other virus, but not morbilliviruses (Bossart et al., 2001, 2002). An exception to this rule appears to be human Parainfluenza virus 3. Peptides to its HR2 region block HeV-induced fusion more efficiently than the homologous virus (Porotto et al., 2006). Further studies to elucidate the mechanism involved would help in the design of more efficient inhibitors.

EPIDEMIOLOGY

Significance as Public Health and Agricultural Problems

The first epidemic episode of NiV emerged in a piggery causing primarily respiratory disease in 1998 through 1999 and then progressed to pig farmers causing lethal encephalitis. In 1998, in Perak State located North from Kuala Lumpur, the causative agent was initially thought to be Japanese encephalitis virus but high mortality in humans and acute respiratory disease in pigs and death did not meet the case definition of a mosquito-borne flavivirus (Chua et al., 1999; Mohd Nor et al., 2000). Indeed, vaccination of the population in the epidemic area against Japanese encephalitis virus and mosquito control did not stop the spread of the disease. From February to April 1999, the virus was probably imported by infected pigs to Negeri Sembilan where intensive pig farms were affected. More than one million pigs were culled to stop the epidemics. The virus isolated from the cerebrospinal fluid (CSF) of a patient was identified as closely related to HeV and was called Nipah, the name of a river in the village from where the patient originated (Chua et al., 2000a). Eleven cases of encephalitis and one death were then identified in pig abattoir workers in Singapore (Paton et al., 1999). Since then no more cases have been reported in this region.

Megacheroptera Fruit Bats as the Natural Host of Henipaviruses and Source of Infection in Animals and Humans

HeV and NiV are the only zoonotic paramyxoviruses known to be highly pathogenic for humans. Serological investigations rapidly showed that fruit bats (flying foxes) of genus *Pteropus* in the suborder *Megachiroptera* could be involved in virus transmission of HeV to horses (Young et al., 1996). HeV was then isolated from two species of *Pteropus* (Halpin et al., 2000). Transmission from bats to horses may have occurred through ingestion of pastures contaminated with infected urine, placenta or aborted fetal material, or from partially eaten fruit or fruit pulp spat out by bats. Transmission between horses appeared to be a rare event, and there was no evidence of direct transmission from bats to humans. One study collecting samples from nasal and throat swabs and urine showed NiV in a significant amount of patients with an acute disease, but no seroconversion was observed in health workers (Chua et al., 2001).

Close phylogenetic and serological relationships with HeV facilitated the rapid identification of Pteropid bat species as the reservoir hosts of NiV (Mohd Yob et al., 2001) and isolation from their urine in Tioman Island (Chua et al., 2002a). It is believed that transmission from bats to pigs was through fruit spats, placental or aborted fetal material, or other contaminated material falling into pig pens. The virus was further isolated from urine of *Pteropus Lylei* in Cambodia (Reynes et al.,

2005). Antibody prevalence was observed in dogs of farmers where the NiV epidemics had emerged (Mohd Yob et al., 2001), but the role of dogs in the virus life cycle has not been identified.

In Bangladesh, most people may have been infected by drinking raw date palm sap contaminated by fruit bats (*Pteropus giganteus*) (Luby et al., 2006). These outbreaks have been characterized by very high fatality rates, by sometimes lack of contact with either bats or a domestic spillover host, and by the probability of human-to-human transmission (ICDDR,B, 2004a, 2004b). This latter feature is of very significant global concern; if correct, future outbreaks may spread to other areas where fruit bats are not part of the normal fauna. It may also have a significant impact in the biothreat potential.

The geographic range of Pteropid fruit bats extends as overlapping populations from Pacific Islands through southern and southeastern Asia, and Australasia to the Middle East. Additional species occur in the southern Indian Ocean, including Pembe Island and Madagascar. There are epidemiological and serological evidence that fruit bats are the major reservoir for HeV and that NiV is widespread in *Pteropus* in Southeast Asia (Mohd Yob et al., 2001; Olson et al., 2002; Wacharapluesadee et al., 2005; Lehle et al, 2007). However, it cannot be excluded that neutralizing antibodies found in several species of fruit bats in Cambodia, Thailand, Malaysia, Madagascar, and Vietnam (Huong VTQ et al., unpublished results) may be cross-neutralizing antibodies to another related but to date not identified virus in bats. However, NiV RNA was found in bat saliva and urine of bats in Thailand, suggesting the persistence of similar NiV infection in these animals (Wacharapluesadee et al., 2005).

Pteropus poliocephalus (gray headed fruit bats) experimentally infected with NiV showed subclinical manifestation, transient systemic virus, and episodic low-level virus excretion in urine in the presence of neutralizing antibodies (Middleton et al., 2007). Low and intermittent excretion of NiV in the urine of infected bats may be sufficient to maintain virus survival among bats. This strain of bats was also infected with HeV and showed subclinical symptoms and virus transfer to the fetus (Williamson et al., 2000). This suggests that henipaviruses may be maintained in nature through transplacental transmission from the mother to the fetus.

Cats, horses, or pigs are natural hosts of HeV and NiV. Recovery of viruses from urine as well as from the nasal discharge or saliva of these viruses may favor viral shedding and possibly field transmission of the viruses between domestic animals and between those animals and humans.

These results confirm that bats carrying henipavirus represent a public health hazard. However, how the virus can be transferred to intermediate host or directly to human remains puzzling.

Since bats are natural hosts of the viruses, epidemiological investigations have observed dramatic changes in the habitats of these animals to explain the installation of bat colonies in new environments planted with fruit trees and occupied by humans and pig farms. In 1997/1998, deforestation due to fires in Borneo resulted in the migration of fruit bats over several regions of Southeast Asia in the months directly preceding the NiV disease outbreak. This was exacerbated by a unusual drought event the same years (Chua et al., 2002b). In Malaysia, NiV found new ideal ecological situation to be transmitted from its reservoir host to pigs and ultimately to the human population (Chua et al., 2002b). In China and Southeast Asia, countless numbers of villages where fruit trees are spoiled by fruit bats, pigs roam freely, and only poor sanitary conditions are available, provide ideal environments for natural transmission of NiV from infected bats.

Potential as Biothreat Agent

NiV and HeV are highly virulent pathogens and are on priority lists of potential bioterrorism agents because of their capacity to rapidly spread in pig farms and stud farms, incurring high transmission and lethality rates in humans, and potentially causing medical and economical disasters (Lam, 2003). Whether preferential neurotropism, or lower virus doses in urine of patients, or other factors may account for low human-to-human transmission remains unknown. However, a strain of NiV has recently been identified in Bangladesh with ability to cause acute respiratory distress syndrome and to be transmitted from person-to-person (ICDDR,B, 2004b).

CLINICAL DISEASE

Clinical Symptoms

There have been only four human cases besides horses infected with HeV, limiting information on clinical and pathophysiological features of the disease. Pathological manifestation of HeV infection in horses and humans is that of flu-like syndrome with severe pneumonitis and respiratory failure, and renal failure and arterial thrombosis (Selvey et al., 1995). Lungs show lesions of congestion, hemorrhages, and edema

(Hooper et al., 2001). Chest radiography may show mild interstitial shadowing. In NiV infection, after an average of 10 days of incubation, patients presented with nonspecific systemic symptoms of fever, desorientation/confusion, guidiness, headache, myalgia, and sore throat. The more severe cases showed drowsiness and altered level of consciousness that required ventilation (Chong et al., 2002). In another study, 40% of them had cough and respiratory syndromes, but only 28% had convulsions (Wong et al., 2002). Duration of illness was quite variable and lasted from less than 5 days to more than 35 days. Most common clinical signs were reduced consciousness, hyporeflexia or areflexia, segmental myoclonus, and seizure. These symptoms reflected brain stem dysfunction (Chua et al., 1999; Goh et al., 2000; Wong et al., 2002). The general status of patients showing hypotension and tachycardia deteriorated rapidly to death. High viral replication in the CNS may be an important factor for high mortality (Chua et al., 2000b). Magnetic resonance imaging (MRI) shows focal and scattered areas of increased signal intensity with a cortical distribution within the white matter in T2-weighted images. Transient punctate cortical hyperintensities were seen on T1-weighted images (Paton et al., 1999; Lim et al., 2002).

Some patients showed late onset of the disease, up to 4 months after the presumed infection episode, and in more than 10% of patients who showed mild encephalitis a few days after infection, relapsed few months to 4 years with severe meningo-encephalitis causing death in up to 18% of the cases. Symptoms were similar compared to acute manifestation, with increased manifestations of seizure and focal cortical signs. The overall mortality was as high as 40%. On the other hand, up to 50% recovered fully. As for the others, the residual neurological signs were mostly mild but some patients retained permanent sequelae (Ng et al., 2004; Sejvar et al., 2007).

Atypical Symptoms

A study of a 24 month follow up after the NiV outbreak in Malaysia observed 12 survivors (7.5%) of acute encephalitis who had relapsed encephalitis and 10 patients (3.4%) had late-onset encephalitis (Tan et al., 2002). The mean interval between the first neurological episode and the time of initial infection was 8.4 months. Patients showed common clinical features observed in primary of NiV infection. Four of the 22 relapsed and late-onset encephalitis patients (18%) died. Cortical lesion were observed by MRI with high intensities of signals (Lim et al., 2002). Focal encephalitis with NiV antigens in neurons was observed in brains of deceased patients.

In Bangladesh, similar symptoms were observed, but respiratory distress and cough were symptoms characteristic of this disease. Chest radiographs showed bilateral infiltrates consistent with acute respiratory distress syndrome. One of the two fatal cases of HeV infection in Australia also showed respiratory infection and lesions in the lung (Selvey et al., 1995).

TREATMENT

An open-label trial of ribavirin was carried out during the NiV epidemics in Malaysia (Chong et al., 2001). The study suggested that ribavirin was able to reduce the mortality of acute NiV encephalitis by 36%. However, reduction of NiV replication by Ribavirin was observed in Vero cells infected with the virus but not in vivo in hamster or guinea pig animal models (Georges-Courbot et al., 2006). The difference of protective efficacy of Ribavirin in humans and in hamsters may have several explanations: (1) the study in humans was not randomized and performed at posteriori, and grouping treated and nontreated patients may have introduced some bias; (2) the dose and mode of infection of NiV used for the challenge or the virus replication in hamsters may be higher and different than in humans, and may have not been blocked by the drug in vivo; (3) Ribavirin may be differently metabolized in humans than in hamsters. Several other drugs known to be active against paramyxoviruses like inhibitors of either S-adenosylhomocysteine hydrolase or of IMP deshydrogenase, or of OMP decarboxylase, or of CTP synthetase, were tested in vitro. A few of them were active in vitro but inactive against NiV infection when tested in the hamster model (Georges-Courbot et al., 2006).

Many viruses are susceptible to interferon (IFN). Viral-derived double-stranded RNA is one of the activating factors of the IFN cascade. One treatment strategy is to inject in infected individuals external IFN to cure or at least to maintain low doses of viruses. Another alternative is to inject an inducer of IFN response. Poly(I)-poly(C12U) (Ampligen), a strong IFN-α and IFN-β inducer, showed anti-HIV activity in clinical trials and in several animal models of positive- and negative-strand RNA viruses. This compound was tested in the hamster model of NiV infection and substantial protection of treated animals was observed if injected for 10 consecutive days after infection (Georges-Courbot et al., 2006). Although no infectious virus was detected, RT-PCR positive viral sequences

were recovered in organs of hamsters surviving from the challenge. These results deserve further studies, in particular to investigate if any virus relapse would occur in animals treated with Ampligen and protected against a lethal challenge.

Galectin-1 is a lectin produced by several cell types which modulates cytokine synthesis and increases IL-6 production by dendritic cells. It was also shown to inhibit cell fusion provoked by NiV infection (Levroney et al., 2005). The combined activities of this endogenous lectin may provide a potent drug candidate to treat patients against henipavirus infection.

PATHOGENESIS

Description of Disease Process

HeV and NiV showed similar pathogenesis and vascular endothelium tropism as pathognomonic of the disease, with resulting syndrome of interstitial pneumonia, meningitis, and atrophic glomeruli (Selvey et al., 1995; O'Sullivan et al., 1997; Wong et al., 2002). In both viral diseases, syncytia in microvascular endothelium were observed. In one case of HeV infection, syncytia developed particularly in the blood vessels of the lung (Murray et al., 1995; Selvey et al., 1995) and in the other case, they were more prominent in brain microvascular (O'Sullivan et al., 1997) (Fig. 31.6). Systemic vaculitis, thrombosis, ischemia, and parenchymal necrosis were the main histopathological hallmarks (Fig. 31.7). Pathological lesions with plaques of necrosis were visible in the white and grey matter in CNS and in spinal cord. Inflammatory cells in perivascular cuffing consisted of macrophages, lymphocytes, neutrophils, and microglia cells (Fig. 31.7). Neuronophagia was active. Multiple eosinophilic viral inclusions were visible in the cytoplasm of few neurons, but only in 63% of the cases (Wong et al., 2002). These inclusions characteristics of paramyxoviruses also identified by electron microscopy (Hyatt et al., 2001; Wong et al., 2002) correspond to inclusion bodies of nucleocapsids. Vasculitis, endothelial cell damage, and thrombosis lead to microinfarctus and microvessel rupture which appear to be the mechanism for the virus to cross the blood–brain barrier and invade the neuronal parenchyma.

Histology of necropsies of one case of HeV and one case NiV relapse were performed (O'Sullivan et al., 1997; Wong et al., 2002). In HeV patient, discrete necrosis was observed in the cortex, brainstem, and cerebellum. Multinucleated cells and viral inclusions were observed in the brain, and other organs. Inflammatory cells were scattered in the brain parenchyma. In one NiV patient, parenchymal lesions were larger with numerous macrophage infiltrates. Intracellular inclusion in neurons were more prominent. No vasculitis or necrotic plaques were observed. HeV genome was amplified from the serum and CSF of the patient and the sequence of 500 nucleotides in the matrix gene was identical to that of the virus that circulated 13 months before. No NiV nucleotide sequence was available from the NiV case. Neither HeV nor NiV was isolated from the brain of either patient.

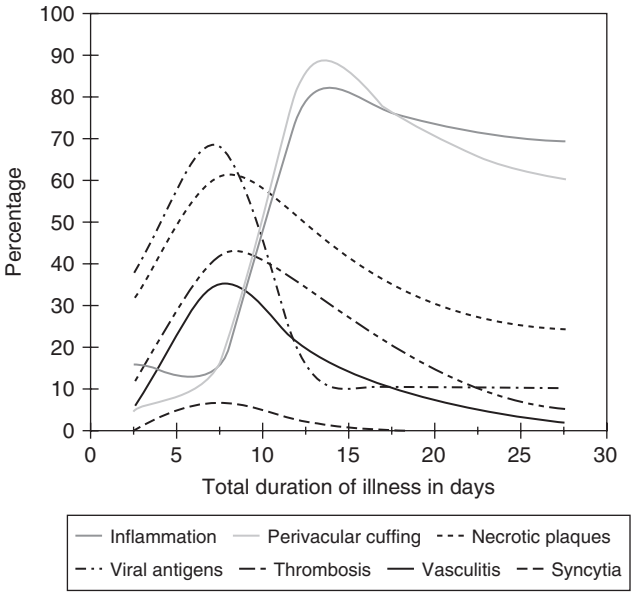

FIGURE 31.6 Temporal distribution of microscopic findings and viral antigen in the CNS in human fatal Nipah virus infection (from Wong et al., 2002).

Animal Models

As in the human disease, NiV and HeV cause systemic infection in several animals. Guinea pigs infected with high doses of HeV develop encephalitis (Williamson et al., 2001), whereas NiV receiving 10^7 pfu only showed transient fever and weight loss (Wong et al., 2003). In contrast, both NiV and HeV induce an acute infection in golden hamsters that appears to reproduce the pathology and pathogenesis of the acute human NiV infection, with primarily vascular infection, perivacular cuffing and thrombosis, and neurotropism with numerous lesions in the brain (Wong et al., 2003) (Fig. 31.8). This model would be useful to study pathological processes of each virus, and in particular the causes and features of delayed onset and relapse characterized in humans for both viruses. In a feline model, infection of cats

(B) Focal areas of parenchymal ischemia, infarction, and edema. (C) Neurons with eosinophilic viral inclusions (arrows). (D) Immunolocalization of viral antigens to neurons in the nucleus (inset, arrow), cytoplasm, and processes near a vasculitic vessel (arrow). (E) Viral antigens localized to ependymal lining (arrow) and neurons. (F) Neurons demonstrating viral RNA in the cytoplasm (arrows). (A–C) Hemalin-phloxine-safranin stain; (D, E) IHC, hematoxylin counterstain; (F) in situ hybridization, hematoxylin counterstain. Original magnifications: 40× (A, B, E, D (inset); 20× (D); 100× (C, F) (from Wong et al., 2003) (see color plate section).

with NiV induces an acute febrile reaction followed by severe respiratory disease. There was an apparent lack of neurological signs, despite the demonstration of NiV genome in brain tissue (Mungall et al., 2006). Detection of NiV in placenta and fetal tissues from pregnant cats infected with NiV suggests that both vertical and horizontal transmission of NiV could play a role in spillover events (Mungall et al., 2007). NiV infection of pigs leads to a 10–15% mortality rate with few animals showing neurological signs (Mohd Nor et al., 2000). Experimental infection of pigs showed that following the initial replication in the upper respiratory tract; the virus invades the CNS directly via the cranial nerves and by crossing the blood–brain barrier. NiV also replicated in the respiratory system, including the lung, concurrently with the spread through the nervous and lymphoreticular systems. The respiratory tract is one of the main targets early in the infection (Weingartl et al., 2005).

Saimiri monkeys were highly susceptible to NiV and showed clinical symptoms of CNS infection and histopathological lesions similar to those described in humans or animal models (Contamin et al., to be published).

Inoculation of fertile eggs via yolk sac with NiV led to embryo's death with severe pathogenesis in CNS and tropism for vascular endothelial cells and neurons (Tanimura et al., 2006). This model has been proposed for virus titration and for study of the vascular and neuronal tropisms of NiV.

IMMUNE RESPONSE TO INFECTION

Innate Immunity

The IFN response is one of the host's primary defense mechanisms against viral infection. IFN-α/β is synthesized and secreted by cells in direct response to viral infection. Viruses have devised various strategies to circumvent this IFN-induced antiviral state through the expression of viral proteins that inhibit specific components of the IFN system. The IFN antagonist functions of the *Paramyxovirinae* are all coded by the *P gene* and in most cases are carried out by one of the accessory proteins: C, V, or W. These proteins all target the IFN signaling, or JAK/STAT pathway, but do so through distinct mechanisms. The Henipavirus V

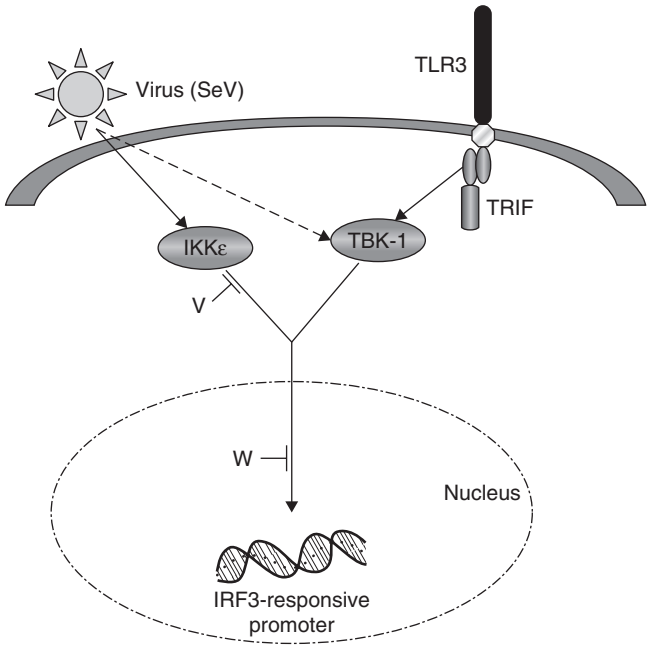

FIGURE 31.9 Illustration of the virus and TLR-3 activated signaling pathways and the points where NiV V and W proteins are predicted to exert their inhibitory activity (from Shaw et al., 2005).

and W proteins localize to the cytoplasm and nucleus, respectively, and have both been shown to function as inhibitors of JAK/STAT signaling (Rodriguez et al., 2002, 2003; Shaw et al., 2004, 2005). The V and W proteins also block viral activation of the IFN-β promoter and the IFN regulatory factor 3-response IFN-stimulated gene 54 promoter. Only the W protein shows strong inhibition of promoter activation in response to stimulation of Toll-like receptor (TLR) 3. The nuclear localization of the W protein enables it to target both virus and TLR pathways, whereas the cytoplasmic V protein is restricted to inhibiting the virus pathway (Fig. 31.9). The V protein of NiV has been shown to antagonize the IFN response in human cells via the sequestration of STAT1 and STAT2. This activity can be inactivated by the mutation of a single amino acid (Hagmaier et al., 2006).

The henipavirus C protein by analogy with other paramyxoviruses has a dual role. It inhibits viral RNA transcription and replication, but also acts by blocking IFN action. Park et al. (2003) have shown that NiV C expression prevents the establishment of an IFN-induced antiviral state.

Protective Immune Responses

Protective immunity to paramyxoviruses has been attributed to both cellular and humoral responses. Children suffering from hypogammaglobulinemia recover normally from measles infections, whereas those suffering from defects in cellular immune responses have complications leading to encephalitis (Good and Zak, 1956). On the other hand, antimeasles hyperimmune serum protects children from infection (Gallagher, 1935). Thus, cellular responses are important in protection, but once in place, the antibodies provide a first line of defense. Studies with a number of paramyxoviruses have shown that both of the viral glycoproteins (the attachment and fusion proteins) can induce antibodies that neutralize the virus in vitro (Giraudon and Wild, 1985) and protect animals from a challenge after passive administration (Malvoisin and Wild, 1990).

Little is known about humoral response against Henipaviruses and nothing about the cellular response. Virus can persist in humans hidden in some cells in the brain or other unknown sites, even in the presence of neutralizing antibodies. The time course of viremia and immune responses have been described by Wong et al. (2002) and are described in Fig. 31.6. Envelope glycoproteins G and F of Henipavirus are highly antigenic and induce antibodies that are able to neutralize virus infection in vitro and in vivo (see below). Zhu et al. (2006) developed human monoclonal antibodies to HeV. They panned a naïve human antibody library with soluble HeV-G. The Fab fragments were selected and showed that one had a high HeV neutralization and also had a cross reactivity with NiV. The conversion of this Fab fragment into an IgG1 immunoglobulin significantly increased its antifusion and neutralization activity.

VACCINATION STRATEGIES

The development of inactivated vaccines against paramyxoviruses in the 1960s showed that they induced virus-neutralizing antibodies, which were protective. The decline in these antibodies levels with time and subsequent exposure to virus led to a disease, which was more severe than if the children had not been vaccinated (Nader et al., 1968). Much later studies, in monkeys showed that vaccination with the inactivated measles vaccine resulted in a priming for a nonprotective type 2 CD4 response, in contrast to the responses induced by the wild-type or attenuated viruses (Polack et al., 1999). In both monkeys and humans, measles infections initially induce a Th1 type response, which converges into a Th-2 response with the induction of antiviral antibodies. These observations led to the conclusion that new vaccines against

paramyxoviruses should induce similar immune responses to that in natural infection.

Few studies have been conducted to develop anti-henipavirus vaccines. To define the antigens inducing neutralizing antibodies, the two NiV glycoproteins have been expressed as vaccinia recombinants and used to immunize mice or guinea pigs. Both G and F glycoproteins induced neutralizing antibodies, although G was more efficient. (Tamin et al., 2002; Guillaume et al., 2004a). Immunization of rabbits with a soluble form of HeV G (lacking the cytoplasmic tail) induced neutralizing antibodies to both HeV and NiV (Bossart et al., 2005a). In contrast, murine monoclonal antibodies against either HeV or NiV G did not cross neutralize although NiV anti-F monoclonal antibodies do (White et al., 2005; Guillaume et al., 2006b). Thus, potential vaccines should contain at least one of the viral glycoproteins. In a hamster model, immunization with either of the NiV glycoproteins (G or F) using a vaccinia vector, protected the animals against a lethal challenge (Guillaume et al., 2004a). The protective mechanisms involved are in part humoral. Hamsters given either monospecific polyclonal or monoclonal anti-G or F antibodies are protected from a subsequent challenge with a lethal dose of NiV (Guillaume et al., 2004a, 2006b). Further, enhanced forms of the disease were not observed when lower levels of antibody were used.

In the pig model, animals immunized with the recombinant canarypox virus (ALVAC) expressing either of the glycoproteins were protected against a challenge. Virus could not be detected after challenge and no virus was shed in the infected animals. These vaccines stimulated both type 1 and type 2 cytokine responses (Weingartl et al., 2006). In the cat model, animals that were vaccinated with an adjuvented preparation of either soluble NiV-G or HeV-G were protected against a subsequent virus challenge (Mungall et al., 2006). The different studies show that protection by vaccination is possible using different preparations of the two viral glycoproteins. However, there is no information on long-term immunity provided by such vaccines.

LABORATORY DIAGNOSIS OF HENIPAVIRUS

Virus identification is a key element in the control of the disease. Henipaviruses grow in a number of human and animal cell lines to high titers, inducing cell syncitia. Due to the lack of BSL-4 facilities in endemic regions for NiV, cell cultures could be handled in BSL-3, but then transferred to BSL-4 containment if any further work has to be carried out. Virus identification is performed either by indirect immunofluorescence of virus-infected cells using group- and type-specific monoclonal antibodies, or RT-PCR on extracts of cell supernatants using specific primers or probes. Several RT-PCR and real-time PCR protocols have been developed for both HeV and NiV (Smith et al., 2001; Guillaume et al., 2004b; Chang et al., 2006; Wacharapluesadee and Hemachudha, 2007). TaqMan assay is usually used for virus genome detection in serum, CSF or urine of patients and animals. Several genes have been targeted depending of the specificity required. The relatively conserved matrix protein M has been used for HeV and NiV gene amplification. But comparative nucleotide sequences available for most of henipaviruses would be valuable to synthesize a set of primers with broad specificity to detect all known viruses in the Henipavirus genus. However, the specificity of each current technique should be validated with NiV variants from Bangladesh, since the probe used in Taqman technique may by too discriminative.

Histology and immunohistology of clinical samples have great value when polyclonal and monoclonal antibodies are available. In particular, antibodies against nucleoprotein of henipaviruses can identify intracellular inclusions in fixed tissues (Wong et al., 2002; Tanimura et al., 2004).

Electron microscopy is one element essential to identify new emerging viruses and should be performed on supernatant and virus-infected cells (Murray et al., 1995; Chua et al., 2000a).

IgM and IgG titration of henipaviruses can be performed by ELISA and neutralization tests. Clinical samples are serum or CSF. Usually, antigens used for ELISA tests are crude extracts from virus-infected Vero cells (Daniels et al., 2001) or recombinant proteins expressed in *E. coli* (Yu et al., 2006; Chen et al., 2006; Kashiwazaki et al., 2004). Reactions should be validated using recombinant F, G, and M proteins prepared in baculovirus-infected insect cells (Esheragi et al., 2005). However, these in-house tests are limited and no commercial kit has been developed up to now. The reference technique remains the seroneutralization test with microplaques, which provides an accurate and specific way to calculate antibody dilution in serum or CSF that neutralize 50% of cell toxicity caused by NiV or HeV ($TCID_{50}$). This test is restricted to BSL-4 laboratories in which live virus can be manipulated. However, production of virus NiV pseudotyped particles was recently made from VSV-ΔG-Luc or VSV-ΔG-GFP viruses, recombinant VSV derived from a full-length complementary DNA clone of VSV in which the G-protein envelope has been replaced with Luciferase or EGFP reporter genes

(Negrete et al., 2006; Patch et al. 2007; Porotto et al., 2007). NiV or HeV envelope proteins F and G were provided in trans, and the VSV-ΔG-NiV and VSV-ΔG-NiV pseudotyped viruses collected from transfected cells were used to transduce new cell's cell lines. Positive neutralization of the pseudotypes by anti-NiV or anti-HeV can then be followed by inhibition of transduction recorded by absence of luciferase or fluorescence (GFP) activity in cells 1 day posttransduction. This very sensitive and rapid test can be used for large series of seroneutralization and epidemiological investigations in BSL-2 containment. Another recent technique does not use live virus but rather the binding inhibition of protein G to ephrin-2 receptor fixed on beads as a new test of anti-NiV neutralizing antibodies (Bossart et al., 2007).

PROSPECTS FOR THE FUTURE

Henipavirus circulation in Southeast Asia should be monitored on a large scale in bats by ELISA and seroneutralization using recombinant technologies. These techniques should be included in any serodiagnosis of encephalitis in all potential endemic countries for NiV where fatal cases are recorded. Epidemiological investigations should address the cause of NiV emergence and the mechanisms of virus transmission from the reservoir to intermediary host and finally to humans (Epstein et al., 2006). The possible role of vectors, such as ticks that feed on bats and occasionally on other animals should be clarified. Countermeasures to prevent virus transmission to livestock and humans should be implemented and information to targeted populations should be diffused. Epidemiologists and health workers should be prepared to identify any unusual clinical manifestation where a bat could be involved. Better prophylaxis and treatments available at low cost to hamper any spread of virus in an epidemic area should be developed in research laboratories and tested in preclinical and clinical trials.

KEY ISSUES

- Endemicity of NiV in Southeast Asia and recurrent outbreaks in Bangladesh with possible human-to-human transmission (Gurley et al., 2007) highlight the importance and urgency of establishing a strong surveillance system supported by a network of laboratories equipped to handle and diagnose highly pathogenic viruses and including patient intensive care units, use of appropriate personal protective equipment, barrier nursing, and safe disposal of potentially infected material in the prevention and control measures for NiV/HeV virus infection.
- Although the major impact of Henipaviruses is human illness, the release of those zoonotic agents would have consequences for both humans and animals because infected and non-infected animals might need to be sacrificed to control the spread of infection. Continued research is necessary to develop effective strategies to limit the impact of these biological threats. Although it is possible to protect animals by vaccination and also by passive administration of antibodies, the main question is if a vaccine is developed should it be for humans or aimed to create a barrier in the domestic animal population such as pigs? The latter policy would be relevant in Malaysia were the pig was an intermediate and amplifying host, but in countries such as Bangladesh, man was infected possibly after drinking contaminated date palm sap (Luby et al., 2006). Before developing a vaccine for humans, it is necessary that the number of cases due to NiV infection be evaluated. It is obvious that until now due to a lack of viral reagents, the number of encephalitis cases due to NiV has been largely underestimated.
- It is highly probable that flying foxes harboring viruses like henipaviruses will continue to be displaced from their native habitat by natural or human forces and will come in close contact with human population or spillover hosts. Accidental or deliberate spray of NiV in pig farms may have a huge economical impact but could be limited if the virus is rapidly identified. Its transmission by aerosol, either by contaminated spillover host or through human-to-human transmission, could be rapidly blocked. But if it is like avian flu or SARS, one henipa-like virus becomes highly transmissible to humans by infecting cells of the upper respiratory tract, it would potentially cause a worldwide threat. Thus, henipaviruses should be considered as potential agents of bioterrorism (Lam, 2003) and handled in strict biosafety condition and security containments.

OUTLINE

ABSTRACT

At the individual level, vaccines have the potential to modulate the severity of illness as well as eliminate or reduce the likelihood of transmission of the pathogen to others making vaccination one of the most effective disease intervention tools available. Several vaccines against arthropod-borne viruses (arboviruses), including yellow fever virus and Japanese encephalitis virus, have been developed and are in widespread use. As there are approximately 600 known arboviruses, many of which cause severe human disease, additional vaccine development is warranted.

Among the arboviruses pathogenic to humans are chikungunya (CHIKV) and o'nyong-nyong (ONNV) viruses. These viruses cause explosive outbreaks and induce a prolonged, debilitating arthralgic illness that can

have a dramatic impact on the affected communities. "Despite these facts, there are no therapeutics or vaccines commercially available for either virus". Preliminary vaccine development and characterization has been initiated for CHIKV leading to Phase 2 human clinical trials. Results from these studies have been promising to date. Unfortunately, the marketability of a vaccine against this virus is uncertain thus limiting the rapid development of a commercial product. As epidemics of illness caused by both CHIKV and ONNV continue to occur with greater intensity and frequency, the possibility of producing a vaccine for widespread distribution may also be more likely. This chapter describes the biology, ecology, and epidemiology of these viruses providing a framework from which to propose and support alphavirus vaccine development.

INTRODUCTION

Arthropod-borne viruses (arboviruses) are the causative agents of some of the most important emerging infectious diseases that are significant, global, public health problems (Gubler, 2001). One group of these viruses transmitted by invertebrate vectors belongs to the family *Togaviridae* and cause diseases ranging from mild febrile illness, polyarthritis, or encephalitis. Two of these viruses, chikungunya virus (CHIKV) and o'nyong-nyong virus (ONNV) are geographically widespread, are associated with severe morbidity, and can cause explosive outbreaks. The lack of specific therapeutics, prophylaxis, or antiviral treatments against these agents clearly highlights the need for an effective vaccine as a first-line defense that can quickly generate strong immunity. However, to accomplish this objective, for CHIKV and ONNV, there is first a need to develop a deeper understanding of the basic pathogenesis and biology of these viruses. A more complete study of the ecology, epidemiology, host immunology, and virus–vector interactions, as well as development of appropriate animal models for disease studies all require additional research for the design and implementation of an appropriate and efficacious vaccine program. Significant progress toward identifying a highly protective vaccine against CHIKV has already been well initiated as described below and further knowledge will continue to improve the likelihood of success.

HISTORY OF THE DISEASE

Chikungunya

CHIKV was first isolated from the serum of a febrile human in Tanganyika (Tanzania) in 1953 during an epidemic of dengue-like illness (Robinson, 1955; Ross, 1956). The highest disease incidence occurred on the Makonde plateau, an area devoid of woodland habitat, and was documented as a disease completely new to the area (Lumsden, 1955; Casals and Whitman, 1957). While the initial assessment was that the outbreak was due to a dengue virus (a flavivirus), serological and antigenic characterization of the isolates from the outbreak indicated that it was an alphavirus closely related to Mayaro and Semliki Forest viruses (Casals and Whitman, 1957; Spence and Thomas, 1959). Since that original epidemic and identification of the etiological agent, a significant period of CHIKV activity occurred between the 1960s and 1980s when the virus was isolated repeatedly from numerous countries in central and southern Africa as well as in Senegal and Nigeria in western Africa. Some of the outbreaks that occurred in Africa during this period included those in Senegal in 1962, Uganda's Entebbe area in 1968 (McCrae et al., 1971), and South Africa from 1975 to 1977 (Jupp and McIntosh, 1988). The virus also spread from these African origins to the Asian continent where frequent outbreaks have been reported covering Malaysia, Indonesia, India, Cambodia, and Thailand from 1960s to 2003 (Chastel, 1963; Jadhav et al., 1965; Myers et al., 1965; Rao et al., 1965; Munasinghe et al., 1966; Rao, 1966; Halstead et al., 1969a, 1969b, 1969c, 1969d; Nimmannitya et al., 1969; Thaung et al., 1975; Marchette et al., 1978; Thein et al., 1992; Thaikruea et al., 1997; Lam et al., 2001; Mourya et al., 2001; Kit, 2002; Laras et al., 2005). Numerous large cities in Southeast Asia including Calcutta and Bangkok have been identified as particularly active sites of transmission and disease (Pavri, 1964; Sarkar et al., 1965b; Halstead et al., 1969c; Burke et al., 1985). Recently, there has been a resurgence of CHIKV outbreaks with major disease clusters documented in Democratic Republic of the Congo (Nur et al., 1999; Pastorino et al., 2004), Ivory Coast in 1996/1997 (Thonnon et al., 1999), Senegal in 1986 and 1996/1997 (Diallo et al., 1999), Indonesia in 2003 (Porter et al., 2004; Laras et al., 2005), Comoros in 2005 (Sergon et al., 2007), Reunion in 2006 (Schuffenecker et al., 2006), and India in 2006/2007 (Arankalle et al., 2007). Retrospective reviews have also suggested that CHIKV epidemics occurred as early as 1779 but were frequently documented inaccurately as dengue outbreaks (Carey, 1971). Overall, CHIKV has caused numerous well-documented outbreaks in both Africa and Southeast Asia, involving hundreds of

FIGURE 32.1 Geographic distribution of (a) ONNV and (b) CHIKV. Viral activity has been documented by viral isolation or serological detection of virus-specific antibodies.

thousands of people (Fig. 32.1). Outbreaks continue to occur with increased frequency and new geographic areas are likely to be involved (Jupp and Kemp, 1996).

O'nyong-nyong

In 1959, one of the largest arboviral epidemics ever documented began in the Acholi region of Uganda and subsequently swept across East Africa, involving over 2 million reported cases and lasting over 3 years (Haddow et al., 1960; Johnson, 1988). The clinical features of the disease resembled those of both chikungunya and dengue with primary symptoms including fever, severe joint and back pain, and rash. During the course of the outbreak, affected regions were estimated to have over 50% of the population

affected (Williams et al., 1965b). A viral isolate was obtained from the serum of a febrile patient and was determined to be closely related to but distinct from CHIKV. The virus was given the name o'nyong-nyong virus (ONNV) after the Acholi word for "very painful and weak" that had come to be associated with the disease (Williams and Woodall, 1961). The virus effectively disappeared until 1996 when the second documented ONNV epidemic occurred in southern Uganda (Rwaguma et al., 1997; Lanciotti et al., 1998; Kiwanuka et al., 1999; Sanders et al., 1999). This outbreak began in the rural south-central regions of Uganda and, over a period of several months, extended into several adjacent areas focusing primarily near lakes and swamps. The outbreak was so extensive that the infection rate in affected areas was estimated to be nearly 70% (Sanders et al., 1999). Between 1962 and 1996, only sporadic evidence of ONNV transmission was documented with some of these infections determined to be caused by Igbo Ora virus, a serological subtype of ONNV (Moore et al., 1975; Woodruff et al., 1978; Marshall et al., 1982; Lhuillier et al., 1988; Olaleye et al., 1988, 1990). During 2003, another outbreak of febrile illness found to be caused by ONNV was reported among Liberian refugees in western Cote d'Ivoire (Posey et al., 2005). While ONNV is extremely closely related to CHIKV, the outbreak patterns and distribution of the two viruses are quite distinct with ONNV causing only periodic massive epidemics in contrast to the more frequent CHIKV outbreaks.

ETIOLOGIC AGENT(S): *CLASSIFICATION AND ANTIGENS ENCODED BY AGENT*

Both CHIKV and ONNV are members of the *Alphavirus* genus in the family *Togaviridae*. The only other genus within the *Togaviridae* is the *Rubivirus* genus whose sole species is Rubella virus (Weaver et al., 2005). The *Alphavirus* genus consists of 29 distinct species that either cause encephalitis, febrile illness with arthralgia, or are not known to cause disease in humans. The members are primarily vector-borne with nearly all utilizing mosquitoes as their invertebrate vectors.

Like all alphaviruses, CHIKV and ONNV have a genome consisting of a linear, positive sense, single-stranded RNA molecule of approximately 11.8 kb. The genomes of CHIKV and ONNV have both been sequenced, Khan et al. (2002) and Strauss et al. (1988), respectively and are 11,826 and 11,835 nucleotides in length, respectively. The nonstructural proteins, required for viral replication, are encoded in the 5′ two thirds of the genome, while the structural genes are collinear with the 3′one-third (Fig. 32.2). The structural proteins are produced by translation of an mRNA that is generated from an internal, subgenomic promoter immediately downstream of the nonstructural open reading frame. The 5′ end of the genome has a 7-methylguanosine cap while the 3′ end is polyadenylated. CHIKV and ONNV have 3′ noncoding regions of 503 and 425 nucleotides, respectively; the repeat sequence elements present in this region of the two virus species are distinct and generate different predicted secondary structures (Levinson et al., 1990; Pfeffer et al., 1998; Khan et al., 2002). Additionally, an internal polyadenylation site [I-poly (A)] of variable length has been identified in the 3′ noncoding region of one CHIKV genome (Khan et al., 2002) but no comparable I-poly (A) has been found in ONNV or other CHIKV strains.

There are four nonstructural genes, designated nsP1-4. All of these proteins are necessary for viral replication and each has specific functions in this process. The nsP1 protein is required for initiation of synthesis of minus-strand RNA (Sawicki et al., 1981; Wang et al., 1991; Sawicki and Sawicki, 1998) and has an additional function as a methyltransferase to cap the genomic and subgenomic RNAs during transcription (Durbin and Stollar, 1985; Mi and Stollar, 1991; Strauss and Strauss, 1994). The nsP2 protein has RNA helicase activity in its N-terminus (Hodgman, 1988; Gorbalenya et al., 1990) while the C-terminal domain functions as a proteinase for the alphavirus nonstructural polyprotein (Ding and Schlesinger, 1989; Hahn et al., 1989; Hardy and Strauss, 1989). There are three sites in the nonstructural polyprotein that are cleaved by both nsP2 and polyproteins containing nsP2, but the cleavage-site preferences of the different polyproteins vary. Differential cleavage results in alternative processing pathways for the nonstructural polyprotein at different times during the infections process (de Groot et al., 1990). For example, early during infection, P123 and P1234 (made by read-through translation of a stop codon present between

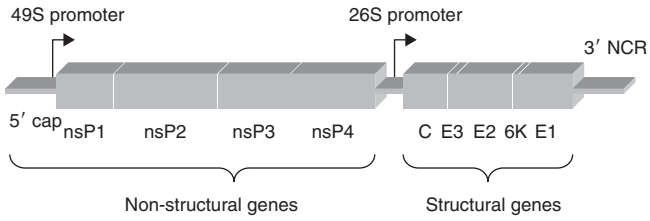

FIGURE 32.2 Arrangement of CHIKV and ONNV genes and genetic elements.

the nsP3 and nsP4 genes) are produced by translation of the genomic mRNA. As the infection proceeds, P123 cleaves between nsP1 and nsP2 to produce nsP1 and P23. The P23 polyprotein is autoproteolytic; it cleaves itself to generate the individual nsP2 and nsP3 proteins. It is likely that the nsP2 proteinase activity has a regulatory function by modulating the rate of viral replication. The functions of the nsP3 gene are not fully understood. This protein consists of two domains, a widely conserved N-terminal domain and a hypervariable carboxy terminus (Strauss et al., 1988; LaStarza et al., 1994b). The C-terminal region has been shown to tolerate numerous mutations, including large deletions, and still produce viable viral particles in vertebrate cells (Davis et al., 1989; Li et al., 1990). Interestingly, some nsP3 mutations in one alphavirus, Sindbis, while doing little to impair replication in mammalian cells, significantly reduced the replicative ability of the virus in mosquito cells (Lastarza et al., 1994a) suggesting that this gene may aid in defining cell type and invertebrate vector specificity. The final nonstructural protein, nsP4, is presumably the viral RNA-dependent RNA polymerase due to the characteristic GDD motif (Kamer and Argos, 1984).

The structural gene products are generated by translation of a subgenomic message to produce a polyprotein that is processed to produce a capsid protein, the two major envelope surface glycoproteins (E1 and E2) as well as two small peptides, E3 and 6K (Simizu et al., 1984; Strauss and Strauss, 1994). The highly conserved capsid protein associates with the nascent positive sense viral RNA to generate nucleocapsids. E1 and E2 are posttranscriptionally modified in the endoplasmic reticulum and Golgi apparatus before being transported to the plasma membrane (Schlesinger and Schlesinger, 1986) where they maintain a close association with each other forming a dimeric spike structure (Anthony and Brown, 1991; Paredes et al., 1993). As virion formation proceeds, the cytoplasmic nucleocapsids are trafficked to the cell membrane where they bind to the surface glycoproteins before budding from the cell (Garoff and Simons, 1974; Ekstrom et al., 1994; Garoff et al., 1998). The E2 protein, in particular, has been found to be an important determinant of antigenicity and cell receptor binding in both the vertebrate host and the insect vector for other alphaviruses. In mice, a single mutation in the Venezuelan equine encephalitis virus (VEEV) E2 glycoprotein delayed replication of the mutant by almost 2 days and significantly reduced the pathogenicity of the virus (Davis et al., 1994), while in the insect, one VEEV strain, containing a single mutation in the E2, was restricted in its ability to disseminate from the midgut following oral infection (Woodward et al., 1991). Additionally, the E2 gene has been implicated in increased vector infection of epizootic mosquito vectors (Brault et al., 2002, 2004).

PROTECTIVE IMMUNE RESPONSE

Both CHIKV and ONNV are highly immunogenic and generate strong antibody responses that are hallmarks of the infection. Antibodies are generated quite early in infection as documented by serological assays using either serum or cerebral spinal fluid (CSF). Serum samples from CHIKV infections collected within 5 days of symptom onset are typically free of neutralizing (N), complement-fixing (CF), and hemagglutination inhibiting (HI) antibodies. However, samples collected as early as 2 weeks postinfection already contain substantial levels of both N and HI antibodies (Carey et al., 1969; Nimmannitya et al., 1969). Additional information on N antibodies against CHIK and ONN viruses has been obtained from serosurveys following outbreaks and during interepidemic periods (Salim and Porterfield, 1973; Rodhain et al., 1989; Adesina and Odelola, 1991). For example, after the 1996–1997 ONNV outbreak in Uganda, 45% of the people surveyed in affected areas had ONNV-specific antibodies (Sanders et al., 1999). An interepidemic serosurvey, conducted in the early 1970s in Sudan, demonstrated 13% and 23% of those tested had neutralizing antibodies against CHIKV and ONNV, respectively (Salim and Porterfield, 1973). High-titered CHIKV neutralizing antibody levels have also been detected in laboratory workers infected by occupational exposure (Tomori et al., 1981).

While both viruses generate high titered N antibodies, these antibodies are not equally cross-neutralizing even though the viruses are extremely closely related. This is and will be an important consideration for vaccine development against the species pair. Single dose (infection immune) antisera reveal a one-way difference in neutralization of homologous versus heterologous viruses. Early studies indicated that CHIKV immune serum could neutralize both CHIKV and ONNV while ONNV antisera neutralized only the homologous virus (Porterfield, 1961; Karabatsos, 1975; Chanas et al., 1976). One study designed to further characterize this one-way relationship compared small and large plaque variants of CHIKV with one strain of ONNV (Chanas et al., 1979). This study revealed that antiserum against ONNV did not neutralize CHIKV to detectable levels but that nonneutralizing antibodies did, in fact, bind to the CHIK virions. At the time, it was suggested that the arrangement of the antigens on the CHIKV virions was sufficiently different to

keep heterologous antibodies from effectively neutralizing the virus. Further studies utilized panels of monoclonal antibodies (mabs) to elucidate the interactions between CHIKV, ONNV, and antibodies against the two viruses. In this study, the authors again found that the majority of CHIKV-specific mabs would react with ONNV but as few of 12% of the mabs generated against ONNV were reactive against certain strains of CHIKV. The results of this study suggested that ONNV had certain antigenic epitopes that were unique to the envelope proteins of this virus and thus, would not bind the closely related CHIKV (Blackburn et al., 1995). The changes in the ONNV glycoprotein epitopes that are reflected by the inability of ONNV mabs to bind CHIKV may correlate with the distinctive ability of ONNV to infect anopheline mosquitoes while the other alphaviruses lack this capacity. Development of vaccines against CHIKV and ONNV would need to consider these epitope differences if broad cross-protection were to be obtained.

The role of cell-mediated immunity has not been extensively studied for either CHIKV or ONNV infections. Due to the lack of mortality associated with these viruses and the frequent misdiagnosis of dengue for CHIKV or ONNV infections, these alphaviruses have not been considered high priority agents until recently. However, another alphavirus in the Semliki Forest antigenic complex, Ross River virus (RRV), was shown to induce the proliferation of T-lymphocytes in infected mouse spleen cells (Aaskov et al., 1983). Curiously, little virus-specific cytotoxic activity was detected in these cells. Studies with other alphaviruses (Semliki Forest and Sindbis) demonstrated that cytotoxic T-lymphocyte (CTL) activity correlated with clearance from peripheral blood (Peck et al., 1979; Blackman and Morris, 1984); however, this CTL activity was not believed to protect against acute alphavirus viremia (Kagi and Hengartner, 1996). Recent work describing the characterization of an alphavirus CD8 CTL epitope that localizes to the capsid protein found that the epitope was conserved across many of the Semliki Forest complex viruses including CHIKV and correlated with CTL cross-reactivity from mice that had been infected with these viruses (Linn et al., 1998). Further examination of the role of CMI in CHIKV and ONNV infections is certainly warranted.

EPIDEMIOLOGY

For two viruses that are so closely related, both serologically and genetically, CHIKV and ONNV have curiously distinct transmission cycles and epidemiology, a condition that could impact any broad control or vaccine strategies for these agents. Geographically, ONNV is fairly restricted with its range limited to select portions of Africa (Fig. 32.1); the virus has been isolated in samples collected from Uganda, Kenya, Tanzania, Malawi, Mozambique, Cameroon, and the Central African Republic (Woodall et al., 1963; Johnson, 1988). The antigenic subtype Igbo Ora has additionally been identified in the Central African Republic and Nigeria, extending the geographic range of ONNV to western Africa (Moore et al., 1974, 1975; Olaleye et al., 1989). In contrast, CHIKV is prevalent throughout Africa as well as Southeast Asia and parts of Oceania. The virus causes not only large outbreaks throughout this distribution but appears to be enzootic across tropical regions of Africa. Molecular epidemiological studies have suggested that CHIKV originated in Africa and subsequently moved to Asia and the Indian Ocean areas (Powers et al., 2000) and that lineages are continually circulating even in the absence of identified vertebrate hosts (Yadav et al., 2003b).

The major distinction between the two viruses is that they are transmitted not only by different species of mosquitoes but by vectors that are in different families. In fact, ONNV is distinct among alphaviruses in that it is the only species to be principally vectored by anopheline mosquitoes; all the other alphaviruses utilize culicine species in their transmission cycles. The majority of mosquitoes collected in both the 1959–1962 and 1996–1997 outbreaks were found to be primarily endophilic and the epidemic transmission of ONNV is most certainly between man and infected *Anopheles gambiae* and *Anopheles funestus* mosquitoes (Corbet et al., 1961; Williams et al., 1965a; Johnson, 1988; Lutwama et al., 1999). During both outbreaks, *An. funestus* was the most abundant mosquito collected and isolates of ONNV were obtained during each epidemic from this species. An isolate was also obtained from *An. funestus* during the interepidemic period in 1978 suggesting that this mosquito may also be involved in the enzootic maintenance cycle (Johnson et al., 1981). *An. gambiae* was incriminated as a vector during the first outbreak but there were too few of this species collected during the second outbreak to confirm its role as an epidemic vector. Additionally, an isolate of ONNV was recovered from a pool of *Mansonia uniformis* during the 1996–1997 outbreak and previous literature has suggested that *Mansonia* species mosquitoes may be ONNV vectors (Haddow et al., 1960; Lutwama et al., 1999). The 1997 isolate was the first ever recorded from a *Mansonia* species so the epidemic and maintenance potential of mosquitoes in this genus remains to be determined.

In sharp contrast to ONNV, CHIKV in the West and Central Africa range appears to be maintained in a sylvatic cycle involving wild nonhuman primates and forest-dwelling *Aedes* spp. mosquitoes. The virus has been isolated from sylvatic mosquito species in several countries including Senegal, Cote d'Ivoire, Central African Republic, and South Africa. The mosquito species involved vary geographically and with ecological conditions; however, the major species involved in sylvatic cycles are *Aedes furcifer*, *Aedes taylori*, *Aedes luteocephalus*, *Aedes africanus*, and *Aedes neoafricanus* (McIntosh et al., 1977; Jupp and McIntosh, 1988; Diallo et al., 1999). Isolates of CHIKV have been obtained from all these species but the principal vectors during epidemics in these geographic regions appear to be members of the *Ae. furcifer-taylori* group (Jupp and McIntosh, 1990). In these primarily rural regions the outbreaks have tended to be of smaller scale and appear to be heavily dependent upon the sylvatic mosquito densities that increase with periods of heavy rainfall (Lumsden, 1955).

While forest-dwelling mosquito species are primary vectors in West and Central Africa, the urban mosquito *Aedes aegypti* has been found to be the most significant vector in Asia with virtually all Asian mosquito isolates coming from this species. These are urban and peridomestic, anthropophilic mosquitoes that maintain close associations with humans and thus, are likely to be responsible for the much larger outbreaks documented there. Urban or large outbreaks in East Africa are also likely associated with the presence of *Ae. aegypti* mosquitoes. Numerous laboratory studies have examined distinct populations of *Ae. aegypti* to understand the variable susceptibilities of this species in the transmission of CHIKV (Soekiman, 1987; Banerjee et al., 1988; Mourya et al., 1994). Other common peridomestic species, including *Aedes albopictus*, *Aedes vittatus*, and *Anopheles stephensi*, that have been found in abundance in CHIKV endemic areas have also been assessed for their vectorial capacity (Tesh et al., 1976; Soekiman et al., 1986a, 1986b; Mourya, 1987; Mourya and Banerjee, 1987; Turell et al., 1992, Yadav et al., 2003a). All three of these species were found to be competent vectors in the laboratory; their role as primary vectors in urban outbreaks of CHIKV disease should be considered.

Numerous field and laboratory studies have been conducted on the mosquito vectors involved in the transmission of CHIKV and ONNV. Unfortunately, there is far less information on the vertebrate hosts involved in viral maintenance. Most of the speculation regarding potential vertebrate reservoirs has been derived from serosurveys and laboratory animal studies that have demonstrated the presence of antibodies against these viruses (McIntosh, 1961; Paul and Singh, 1968; Bedekar and Pavri, 1969; Johnson et al., 1977; Marshall et al., 1982). Both humans and wild nonhuman primates throughout the humid forests and semiarid savannas of Africa have been found to have significant antibody levels against CHIKV. It is postulated that the appearance of CHIKV epidemics follows a 3–4 year cyclical pattern that coincides with the repopulation of susceptible, nonimmune, wild primates (Jupp and McIntosh, 1988). To date, a vertebrate reservoir or sylvan transmission cycle for CHIKV has not been identified outside Africa. Similarly, a vertebrate host for ONNV has not been determined although antibody has been detected in cattle, goats, lizards, and several species of rodents (Johnson et al., 1977).

The two major ONNV epidemics were both extensively characterized epidemiologically and revealed that the virus moved extremely rapidly through the affected areas and infected a significant proportion of the population (Lumsden, 1955; Ross, 1956; Williams et al., 1965b; Sanders et al., 1999). In 1959–1961, over 2 million people were infected during the 2-year outbreak. Similarly, during the 1996 outbreak infection rates were estimated to be as high as 68% with attack rates over 40% (Sanders et al., 1999). CHIKV outbreaks have varied dramatically in magnitude depending upon whether the outbreak was localized to urban or rural settings. However, in both settings, the attack rate has been found to be significant and comparable; morbidity rates between 30% and 70% are typical with postoutbreak seroprevalence rates commonly ranging from 50% to 80% (Halstead et al., 1969c; Padbidri and Gnaneswar, 1979; Jupp and McIntosh, 1988). The seropositivity rate has been found to be slightly lower in rural outbreaks suggesting that the vectors transmitting the virus in rural ecological settings have insufficient human contact or are less efficient at transmission to human hosts (McCrae et al., 1971). Rates of immunity are also lower in young children as is the percentage of people over 60 years of age demonstrating clinical illness during outbreaks. This indicates that the virus produces long-lived antibody that is presumably protective for life (Kokernot et al., 1965a, 1965b; Reuben, 1967). Occupational exposure differences to mosquitoes are likely the cause of any higher incidence rates that may be associated with males compared with females.

Although mortality is not a major concern of either ONNV or CHIKV infection, these viruses are still significant public health problems. The acute phase of the illness causes fever and joint pain that is so incapacitating that inactivity for several weeks is not uncommon. With the accompanying high attack rate, this can lead to crippling absenteeism rates as well as a significant

drain on local health care systems. For example, in the initial ONNV outbreak, up to 10% of the local workforce was ill at any given time with 25% being incapacitated for 5 days or more (Williams et al., 1965b).

POTENTIAL BIOTHREAT AGENT

Neither CHIKV nor ONNV has been classified as potential biothreat agents as the encephalitic alphaviruses VEEV, eastern equine encephalitis virus (EEEV), and western equine encephalitis virus (WEEV) have been. However, CHIKV has been documented to cause laboratory infections that could be associated with aerosol route of transmission so the possibility of using this virus as an aerosolized biothreat agent cannot be completely excluded.

CLINICAL DISEASE

A classic triad of signs for CHIKV and ONNV infection includes fever, arthralgia, and rash that may or may not be accompanied by other indicators of disease (Deller and Russell, 1967; Tesh, 1982; McGill, 1995; Adebajo, 1996). The overall clinical illness is virtually identical between these two alphaviruses but there are occasional distinctions that may be suggestive markers for differential diagnosis in regions where the viruses overlap (Fig. 32.1 for geographic distributions).

CHIK virus infection produces an illness in humans that typically begins with a sudden onset of fever reaching as high as 104°F (Deller and Russell, 1967) that may last as long as 10 days. The fever almost always precedes the rash and joint pain and has occasionally been reported as biphasic with the recurrence noted on the 4th or 5th day of illness (Robinson, 1955; Jadhav et al., 1965). Additionally, there have been reported cases of febrile convulsions in young children (Moore et al., 1974). Fever is also documented with ONNV infection; however, it usually ranges from 99°F to 101°F and lasts for only 2–3 days. No biphasic fevers have been reported for ONNV.

The rash associated with infection is maculopapular and erythematous in character, is visible starting 2–5 days postinfection, and may last up to 10 days. The nonpruritic rash is distributed primarily on the face, limbs, and trunk of the body. There has also been infrequent documentation of hemorrhagic manifestations including hematemesis and melena due to CHIKV infection in Southeast Asia (Sarkar et al., 1965a) where hemorrhagic disease is typically attributed to infection with dengue viruses.

Perhaps the most significant manifestation of the illness associated with these viruses is the severe joint pain that occurs with virtually every clinical case (Deller and Russell, 1968; Fourie and Morrison, 1979). Even the names given to the virus indicate the degree of discomfort caused: "chikungunya" is Makonde meaning "that which bends up" and "o'nyong-nyong" is an Acholi word for a similar sentiment. The arthralgia is most commonly symmetrical and peripheral being noted in the ankles, toes, fingers, elbows, wrists, and knees. The joints exhibit extreme tenderness and swelling with the patients frequently reporting incapacitating pain that lasts for weeks or months. Paresthesia of the skin over the affected joints is common with CHIKV infection suggesting neurological involvement but no evidence of neurologic sequelae have been observed. Most infections completely resolve at that time but there have been documented cases of CHIKV-induced arthralgia persisting for several years (Brighton et al., 1983; McGill, 1995) with up to 12% of patients with CHIKV disease developing chronic joint problems (Calisher, 1999). In a rare instance, the rheumatic manifestations resulted in joint destruction before resolution after numerous years (Brighton and Simson, 1984).

Other symptoms that have been reported with CHIKV or ONNV infection include headache, retroorbital pain, photophobia, lumbar back pain, chills, weakness, malaise, nausea, vomiting, and myalgia (Shore, 1961; Brighton, 1981; Johnson, 1988; McGill, 1995; Calisher, 1999). Some combination of these symptoms is generally reported by all patients but their presence and frequency are variable. Additionally, signs including conjunctivitis, pharyngitis, and lymphadenopathy may be observed. In particular, enlargement and tenderness of the cervical lymph node is frequently quite severe and a distinctive characteristic of ONNV infection. Other nodes including the postoccipital, axillary, and inguinal may also be enlarged.

Occasionally, unusual clinical presentation due to CHIKV infection has been observed. For example, one study revealed evidence of myocarditis after acute febrile illness and serologic evidence of CHIKV infection (Obeyesekere and Hermon, 1972, 1973). Presentation included sinus tachycardia, ventricular ectopics, cardiomegaly, and abnormal electrocardiograms. Signs of congestive heart failure were documented several months after initial illness. Cases of mortality, neurological disease, and intrauterine transmission were also reported in the 2006 Reunion outbreak (Schuffenecker et al., 2006; Powers and Logue, 2007). While clinical cases of this nature are not typical, they serve as a reminder that the viruses may have diverse and perhaps evolving patterns of virulence.

Laboratory parameters for CHIKV or ONNV infections can be quite variable and frequently do not aid in diagnosis. Results include a normal hematocrit (varying from 40% to 50%), thrombocytopenia or alternatively, no obvious platelet deficiencies, normal urinanalysis, and low to normal WBC counts of 4000–7000 although leukocytosis has been documented (Shore, 1961; Jadhav et al., 1965; Deller and Russell, 1968; Tesh, 1982). The erythrocyte sedimentation rate may be slightly elevated which is suggestive of rheumatoid arthritis and may confound diagnosis of isolated CHIKV infections. Overall, standard laboratory testing is of little value and diagnosis is dependent upon isolation of virus or confirmation of virus-specific antibodies using acute and convalescent sera. Diagnosis is facilitated during large epidemics while small rural outbreaks or individual cases are often never diagnosed. Unfortunately, the symptoms of both CHIKV and ONNV infection are quite similar to those of many other pathogens affecting people in the endemic areas. One particular difficulty in identifying the widespread nature of CHIKV infection is its overlapping distribution with dengue viruses. Because the clinical symptoms of CHIKV infection often mimic those of dengue fever and because CHIKV circulates in regions where dengue virus is endemic, it has been postulated that many cases of dengue virus infection are misdiagnosed and that the incidence of CHIKV infection is much higher than previously reported (Myers and Carey, 1967; Carey, 1971).

TREATMENT

Because both CHIKV and ONNV induce nonfatal, self-limiting diseases, treatment is entirely supportive for the symptoms. With the primary signs including fever and joint pain with swelling, analgesics, antipyretics, and anti-inflammatory agents are the most appropriate treatment. Commonly, these agents would include aspirin but due to the reports of possible hemorrhagic manifestations, aspirin should be avoided in favor of other options (Tesh, 1982) including acetaminophen, ibuprofen, steroid therapy, and nonsteroidal agents such as indomethacin. However, as some of these therapies can have serious side effects, the need for prolonged use should be a consideration in treatment regimens. For chronic cases of arthritis due to CHIKV, chloroquine phosphate was shown in one study to provide relief to patients that had limited response to nonsteroidal anti-inflammatory drugs (Brighton, 1984). Additional actions including bed rest and fluids are recommended.

The lack of specific treatment for CHIKV and ONNV infection has prompted laboratory studies to identify antiviral agents effective against these viruses. Compounds including ribavirin, sulfated polysaccharides (iota carrageenan, fucoidan, and dextran sulfate), 6-azauridine, glycyrrhizin, and interferon-α have been evaluated for their ability to inhibit replication of CHIKV in cell culture. With the exception of the polysaccharides, all were found to have both potent and selective antiviral activity (Briolant et al., 2004). Additionally, these four compounds have demonstrated efficacy in the treatment of other diseases (Deneau and Farber, 1975; Andrei and De Clercq, 1993, Grieder and Vogel, 1999; van Rossum et al., 1999; Ryman et al., 2000) warranting additional testing for their use against these arthralgic alphaviruses. In particular, multidrug therapies may prove useful as each treatment has distinct pharmacological actions that may produce synergistic effects as well as reduce the likelihood of resistance.

PATHOGENESIS

While numerous field and laboratory studies have investigated serological outcomes of CHIKV or ONNV infection, virtually no effort has been placed on direct examination of the mechanism(s) of pathogenesis due to infection with these viruses. However, several recent papers elucidating the molecular and cellular aspects of RRV disease development may also be applicable to CHIKV and ONNV infections. RRV is another alphavirus in the Semliki Forest antigenic complex and is closely related to both CHIKV and ONNV genetically. Additionally, RRV causes epidemic polyarthritis generating a pattern of illness including rheumatic symptoms, rash, and fever (Harley et al., 2001) similar to that seen with CHIKV and ONNV. Also, like CHIKV disease, the symptoms may persist for several months with prolonged painful arthralgia suggesting the development of disease may result from similar pathways.

RRV patients with chronic joint pain were found to have viral antigen in the synovial fluid and this virus attracted inflammatory infiltrates to the affected joints (Rulli et al., 2005). CHIKV patients with prolonged joint pain demonstrated high titers of specific antibodies suggesting persistent antigen presence, but no virus could be cultured from synovial fluid in a small cohort of subjects (Brighton et al., 1983). In addition, RRV has been found to persistently infect macrophages and evidence suggests that the ability of the virus to be maintained in these cells for extensive periods contributes to their pathogenesis (Way et al., 2002). Macrophages were found to be directly responsible for muscle tissue destruction as treatment of animals with macrophage toxic compounds prior to RRV infection completely prevented clinical diseases and clearance of macrophages from infected tissue

was associated with a decrease in symptoms (Lidbury et al., 2000). Because macrophages were found to be infected by and responsible for RRV disease, it was postulated that chemokines may also be involved in pathogenesis (Lidbury et al., 2000; Mahalingam et al., 2003) and some evidence has been accumulated supporting this idea (Mateo et al., 2000). The proposed model is that RRV-infected macrophages secrete chemokines that are attractive for additional macrophage. The newly immigrated macrophages are then susceptible to further infection thus propagating the cycle. Additionally, RRV can bind specific antibodies resulting in complexes that can bind and infect monocytes and macrophage via their cellular Fc receptors (Rulli et al., 2005). This antibody-dependent enhancement (ADE) pathway could have implications for vaccination potential including suppression of the host cell antiviral responses (Lidbury and Mahalingam, 2000; Suhrbier and La Linn, 2003). Due to the similarities in clinical symptomology between RRV and CHIKV, these mechanisms need to be closely examined in the case of CHIKV infections.

The T-cell response may also be a factor in CHIKV/ONNV pathogenesis as it is with RRV. CD8+ T cells are the major immunological cell type associated with epidemic polyarthritis patients that quickly recover from the febrile rash in contrast to the CD4+ cells that predominate in the synovial fluid of patients with chronic disease (Fraser and Becker, 1984). When productively and persistently infected *in vitro* macrophages are treated with CD8+ T cells generated by vaccination of mice with RRV capsid protein, the infection is completely cleared (Linn et al., 1998). This suggests that a defective cell-mediated immune response may also play a role in chronic disease and viral persistence (Fraser, 1986). Again, these studies need to be extended to the other alphavirus arthritides to determine if this is a broad-spectrum occurrence.

VACCINES: *HISTORY*

Due to the significant infection and attack rates during outbreaks, the extensive geographic distribution of these viruses, and the severe morbidity associated with clinical disease due to CHIKV or ONNV infection, a vaccine is highly desirable for control of disease caused by these agents. In addition, there have been numerous documented cases of laboratory acquired infections of CHIKV (U.S. Department of Health and Human Services: Biosafety in Microbiological and Biomedical Laboratories) indicating that a vaccine would also be beneficial to personnel with occupational risk. However, while there has been extensive work in vaccinology for several other alphaviruses (Rayner et al., 2002; Nalca et al., 2003; Johnston and Davis, 2004), the history of vaccine development for ONNV and CHIKV is short. This is particularly true for ONNV where no vaccine development has ever been documented. For CHIKV, scientists at the Walter Reed Army Institute of Research, The Salk Institute, and the U.S. Army Medical Research Institute of Infectious Diseases have been the primary investigators to undertake vaccine development and characterization. Some additional work focusing on potential CHIKV vaccines has been performed at the Japanese National Institute of Health (Kitaoka, 1967) and the Kobe University School of Medicine (Nakao and Hotta, 1973). However, none of these efforts have yet resulted in a licensed vaccine. Some human clinical trials have been performed with promising results but, to date, all CHIKV vaccine candidates must be considered "vaccines in development."

One of the first published reports of a possible vaccine against CHIKV was the description of a formalin-killed, CHIKV-infected, suckling mouse brain (SMB) preparation. This project began as an attempt by researchers in Japan to protect children against Thai hemorrhagic fever that was found to be caused by dengue and chikungunya viruses (Halstead and Buescher, 1961; Halstead et al., 1963). The SMB preparation of CHIKV vaccine was derived from 2- to 5-day-old mice that had been infected with the prototype strain of virus. The material was formalin inactivated and assessed for the ability to induce N and HI antibodies in immunized mice. At 15 days postinoculation, mice were found to have both HI and protective N antibodies suggesting that a CHIKV vaccine could be protective (Kitaoka, 1967).

A second early examination of a potential CHIKV vaccine was the use of an African strain of virus, one that had previously been through 177 SMB passages, and harvested from baby hamster kidney (BHK) cell culture. The recovered virus was either ultraviolet (UV) or formalin inactivated to determine if inactivation method would impact protective efficacy. The purified preparations were injected subcutaneously (s.c.) into monkeys using a 3-dose schedule at days 0, 14, and 63. Both induced N antibodies with the UV-inactivated material proving to be the better approach (Nakao and Hotta, 1973). For both this study and the SMB vaccine screened above, no additional information was published as follow up to this initial developmental work.

VACCINES IN DEVELOPMENT

The most extensive work performed in the development of a human CHIKV vaccine was initiated by investigators at Walter Reed Army Institute of Research.

Their first efforts involved comparative testing of vaccines prepared in both avian and mammalian cells. This early work utilized CHIKV strain 168 that was obtained from the 1952–1953 outbreak in Tanganyika (Mason and Haddow, 1957). The virus was used to infect chick embryo (CE), SMB, and African green-monkey kidney cell (GMKC) cultures to ascertain the most appropriate production system (Harrison et al., 1967). Virus harvested from each of these preparations was formalin inactivated using the standard techniques that had been developed for a Rift Valley fever vaccine (Randall et al., 1962). Potency testing for the products consisted of two intraperitoneal (i.p.) inoculations of the vaccine into adult mice at 0 and 7 days. Challenge of the vaccinated animals occurred 14 days later by the intracerebral (i.c.) route. This first round of potency tests suggested that the CE preparation would be unsuitable for further development, as serological responses and protective capacity in the mice were poor. A separate study comparing CE and GMKC products indicated that CE cultures were quite efficacious generating 4–5 times the level of antibodies developed in response to the GMKC vaccine and providing more protection against homologous challenge virus (White et al., 1972). The distinction between these two disparate results was the infectivity titer of the virus prior to formalin inactivation; to generate suitable CE vaccine, highly concentrated CE suspension cultures as described for EEE vaccine production were required (White et al., 1971). While the SMB product did induce antibodies and was found to be protective, the possibility of allergic reactions in humans limited enthusiasm for further development of this material. The GMKC vaccine was also found to induce high levels of antibodies and was protective against i.c. challenge with homologous virus; therefore, these cells were used for further characterization of their vaccine potential. Further tests included cross-strain challenge in both mice and monkeys, viremia profile determinations, and antibody development assessment. The immunogenic potential of the GMKC vaccine was demonstrated in all these tests with no detectable viremia and good protection in monkeys after challenge with four strains of CHIKV (Harrison et al., 1967) and indicated that further development of this vaccine was warranted.

The next step in development of the GMKC CHIKV vaccine examined alternate methods of inactivation of the virus. The first products were prepared by the long used approach of formalin inactivation. Because CHIKV virions are lipid-containing particles, the methodology being tested for experimental influenza and measles vaccines (Davenport et al., 1964; Norrby et al., 1966) of extracting the virus with surfactant (Tween 80) and ether was investigated (Eckels et al., 1970). The approach had been shown previously to produce an immunogenic vaccine that lacked any infectivity and that same phenomenon was observed with GMKCs infected with CHIKV. Additionally, this vaccine stimulated the development of CF, HI, and N antibodies as well as protecting mice against challenge with homologous virus. In fact, the hemagglutination (HA) activity of the tween-ether vaccine was maintained or even slightly enhanced while the formalin treatment destroyed the HA activity. A lack of knowledge as to the character of the immunizing antigen of the CHIKV particles precluded an explanation for this phenomenon. No further development of CHIKV vaccine using this method of preparation has been published.

The continuation of work by these investigators focused on safety and immunogenicity by looking for immune response, adverse events, and possible side effects of the formalin-inactivated product from GMKC culture. In this phase, the strain of virus used was changed from the highly passaged strain originating from the first outbreak in Africa to an isolate obtained directly from the serum of an infected patient in Thailand. The strain was designated 15561 and was used for all further development by these investigators. Extensive actions to provide purity assurances were undertaken to confirm the elimination of hepatitis agents and simian and murine adventitious agents from the starting material and all culture materials used. A vaccine lot was produced, formalin-inactivated, lyophilized, and used in safety and sterility tests. Potency tests were conducted in mice and were followed up with a human volunteer study consisting of 16 subjects. Subjects were given two doses of vaccine s.c. 28 days apart and examined for local and systemic reactions during the course of the study. No adverse events were noted in any of the volunteers and most developed N antibody by day 14 with all subjects demonstrating significant levels by day 42. CF and HI antibody levels remained low throughout the study in all subjects (Harrison et al., 1971). However, the initial results demonstrated both safety and immunogenicity and were promising enough to continue with further serologic studies examining long-term persistence of antibody. This antibody persistence study was undertaken using 12 laboratory or office workers (all employed in the building housing the research facilities) who were immunized with 4 distinct alphavirus vaccines (DeMeio et al., 1979). Subjects received the CHIKV vaccine after all other alphavirus vaccines; this occurred at 7 years 9 months after immunization with the VEE live-attenuated vaccine, 3 years and 1 month post-EEE vaccination, and 11 months after the WEE vaccine. Unfortunately, the CHIKV vaccine failed to elicit any significant N antibody levels in any of the participants. The lack of efficiency was attributed to the low potency

of the CHIKV vaccine lot used as the ED_{50} value of 0.33 found in mice may not have been expected to generate significant levels of antibodies. Curiously, this vaccine did induce a significant rise in titer against EEEV in one subject and two other subjects developed CHIKV N antibody in response to immunization with the VEEV vaccine.

The disappointing immunogenicity demonstrated by the formalin-inactivated CHIKV vaccine in the long-term antibody persistence study led to the development of a second generation CHIKV vaccine. The 15561 strain from human serum was used as seed material to generate vaccine CHIK 181/clone 25 resulting from a series of 18 plaque to plaque passages in MRC-5 cells of the starting virus which had been passaged 11 times in GMKC culture (Levitt et al., 1986). The CHIK 181/clone 25 strain exhibited small plaques, was temperature sensitive (ts), had decreased virulence for suckling mice, and showed a reduced level of viremia in monkeys. All of these characteristics have been associated with attenuation in other host systems (Eckels et al., 1980; Halstead et al., 1984) suggesting that 181/25 would have reduced virulence as well. The protective efficacy of this vaccine was evaluated in both mouse and monkey model systems. Mice were inoculated with a single 0.5 mL dose, i.p. and challenged i.c. with a virulent, heterologous strain of virus (168) 2 weeks following immunization. Monkeys received an intramuscular (i.m.) dose of pilot lot of vaccine 37 days prior to i.m. challenge with 5.0 $\log_{10}$ plaque-forming units (pfu) of nonattenuated parental virus (15561). The CD-1 mice were protected completely when immunized with 4.5–6.5 $\log_{10}$ pfu of vaccine and 50% of the mice survived when vaccinated with only 2.5 $\log_{10}$ pfu. In the monkey study, all the animals developed neutralizing antibody and were completely aviremic upon challenge indicting strong protective immunity. Additionally, the 181/clone 25 seed generated either no viremia or significantly reduced levels with a marked delay in onset compared with the parental virus in monkeys. Presumably, this reduced virulence in monkeys would correlate with virulence patterns in humans.

Because this was a live virus, additional safety testing included examining the potential of the vaccine to be transmitted by mosquitoes in the case a viremic vaccinee was bit by a mosquito (Turell and Malinoski, 1992). This phenomenon has been reported for the live attenuated VEEV vaccine (Pedersen et al., 1972). Of concern was the possibility that the vaccine characteristics could be ablated during replication of the virus in the mosquito and that the virus would revert to virulence before being transmitted to another vertebrate host. The vaccine was examined in both *Ae. aegypti* and *Ae. albopictus*, the two mosquitoes known to be competent urban vectors of the virus (Tesh et al., 1976; Banerjee et al., 1988; Turell et al., 1992). While the vaccine strain was able to replicate in both species and even be transmitted by the mosquitoes that received the virus via intrathoracic inoculation, there was no evidence of reversion to virulence. Based upon the low viremias the vaccine strain generated in test subjects, it was postulated that it would be unlikely for either mosquito vector to become infected from feeding upon a vaccinated human (Turell and Malinoski, 1992). The promising results generated by these studies led to the submission of an investigational new drug (IND) application for the CHIK 181/clone 25 vaccine strain to provide a route for the initiation of human clinical trials.

CLINICAL TRIALS

Phase 1 clinical trials consisted of both alphavirus naïve individuals (38) as well as 36 additional subjects that had previously been immunized with a live attenuated VEEV vaccine (McClain et al., 1998). Vaccines were delivered s.c. at a dose of 4.4 $\log_{10}$ pfu/0.5 mL. Mild symptoms including headache, fever, myalgia, and injection site tenderness were reported with equal frequency for both the placebo and CHIKV vaccine cohorts in the naïve subject study. Approximately one-third of these subjects had transient but detectable levels of viremia. However, the levels were too low to be detected directly from the serum but were only documented after cell culture amplification. All CHIKV vaccine subjects seroconverted as noted by the appearance of IgM and IgG antibody detected in ELISA as well as N antibody with a peak titer occurring at 28 days. Of those with preexisting alphavirus vaccine history, no local or systemic symptoms were reported after immunization. Antibody responses were poor in this group with only 36% of the subjects generating detectable levels of CHIKV-specific antibodies. However, there was some cross-reactivity as subjects vaccinated against CHIKV generated antibodies that were detected in a VEEV IgG ELISA with an anamnestic response upon subsequent immunization with VEEV vaccine. This information suggested that the live attenuated CHIKV vaccine was both safe and efficacious but that sequential immunization with live-attenuated alphavirus vaccines could hinder the development of protective immune responses to subsequent alphavirus vaccines or infections.

The positive results derived from the Phase 1 clinical trial were sufficient to progress to a Phase 2 randomized, double-blind, placebo-controlled CHIKV vaccine trial to further assess safety and immunogenicity. A total of 73 subjects was enrolled in this study with

59 receiving a single s.c. inoculation of ~10^5 pfu of TSI-GSD-218 vaccine (CHIK 181/clone 25 strain) in 0.5 mL (Edelman et al., 2000). After clinical and serological evaluation of both vaccine and placebo groups, the incidence of local or systemic reactions was found to be comparable in both groups; this indicated safety of the vaccine. The only differences noted were the descriptions of minor joint pain by five subjects in the vaccine group with all symptoms lasting less than 24 h. Serologically 98% of those receiving the CHIKV vaccine developed N antibodies that peaked in titer by day 28 postimmunization and over 85% were still seropositive at 1 year. This vaccine was found to be highly immunogenic, well-tolerated, and safe. It appears to be a very promising alphavirus vaccine for those at risk and additional long-term studies of duration of immunity are certainly warranted.

POSTEXPOSURE IMMUNOPROPHYLAXIS

No studies have examined any possibilities for postexposure immunoprophylaxis to either CHIKV or ONNV. Potential approaches may include passive transfer of antibodies from sera of previously infected patients or produced from specific donors, monoclonal antibody therapy, or immediate postexposure vaccination. Because these viruses have a short incubation period and can produce illness in just a few days, some of these options are not particularly attractive. Early identification of outbreaks would be an essential component of disease control to insure that people in affected areas but not yet exposed or infected could receive any vaccine that should become available.

PROSPECTS FOR THE FUTURE

While the preliminary basic science studies and clinical human trials provide promise for a CHIKV vaccine that would be extremely beneficial from a public health perspective, the lack of mortality and marketability are certainly factors that may limit rapid development of any licensed vaccine. Additionally, continued advancement in the understanding of the basic biology of the viruses themselves and their ability to induce immunity in the vertebrate hosts is necessary to aid in the design of the most appropriate vaccine strategy. Ultimately, given the areas where the viruses are found, any vaccine distribution must be used in concert with a comprehensive mosquito control program that would employ a diverse group of measures to be implemented for both short-term (during outbreak situations) and long-term (sustained) control of vector mosquitoes. A successful program will be a partnership among the local population, government and health ministry officials, the scientific community, and the members of the communication network providing accurate and timely information. Examples of short-term vector control measures include covering of open water breeding sites or applying larvicidal products if coverage is not feasible, elimination of artificial breeding sites such as discarded waste or used tires, and the use of adulticide products for immediate control of adult mosquito populations early in an outbreak. However, these temporary and short-term vector control measures must be used in conjunction with long-term solutions including monitoring of levels of vector mosquitoes, developing a system of communication between disease surveillance activities and vector control activities to insure that control measures are implemented rapidly when clusters of vector-borne disease are identified, and education of the public on measures to maintain a mosquito-free environment at their homes and places of work. Hopefully, these immediately available options for mosquito control can be implemented while the scientific, political, and social barriers to CHIKV and ONNV vaccine development and distribution can be resolved. Given the intraglobal atmosphere currently present and the potential for any disease to suddenly appear in unexpected areas such as West Nile virus has demonstrated, vaccination strategies for CHIKV and ONNV should be seriously considered.

KEY ISSUES

- CHIKV and ONNV cause significant morbidity, are widely distributed, cause explosive outbreaks, are responsible for numerous laboratory acquired infections, and can easily be imported into naïve regions due to travel from endemic areas. These traits clearly demonstrate the need for a highly immunogenic vaccine.
- Distinctly different ecological and epidemiological patterns exist for these closely related viruses potentially impacting the utility of a single vaccination strategy.
- No licensed vaccines are currently available. Various formulations of potential CHIKV vaccines have been examined and subjected to human clinical trials. No ONNV vaccine development has ever been published.
- There is significant cross-reactivity among alphaviruses and the antibodies developed against

them. This has led to concerns including the possibility of ADE of infection as well as impaired development of neutralizing serologic responses and protective immunity. Vaccine strategies such as the use of live, attenuated preparations must consider these possibilities.

Rabies

Anthony R. Fooks[1], *Nicholas Johnson*[1] *and Charles E. Rupprecht*[2]
[1]Rabies and Wildlife Zoonoses Group, Veterinary Laboratories Agency (Weybridge), Addlestone, Surrey, UK
[2]Centers for Disease Control and Prevention, Atlanta, GA, USA

OUTLINE

ABSTRACT

Rabies is unique among the viral diseases of man in that it kills virtually every individual it infects. The illness associated with the disease, in previous times referred to as hydrophobia, is particularly unpleasant for the victim but also for health care workers and relatives who have to witness it. Global estimates of death from rabies suggest that one person dies from the disease every 10 min, and more than 300 others are exposed. This claim is supported by a study of Malawian children with viral encephalitis, where 3 (11.5%) of 26 children originally clinically diagnosed with cerebral malaria were later laboratory-confirmed as having rabies suggesting that human

disease is underreported in some rabies-endemic countries. The disease is distributed worldwide and is endemic in many countries causing an estimated 50,000–70,000 human deaths each year, although the true burden of the disease is unknown due to underreporting and poor surveillance systems in many areas of the world (Meltzer and Rupprecht, 1998; Fooks, 2005). Following exposure, the virus invades the peripheral nervous system before entering the CNS leading to malfunction, organ failure, and ultimately death. Two clinical manifestations, "furious" and "dumb" (paralytic) rabies are observed following infection although the mechanisms of both syndromes are still not well understood. Rabies virus belongs to the *Lyssavirus* genus, which contains seven recognized genotypes. The genus can be divided into two broad groups or phylogroups. Genotype 1 ("classical" rabies virus), 4, 5, 6, and 7 belong to phylogroup I, while genotypes 2 and 3 have been placed in phylogroup II on the basis of glycoprotein sequence, pathogenicity, and immunogenicity. Additionally, there are four newly described lyssavirus species: Aravan, Khujand, Irkut, and West Caucasian Bat Virus that have been recently isolated from bats in Eurasia. All lyssaviruses are capable of causing clinical "rabies" in mammals.

Throughout the world, greater than 10 million people, many of whom are unvaccinated, have to endure extreme anxiety of "suspect" rabies following exposure from a rabid animal. Although preexposure vaccination and postexposure prophylaxis (PEP) for rabies is highly effective, ignorance about the disease, especially in developing countries, impedes timely intervention. In rare circumstances, vaccine failures have been reported. Highly effective vaccines have been developed for both animal and human use that induce long-term immunity against virus challenge; however the rabies virus vaccines were derived from isolates obtained between 50 and 100 years ago. Such strains are unlikely to take into account the genetic variation of the virus in the field accompanying the spatiotemporal fluctuation of reservoir species. Current evidence suggests that human vaccines, based on inactivated rabies virus, are not fully protective against all of the lyssavirus genotypes.

The ease of obtaining live virus from an animal reservoir is straightforward although propagating the virus requires specific skills and specialist laboratory facilities. Rabies virus is poorly transmitted by the airborne route, but does present a substantial hazard to personnel exposed to aerosols of rabies virus. The virus is unlikely to be an effective bioweapon if the aim of any terrorist act is to achieve rapid dissemination of the agent with maximum human exposure, largely due to the unpredictability of transmission and long incubation periods. However, the ability of the disease to provoke fear makes the virus a biothreat agent that could result in considerable public concern if deliberately reintroduced into a rabies-free region, i.e., Western Europe. In addition, governments confronted with a deliberate reintroduction would be obliged to instigate costly elimination strategies, protection of domestic livestock, and public information programs suggesting that the virus could be used as a means of "agroterroism." As a result the virus is classified as a "category C emerging infectious disease threat."

Future candidate vaccines need to be designed with broad-spectrum activity against all lyssaviruses, and ease of delivery using either oral or parenteral routes focusing on the creation of herd immunity among species. Furthermore, they must elicit long-term immunity, inducing both adaptive and innate immunity in a single-dose and produced at a cost that will allow widespread use throughout the world but especially in developing countries where rabies is still endemic. No antiviral agents are effective against the rabies virus and there is an urgent need for biologicals that inhibit the virus and provide relief from this devastating disease.

INTRODUCTION

Rabies is an ancient, if not one of the oldest reported diseases of man and has been reported in the writings of most civilizations for more than three millennia (Blaisdell, 1994; Neville, 2004; Swabe, 2004). The Greek word for rabies is "lyssa," a word of unknown origin although the earliest documented use of the word *lyssa* is from Homer's Iliad where it refers to a "raging dog" (Neville, 2004), and has been adopted as the genus name (*Lyssavirus*) for the group of viruses to which rabies belongs. This observation suggests that rabies did exist in Homer's time (8th–9th century BC). It is likely however, that rabies existed a long time before Homer first used the word *lyssa* to describe the disease. In the 3rd century BC, Andreas of Carystos wrote a treatise on rabies making him the first author of a script devoted entirely to rabies (Neville, 2004). Some of the first reports of animal rabies may date to the *Laws of Eshunna* in Mesopotamia, in the 23rd century BC, where the Babylonian word *Segû* meant both *to be mad* and *to become rabid*, and where the word *kaduh-hu*, which meant *to have the mouth open*, was synonymous with canine rabies. In the 17th century, the ancient word *rabiem* ("the madness") was used to describe the disease. Canine rabies was also reported in the 6th century BC, in the *Avesta* (Persia), in the 4th century BC by Aristotle (Greece), in the 1st century BC in the *Susrutasamhita* (India), in the 1st century AD by Rhazes and Avicenna (Arabia), in the 4th century in the *Talmud* and in Egyptian texts, then by Roman authors (Dioscorides, Galen), by the Byzantine

Hippiastrians (5th century), by Arab authors (10th century) (Neville, 2004; Swabe, 2004). In the 4th century BC, the absence of any mention of rabies by the "Father of Medicine," Hippocrates, led historians to deduce that rabies had not reached Europe by the 5th century BC. However, Hippocrates did refer to "frenetics" who drink little, are disturbed by every sound and afflicted with trembling suggesting that rabies was indeed present.

Lacking scientific knowledge of the disease, the proposed methods at the time for preventing rabies were largely improbable without any real prospect for success. In the 1st century BC, the considered cause and prescribed treatment that was used until the 17th century for rabies was defined. Grattius Faliscus wrote a poem describing a "little grub" supposed *small worm* (*lyssa*, in Greek), that was located under the tongue of rabid dogs. While the dogs were still young, the part of the tongue thought to be responsible for the malady was removed in an attempt to prevent the dog contracting the disease. It was during the reign of Tiberius (14–37 AD) that detailed instructions from an encyclopedia compiled by Aulus Cornelius Celsus for the treatment of bites from rabid dogs was reported (Neville, 2004). Celsus concluded that the bites from rabid animals contained a poisonous substance which, unless treated, would prove fatal. The "poison" that Celsus referred to was from the Latin word for "virus." Throughout the period, many diagnostic and control methods were also proposed. Two influential medical authorities were Rufus and Soranus. Rufus believed that rabies was sexually transmitted and Soranus reported a baby afflicted with rabies as being terrified of its mother's breast. A treatise, probably written by Soranus, described the contagious nature of rabies, not just from a bite, but also from the breath or claws of a rabid dog. The accurate recording of detailed clinical symptoms and the logic behind observing and recording the results from different treatments for rabies was undertaken by Galen in the 2nd century AD. He reported that clinical signs from a rabid dog included having saliva flowing from its mouth, irrationally running and then stopping, and biting with furious rage (Neville, 2004). Some of the earliest reported descriptions of the clinical signs of rabid dogs and subsequent treatments that were based on scientific evidence came from Aretaeus (2nd century AD), Philumenis (2nd century AD), Felix (2nd century AD), Aphrodisiensis (3rd century AD), Oribasius (4th century AD), Pelagonius (4th century AD), Vegetius (4th century AD), Aetius of Amida (5th/6th century AD), and Paul of Aegina (7th century AD).

In 1576, George Tuberville reported that the time of an animals' breeding influenced the animals' susceptibility to madness. A decade later, in 1587, Conrad Gesner described several variations of "madness" followed by an overview of the characteristics, habits, and diseases of numerous animal species by Edward Topsell in 1607. The latter identified rabies as being the most important disease of dogs. In 1613, Thomas Spackman, an English physician, devoted a whole book to the description of rabies. In the 17th century, religious popularity endorsed the faith in miracles, not least of all from St. Hubert, the patron saint of hunters, who by the custom of visiting his shrine could cure the afflicted from rabies (Swabe, 2004).

The "furious" stage of rabies is characterized by radical changes in the patient's behavior; changes that would be of grave concern to all those in attendance. In addition, the "madness" that embodies the final stages of the disease has a deep social and metaphysical significance, especially in ancient cultures (Swabe, 2004). The fear of a rabid person is therefore deep-rooted in history, hence the universal dread of the disease. Following infection, the human patient is undoubtedly reduced to a wild, uncontrolled animalistic state. A rabid person breaches the gap between humans and other animals thus opening the realms of reality to fantasy, myth, and folklore. The result to onlookers was to promote their prejudices and inspire their imaginations, sense of danger, and disgust. The domesticated dog was also reduced to an uncivilized and highly dangerous state, shocking to humans who were unaccustomed to witnessing savage canine behavior.

Popular fantasies about vampirism and werewolves were also deeply entrenched beliefs in medieval folklore and have accounted for the demonism of the disease that reduces perfectly healthy individuals to an "inhuman state" (Gomez-Alonso, 1998). It became apparent that the earliest medical practitioners were prepared to attempt any possible outlandish practice for rabies whether the treatment used was based on accurate scientific and medical knowledge or not. Many writers of the time had recognized the "hydrophobia" in patients and also the changes in behavior. In addition, the link between a "poisonous substance" in the saliva of dogs and in human disease had been reported in many ancient texts. The practice of "worming" young puppies has been described previously. Celsus in the 1st century AD stressed the need to attend to the wound afflicted by the bite of a rabid animal as soon as possible, suggesting cauterization to draw out the poison. An alternative approach that was practiced in ancient times was to immerse someone in water, usually a well. The patient was left in the well until they had drunk sufficient water to overcome the hydrophobia. More bizarre and tenuous treatments ranged from the healing power from a piece of hyena skin wrapped in cloth (Scribonius Largus)

as a supposed prophylactic against rabies to curative substances including one remedy that was derived from the skull of a hanged man to treat patients afflicted from the bite of a mad dog (Antaeus). Numerous antidotes for rabies were "herbal remedies," often adopted as a "pick-and-mix" approach from previous medical writers. These included the root of the dog rose, a bitch's menstrual fluid, the ash of sea-crabs, garlic, hellebore, castoreum, rose oil, honey, laurel berries with latter supposed improvements including chamomile, sorrel, saffron, and nut kernel. Although many of these remedies were reputed to be efficacious including the mixture of river-crab ash and gentian, which was reported to never fail, yet in fact, not one remedy was ever proven to be effective (Neville, 2004). If any animal survived any of the practices/remedies that were on offer, it was certain that the animal was not suffering from rabies (Swabe, 2004).

The 19th century saw the application of scientific method in attempting to understand the nature of rabies and effective preventative measures. In 1804, the German scientist, Zinke, demonstrated the infectious nature of saliva from rabid dogs. Galtier succeeded in protecting sheep and goats by intravenous inoculation with virulent saliva, with a series of experiments between 1879 and 1881. However, no effective prophylaxis in animals was available before Pasteur's discovery in 1885. It should be recalled that the original goal of Pasteur's research was to develop a vaccine for use in dogs before exposure and that his decision to use this vaccine in man, after exposure, was only taken under pressure from his peers. Pasteur was, moreover, working on *virulent matter* (nerve tissues) and had not isolated the pathogen. It was not until the advent of the concept of "filterable agents," that in 1903, Remlinger isolated and identified the etiology of rabies as a virus. Some of the first vaccines used extensively in exposed animals consisted of Hogyes' method, using six injections of fixed virus diluted in saline. Thereafter in the early 20th century, many domestic animal vaccines contained the attenuated virus (Flury), or were viruses partially inactivated by phenol, as described initially by Fermi, and later by Semple. Effective adjuvanted vaccines containing inactivated viruses were not available largely until the latter half of the 20th century.

ETIOLOGIC AGENT(S)

Classification

Rabies virus is single-stranded, negative-sense, nonsegmented RNA virus within the *Lyssavirus* genus, which along with three other recognized animal virus genera form the family Rhabdoviridae within the order Mononegavirales. Four families comprise the Mononegavirales including: Filoviridae (e.g., Ebola virus), Paramyxoviridae (e.g., measles virus), Bornaviridae (Borna disease virus), and Rhabdoviridae.

The *Lyssavirus* genus is subdivided into four serotypes and seven major species, or genotypes, all adapted to replication in the mammalian CNS (Bourhy et al., 1993; Badrane et al., 2001). The archetype virus of the genus is classical rabies virus (RABV) (Fig. 33.1). Prior to the wider availability of genetic analysis, strains of RABV were identified by serotype analysis using hyperimmune sera and later by panels of antinucleocapsid monoclonal antibodies. These panels were able to differentiate lyssaviruses into four distinct serotypes. The first serotype (serotype 1) contained classical rabies virus and Australian bat lyssavirus (ABLV); serotype 2 included Lagos bat virus (LBV); serotype 3

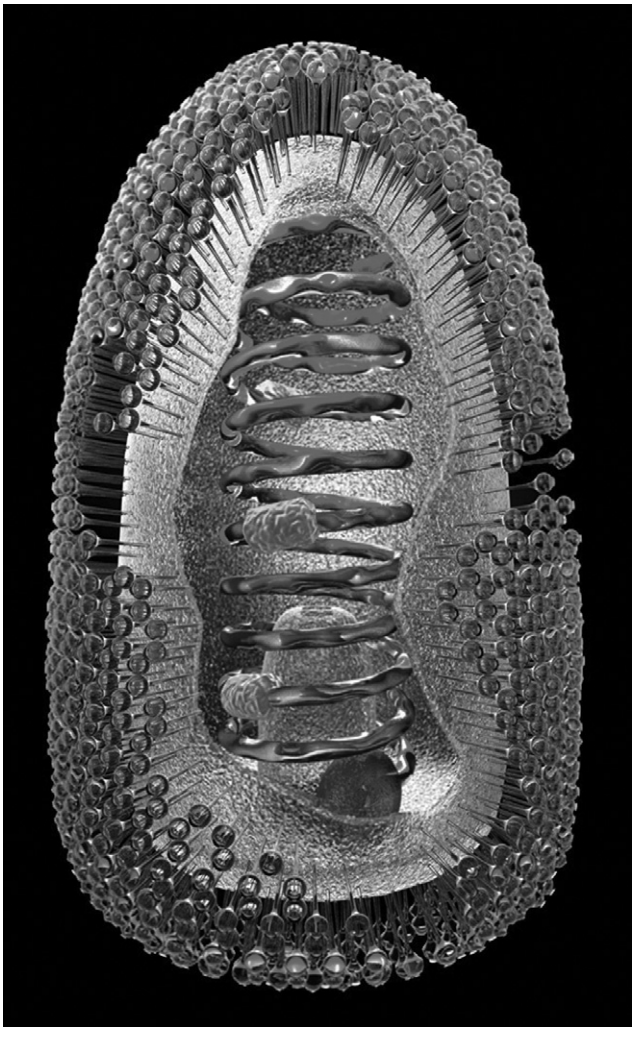

FIGURE 33.1 Schematic diagram of rabies virus (see color plate section).

included Mokola virus (MOKV); and serotype 4 consisting of Duvenhage virus (DUVV), European Bat Lyssavirus type-1 (EBLV-1) from Denmark and European Bat Lyssavirus type-2 (EBLV-2) from Finland.

With the development of molecular genetic analysis the *Lyssavirus* genus was differentiated into seven genetically divergent lineages. These include, RABV (genotype 1), LBV (genotype 2), MOKV (genotype 3), DUVV (genotype 4), EBLV type-1 (genotype 5), EBLV type-2 (genotype 6), and ABLV (genotype 7). With one exception (MOKV), all genotypes have been isolated from bats (Shope et al., 1970; Kuzmin et al., 2005). Four additional rabies-related viruses have recently been isolated from bats in Eurasia (Botvinkin et al., 2003; Fooks, 2004): Aravan virus, Khujand virus, Irkut virus, and West Caucasian Bat Virus (WCBV). These have been proposed as new members of the *Lyssavirus* genus. Aravan virus was isolated from the brain of a lesser mouse-eared bat (*Myotis blythi*) in Southern Kyrgyzstan in 1991 (Arai et al., 2003). A decade later, Khujand virus was isolated from the brain of a whiskered bat (*Myotis mystacinus*) in Northern Tajikistan (Kuzmin et al., 2003). In 2002, Irkut virus was isolated from a greater tube-nosed bat (*Murina leucogaster*) in Eastern Siberia. Later that year, WCBV was isolated from a bent-winged bat (*Miniopterus schreibersi*) in the Caucasus Mountains, approximately 100 km southeast of the town of Krasnodar and 150 km from the Eastern Turkish border. Subsequent studies have segregated the various genotypes into larger groups or phylogroups based on a number of genotypic and phenotypic characteristics (Badrane et al., 2001). Genotypes 1, 4, 5, 6, and 7, Aravan virus, Khujand virus, and Irkut virus comprise phylogroup I, while phylogroup II contains the two divergent African viruses, genotypes 2 and 3 and the most divergent, WCBV (which may be considered eventually in its own phylogroup).

Within genotypes, and especially for classical rabies, variants or biotypes are associated with different hosts (dog, fox, bat) and represent coevolution of particular lineages of virus with a specific reservoir.

EPIDEMIOLOGY

Rabies is a fatal zoonotic disease of mammals and is endemic on all continents with the exception of Antarctica and several islands (Hawaii, New Zealand) and, at least in regards to rabies in carnivores, an increasing number of European countries (Fig. 33.2). However, maintaining a rabies-free status

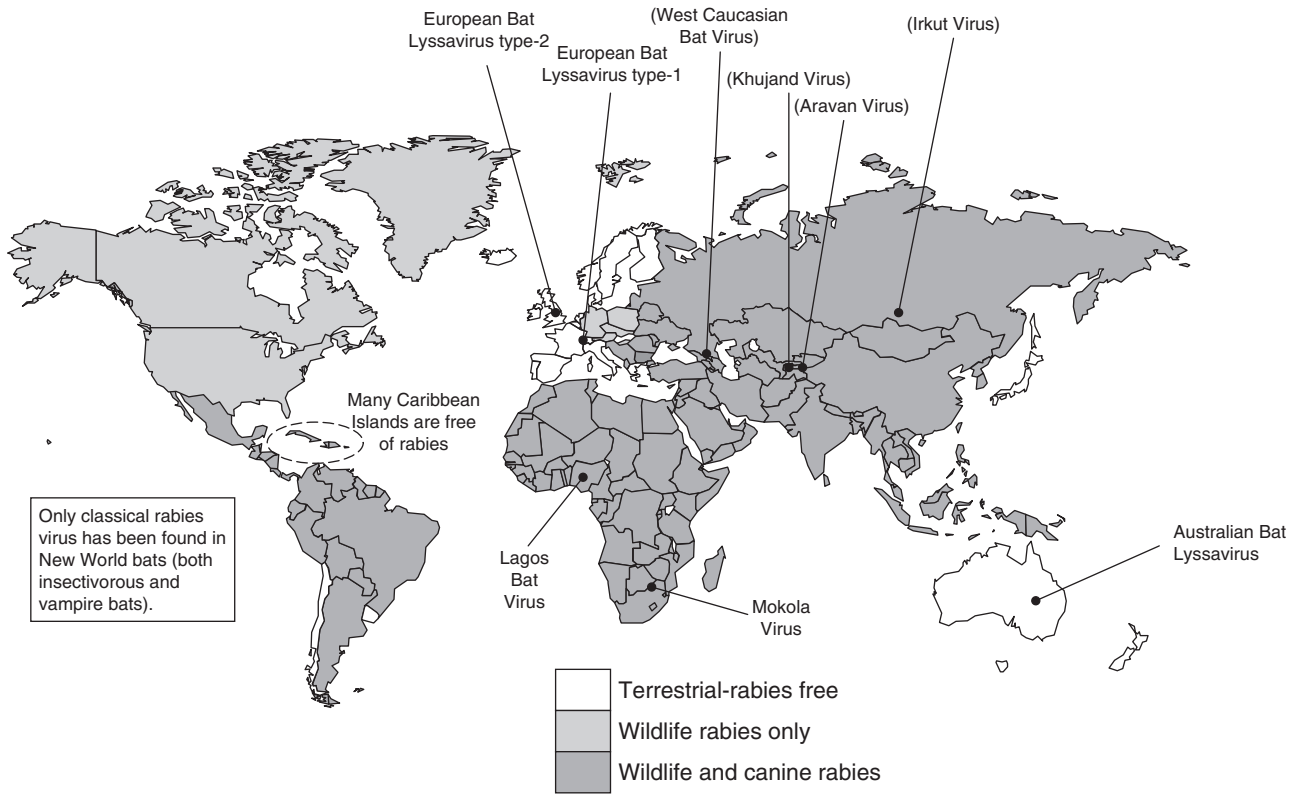

FIGURE 33.2 Global distribution of rabies virus variants.

incurs considerable costs and there is a continual risk of reimportation. Although targeted vaccination programs have been successful in eliminating the disease from carnivores over large areas, the virus still causes 30,000–50,000 human deaths per year. Fortunately the virus is limited in the range of species that can serve as suitable hosts. Those taxa that support cycles of infection are termed reservoir species and are limited to members of the Carnivora and Chiroptera orders. Factors such as the capacity to inflict a skin puncturing bite, high mobility and density and the degree of within-species interactions appear to favor certain species in their ability to transmit virus from one member to the next. All other species, including man, are considered spillover hosts in which the virus infects individuals, but is rarely transmitted further. Principal among the reservoir hosts is the domestic dog (*Canis familiaris*). Its proximity to humans as a companion animal, make it a key link in the transmission of rabies to man. Where data are recorded, the main source of human infection are bites from rabid dogs. Cats are often implicated in the transmission of rabies but due to their solitary nature act as a spillover host. A range of wildlife species also harbor the virus including the fox, raccoon, skunk, mongoose, and many species of bats (Bourhy et al., 1992; McColl et al., 2000; Rupprecht et al., 2002), and all are capable of transmitting rabies virus to humans.

Until recently, epidemiological studies were limited to recording the prevalence of cases and associating rabies with particular hosts. The ability to distinguish individual rabies viruses from the same host species has greatly increased our understanding of the interaction of viruses with particular reservoir hosts and has enabled retrospective investigations in human and domestic animal cases based on the particular rabies virus variant identified. This capacity to analyze the rabies virus variant has been dependent on developments in the field of molecular biology and as a result of the large variation observed within the viral genome. The gene structure of RABV, and the related lyssaviruses, is highly conserved but within these genes there appears to be variation in the length of coding and noncoding sequences and enormous sequence variation that often translates to amino acid variation in the expressed proteins. This has enabled researchers to measure viral variation and link this to geographical distribution, host reservoir, and transmission by spillover hosts. Originally, virus typing using panels of monoclonal antibodies was used to discriminate antigenic variants between other lyssaviruses and RABV (Smith, 1989). This approach has largely been superceded by genome sequence analysis. Many regions of the genome have been used to measure virus variation and as yet there appears to be no consensus as to which is the most appropriate sequence to use. Where comparative studies have been attempted, similar relationships between virus variants have been obtained (Bourhy et al., 1999; Johnson et al., 2002a). However, to date, surveys of GenBank indicate that most information is available for the viral nucleoprotein gene. Early studies attempted to compare rabies viruses from throughout the world (Smith et al., 1992; Kissi et al. 1995). A large number of later studies have focused on more meaningful panels of viruses based on rabies-endemic developing countries. For example, a molecular epidemiological study of rabies in Turkey demonstrates a clear distinction between rabies in the west of the country and viruses in the east (Fig. 33.3). Similar work has been conducted in Latin America, including Colombia and Mexico (Pãez et al., 2005; Velasco-Villa

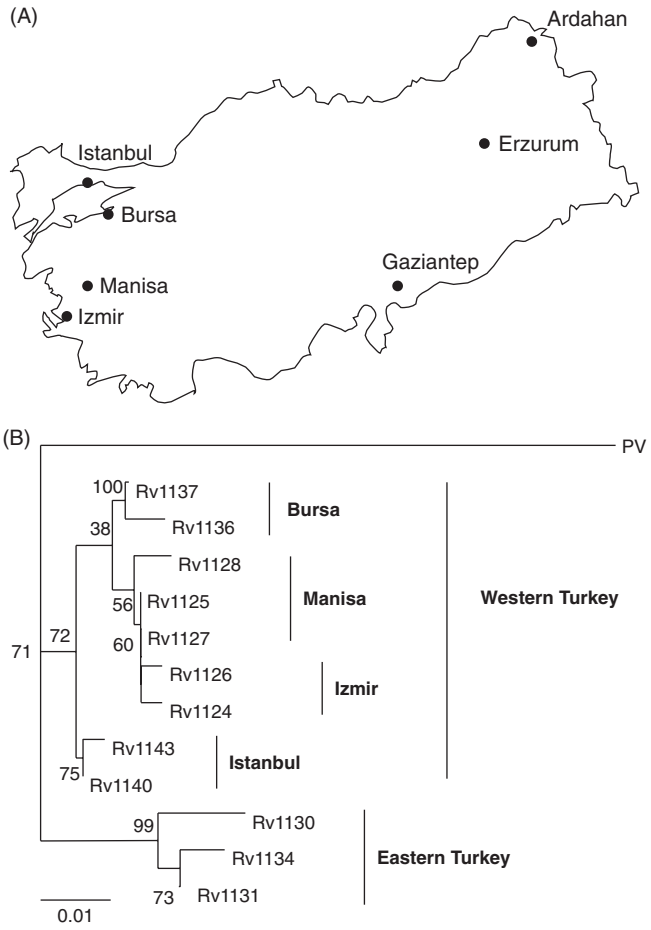

FIGURE 33.3 (A) A map of Turkey showing the principal cities that have reported rabies in recent years. (B) A phylogenetic tree demonstrating the division of rabies viruses in Turkey between those found in the western cities including the capital, Istanbul, and those found in eastern cities.

et al., 2005). Such studies could form the basis of rabies elimination programs by allowing investigators to distinguish between endemic variants and reintroductions. A further application has been the ability to confirm the source of human rabies cases where little information is available from the case history (Smith et al., 2003; Willoughby et al., 2005; Johnson et al., 2002b, Fooks et al., 2003).

SPECIES AFFECTED

In practice, it is possible to infect experimentally any mammalian species with rabies virus, although the degree of resistance of each species varies considerably according to the isolate and dose of rabies virus inoculated, the age of the animal, and the route of inoculation. This variation in resistance (species barrier) could explain why natural infection is unevenly distributed in different species, the majority of which are simply victims and not vectors of rabies virus (Rupprecht et al., 2002). Birds are also susceptible, but appear more naturally resistant to rabies (Schneider and Burstler, 1967). The range of species which is susceptible to rabies virus is large and differs according to continent.

Circumstantial evidence suggests that lyssaviruses may have evolved from the African continent and since became established outside of Africa as a result of zoogeographic spread (Rupprecht et al., 1991). Urban (dog) rabies predominates in Africa. In sub-Saharan Africa, the domestic dog is the principal reservoir whereas in the countries of southern Africa, a rabies cycle circulates in specific hosts, which is independent of the canine cycle. Different biotypes are maintained in the side-striped jackal (*Canis adustus*), the yellow mongoose (*Cynictis penicillata*) (Nel et al., 2005b), and the bat-eared fox (*Otocyon megalotis*) (Sabeta et al., 2007). Infections into occasional hosts such as kudu antelopes in Namibia as a result of spillover from the jackal population have been reported (Mansfield et al., 2006).

The domestic dog is also the principal reservoir in the Indian sub-continent (including India, Pakistan, and Bangladesh), where human fatalities from rabies are the highest in the world.

In contrast to most of the globe, no wild carnivore vectors/reservoirs of rabies have been identified definitively in southeast Asia, the dog being the only species responsible for enzootic rabies in this region. Insectivorous and frugivorous bats are also hosts of lyssavirus variants throughout Asia and have independent cycles of infection (Tacal and Boado, 1966; Pal et al., 1980; Arguin et al., 2002; Lumlertdacha et al., 2005; Tang et al., 2005). Although Australia is free of terrestrial rabies, several species of bats (frugivorous, insectivorous) are also responsible for perpetuating rabies (Gould et al., 1998; Samaratunga et al., 1998; McColl et al., 2000).

In the United States, in the early part of the 20th century, there were scores of cases of human rabies each year but this has decreased to between one and three cases in the 1980s. In 2004, rabies was responsible for eight cases, including four people who died following receipt of infected organs and tissues from an Arkansas donor bitten by a bat (Srinivasan et al., 2005). In addition, a Wisconsin teenager contracted rabies from a bat bite and survived rabies (Willoughby et al., 2005). Widespread vaccination of companion animals post World War II has been largely responsible for the decrease in human cases. Vaccination campaigns were implemented in the 1940s and greatly reduced canine variants of rabies virus by the 1960s. In 2005, wild animals accounted for the majority of all reported cases (greater than 92%), whereas domestic species accounted for 8%. Raccoons are the most commonly reported wildlife species (40%) followed by skunks and bats (23 and 22%, respectively) (Blanton et al., 2006).

In the Americas, all cases of bat rabies are caused by a variant of genotype 1. For example, the most common species found in the US include: the big brown bat (*Eptesicus fuscus*); the Brazilian (Mexican) free-tailed bat (*Tadarida brasiliensis mexicana*); the little brown bat (*Myotis lucifugus*); the hoary bat (*Lasiurus cinereus*); and the western pipistrelle bat (*Pipistrellus hesperus*). The variants of rabies virus that are predominantly reported to cause cases in humans are associated with the silver-haired (*Lasionycteris noctivagans*) and the eastern pipistrelle (*Pipistrellus subflavus*) bats. Bats account for an increasingly larger proportion of human rabies incidents in the US (Messenger et al., 2002). As the majority of cases of indigenous human rabies in the US since the 1950s was caused by insectivorous-bat variants of rabies virus, it led to conclusions that the silver-haired bat variant demonstrated a higher neuroinvasiveness and subsequent virulence in man. Although the route of entry into nerves in the epithelium leading to invasion of the CNS has never been established, the silver-haired bat variant does replicate more efficiently and at lower temperatures than dog variants of rabies virus (Dietzschold et al., 2000).

In contrast, the dog is also the main vector/reservoir in many countries of Central and South America, and a totally independent rabies cycle exists in hematophagous bats (vampire bats), chiefly the species *Desmodus rotundus* (Lord et al., 1975). This species is still responsible for the infection of thousands

of domestic livestock and many cases in humans. Insectivorous bats also act as a reservoir for rabies but are rarely the cause of spillover infections.

Since 1989, the increased use of oral rabies vaccines (ORV) has been instrumental in successfully eliminating sylvatic rabies from large areas within Europe, Canada, and the US (Slate et al., 2005; MacInnes et al., 2001). For example, from 1990 onwards, we have witnessed the elimination of rabies from terrestrial mammals (principally the red fox) in many Western European countries: the Netherlands (1991), Switzerland (1999), France (2000), Belgium and Luxembourg (2001), and the Czech Republic (2004) resulting in these countries being declared "rabies-free." The last recorded case of terrestrial rabies in Germany occurred in February 2006 close to the city of Mainz (Thomas Muller, personal communication). Oral rabies vaccination field trials were first reported in Switzerland in 1978 using a live-attenuated rabies virus strain (Street Alabama Dufferin, SAD). The use of a genetically modified vaccine (vaccinia recombinant expressing the rabies virus glycoprotein, VRG) has also been widely used in recent years. While the threat in Europe from rabies in foxes has diminished in western Europe as reported by Bourhy et al. (2005), dog rabies in some eastern European countries, fox rabies in central and eastern Europe, and raccoon dog rabies in northeastern Europe continue to pose a risk. Similar ORV efforts focusing upon raccoons, foxes, and coyotes are operative throughout North America (Slate et al., 2005).

Among bats, rabies virus perpetuates itself in a cycle that is usually independent of rabies in terrestrial mammals, even though the latter, especially man, may be the victim of bites by rabid bats, from time to time. However, on rare occasions in the US, "spillover" cases of bat variants to terrestrial mammals have resulted in infection, and may occasionally lead to local enzootic establishment (Daoust et al., 1996; Leslie et al., 2006).

Animal rabies is distributed virtually worldwide. However, some areas (particularly island countries, such as the British Isles, Hawaii, Australia, New Zealand, Japan, Taiwan) have succeeded in protecting themselves against further incursion of the disease in terrestrial carnivores. Other countries have progressively eliminated rabies by disease prevention measures or prophylaxis: this is the case in Western Europe, and in some countries in the Southern Cone of Latin America. However, maintaining a rabies-free status incurs considerable costs and there is a continual risk of reimportation as was the case in July 2004, when a 4-month-old female dog was introduced to France via Spain and caused possible exposure to several dogs, cats, and human beings (Servas et al., 2005). Moreover, given their ability to fly, rabies in bats creates special circumstances in considering the indigenous global occurrence of disease (Constantine, 2003).

PATHOGENESIS

Rabies is transmitted through the saliva of rabid animals (Fig. 33.4A). Bites are the most common means of transmission. Occasionally less traumatic transfer of saliva such as the licking of a wound or broken skin can lead to deposition of virus. Deeper bites that lead to exposure of muscle tissue appear to be the most effective at transmitting the virus. As a result, the World Health Organization (2005) categorizes wounds for humans into three groups of increasing severity from category 1, which involves licking of intact skin and requires no action, to category 2, licking of broken skin, and category 3 single or multiple transdermal bites or scratches that warrant postexposure prophylaxis (PEP). The virus appears to persist at the bite site that leads to the long incubation times associated with rabies. Several unusual case records document that years elapse between a bite and the development of symptoms, although in humans the time between exposure and disease is usually measured in weeks to months. What the virus is doing, if anything is unclear, mainly because it is a very complex scenario to model with any accuracy. One theory suggests that some pathogenic strains are more adapted to replication at lower temperatures that may enhance persistence in the dermal layers (Dietzschold et al., 2000). Alternatively the virus persists in a dormant state or replicates at low levels in muscle or other tissues. However, it is clearly capable of evading the immune system for a considerable length of time. At some point, possibly a random event, RABV encounters a nerve cell, either directly or at nerve–muscle junctions where it enters the neuron through interaction of the viral glycoprotein with one of a number of protein receptors (Fig. 33.4B). At least three have been identified to date, the acetylcholine receptor (Lentz et al., 1982; Lewis et al., 2000; Gastka et al., 1996) shared with muscle cells, the neuronal cell adhesion molecule (Thoulouze et al., 1998) and the p75 neutrophin receptor (p75NTR) (Tuffereau et al., 1998; Langevin et al., 2002). The relative importance of each of these receptors is unclear but could be interpreted as a sign that the virus glycoprotein has adapted to bind a range of receptors to maximize the chance of entering a nerve cell. Once within the peripheral nervous system, virus migrates

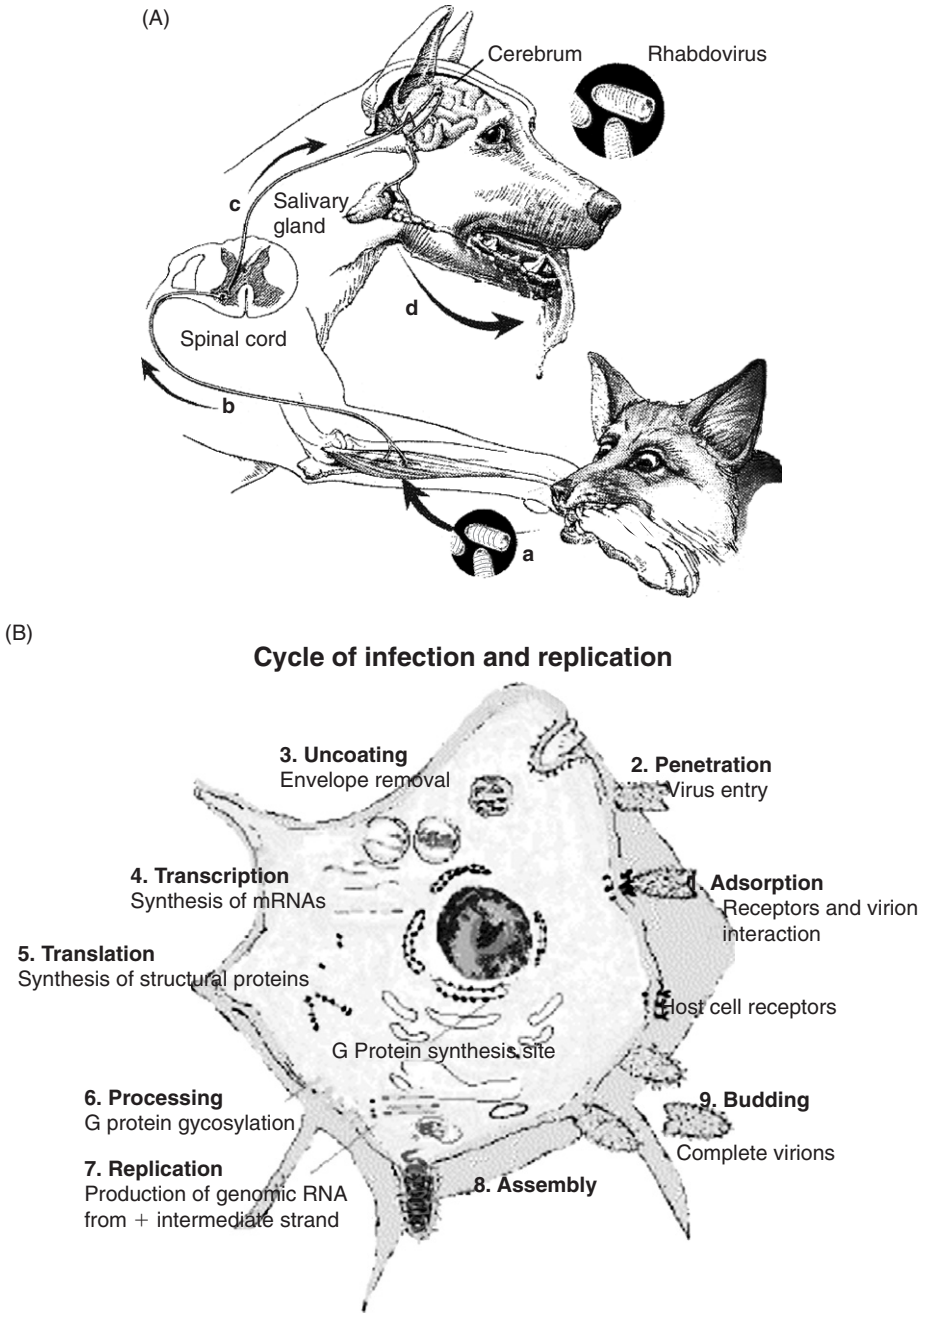

FIGURE 33.4 The infectious path of rabies virus. (A) From animal bite to CNS. (B) Intraneuronal: from reception to assembly (see color plate section).

along peripheral nerves by retrograde movement toward the CNS at approximately 50–100 mm per day. Virus replication is detectable within nerve cell bodies (Tsiang, 1993). In humans, this often leads to the first overt symptoms of disease with paresthesia, a tingling sensation at the site of the bite. Once within the CNS the virus appears to replicate rapidly with associated developments of disease symptoms. The host response to infection varies. The immune-privileged status of the brain may limit the ability of the adaptive immune system to react to infection. More recent data suggest that alternative innate-mechanisms of immunity within the CNS do respond to infection, such as the generation of interferon, although this does not appear to effectively limit the infection and may lead to further damage to the brain (Stewart and Sulkin, 1966; Turner, 1972; Marcovistz et al., 1984, 1994; Prosniak et al., 2001; Saha and Rangarajan,

2003; McKimmie et al., 2005; Johnson et al., 2006a). Subsequently, the virus disseminates centrifugally out from the brain to a wide range of organs. Critically for the virus, one of the major portals of exit is the salivary glands through which the virus is shed, leading to further cycles of infection. Although not proven, it is possible that the virus targets areas of the brain that modulate behavior thus making the victim more likely to bite further individuals (Fig. 33.4A).

QUASISPECIES

The concept of quasispecies has been difficult to confirm in virus samples. One difficulty in molecular epidemiology and phylogeny is that the methods used select a single (presumably dominant) isolate from a virus strain, therefore population variants would be excluded. In addition, nearly all virus studies are selective in that they examine a subset of viruses that lead to disease fatalities. Currently no field isolate, particularly from wild animals, which are clinically silent and fail to kill the host have been detected. If they exist they have been overlooked in these analyses.

Benmansour et al. (1992) have suggested that quasispecies exist in RABV using the glycoprotein sequence. A high level of intrinsic heterogeneity has been directly observed during the adaptation of a human RABV isolate to growth in cell culture (Benmansour et al., 1992). Using G gene sequence, a street RABV isolate from a dog was compared with that of CVS displaying a 10% divergence in overall amino acid composition. Only 6% divergence was noted in the ectodomain, suggesting that structural constraints are exerted in this portion of the glycoprotein. A human RABV isolate cultured from saliva had only five amino acids difference (1%) from a canine isolate, an indication of their close relatedness. These differences could have originated during transmission from dog to dog, dog to human, or during isolation on cell culture; nonetheless they do demonstrate genetic evolution of street RABV. This evolution was further evidenced by the selection of cell-adapted virus variants, which displayed new amino acid substitutions in the glycoprotein, one of which was associated with neurovirulence in mice (Arg333) (Benmansour et al., 1992). This intrinsic heterogeneity was further demonstrated by sequencing molecular clones of the G gene, which revealed that only one-third of the viral genomes present in the brain of a rabid animal (dog) had the consensus sequence. Two-thirds of the clones analyzed displayed from one to three amino acid substitutions. These heterogeneous populations provide the virus with the capacity to adapt quickly and easily to new environmental conditions.

The occurrence of RABV quasispecies has also been shown to have implications in disease pathogenesis. Two virus variants of the ("fixed") CVS-24 stain have been described that differ genotypically and phenotypically. One is dominant in neuronal cells, the other in nonneuronal cells, both in vitro and in vivo (murine model) (Morimoto et al., 1998). The 10 amino acid differences in the G protein between these two variants have been shown to produce differences in pathogenesis. Both are virulent in neonatal mice but only the neurotropic variant retained the ability to infect adult mice. This suggests that certain aspects of host development, such as nervous and immune system maturation may be important in the virus variant selection process (Morimoto et al., 1998). Other factors that may be involved in generating sequence heterogeneity in RABV, include duration of infection, route of transmission, virus load, virus and host protein cooperation (Kissi et al., 1999).

Kissi et al. (1999) examined the potential for variation in a wild RABV isolate from a fox and examined mutation in several genes following passage in mice, dogs, cats, and cell culture. Again substitutions in the G protein were the most common. However, passage (2–3) in animals other than mice was not sufficient to produce a new dominant variant from the quasispecies population. It has been suggested that two mechanisms of genomic evolution of the RABV quasispecies exist during adaptation to environmental change. Firstly, a limited accumulation of mutations with no replacement of the dominant sequence (conservative changes) and secondly, a less frequent but rapid selective enrichment of favored variants where advantageous mutation has occurred (Kissi et al., 1999).

In the field, genetic variability has been especially evident at wave fronts of disease spread, an observation that reflects and supports the quasispecies concept, i.e., the hypothesis that virus populations evolve most rapidly in a new environment, but that after a few "passages" the most fit variants are stabilized rapidly (Domingo et al., 1985; Holland et al., 1991). Despite the obvious potential for random mutation, overall high levels of genetic conservation are found in wild RABV. This suggests that substantial selective pressures are operative in vivo, during productive infections in various "host-adaptive landscapes." RABV genomes appear to become trapped at local fitness optima, adaptations to new hosts, or the adoption of other transmission strategies may be difficult due to structural and functional constraints on the virus. Several simultaneous coadaptive changes may be required to affect host species transfer (Wandeler

et al., 1994) as appears to have occurred with the wolf to dog and fox to raccoon dog.

POTENTIAL AS BIOTHREAT AGENT

Lyssaviruses are potential biothreat agents because confirmation of rabies in a population would spread "terror"; a principal goal of any terrorist. One reason for rabies being used as a weapon is for "notoriety" and "fear," largely related to the public familiarity with the disease. In addition, media attention associated with the presence of the disease in a population would promote "event" and "purpose." The viruses are capable of causing disease in all mammals including man resulting in widespread disruption, especially to the agricultural industry and related economies such as tourism or disruption in food supply. In addition, the disease has the capacity to confer a severe burden to human health. Although lyssaviruses are naturally fragile, are easily inactivated, and do not persist in the environment (Rupprecht et al., 2002), this group of viruses is capable of genetic change and new and emerging strains are being identified. Currently used human vaccines are not fully protective against all of the members of this genus. Limitations of biologicals could exacerbate a scenario with even conventional rabies viruses, as even a single rabid animal can result in hundreds of human exposures (Rotz et al., 1998). Lyssaviruses are primarily spread by the bite of an infected animal. However, recent data support the hypothesis that under optimum environmental conditions, virus can be spread by the airborne route (Johnson et al., 2006b). Rabies has a worldwide distribution ensuring the relative ease of obtaining a source of virus via an infected animal. The most important, and probably intangible, facet of rabies is the "fear" the disease provokes. Although the disease is usually vaccine preventable and there is a need for an appropriate transmission vector to cause infection in man, any perceived threat in the form of rabies used as a bioweapon is realistic. Deliberate release of virus in the form of a reservoir host in a previously rabies-free area could result in economic losses due to livestock death and subsequent costs of elimination. It could also invoke "fear" in a human population without requiring large-scale human fatalities. For these reasons, rabies could be perceived as a both an economic and psychological bioweapon. To date, there are no substantial documentations that lyssaviruses have been weaponized. Nevertheless, with adequate technology, concentrations in cell culture can be obtained that exceed 1×10^8 $TCID_{50}$ without a loss in virulence.

CLINICAL DISEASE

The first characteristic signs of rabies usually appear after an incubation period of 15–30 days. This period is only an approximate indication, corresponding to an exposure of average intensity in a species of average receptivity to a given virus. The incubation period can be much longer and may extend from weeks to months and even years (Rupprecht et al., 2002). The clinical signs of rabies may vary according to the species; "furious" (encephalitic) or "paralytic (dumb)" forms of the disease being observed in almost all species affected (Warrell and Warrell, 2004). The majority of patients (70%) demonstrate rabies in the "furious" form. In humans, the onset of clinical rabies is characterized by nonspecific prodromal features consisting of headache, fever, anorexia, nausea, vomiting, and diarrhea. This may be associated with symptoms such as anxiety, aggression, insomnia, hallucinations, and nightmares. Clinical symptoms progress rapidly especially as the virus spreads through the central nervous system (CNS) and the neurological impairment increases. Symptoms often fluctuate with paroxysms of hyperventilation and dysphasia, usually provoked by sight or sound of water, which are punctuated by periods of relative lucidity. The patient may also complain of intolerance to tactile, auditory, and visual stimuli. Paraesthesiae or pain at the bite site is observed in about 45% of cases, which may be followed by progressive pain or numbness in the limbs. Usually within 4–7 days, from the onset of symptoms, pain is reported in the neck region, which increases in intensity before becoming a permanent headache.

Hyperexcitability and hydrophobia are characteristic of the furious (encephalitic) form of rabies. These patients usually die within 7 days (average 5 days) after the clinical onset (Hemachuda and Phuapradit, 1997). In patients suffering from "paralytic" rabies, the average length of survival is 13 days. The initial clinical features of "furious" rabies are fever and hyperactivity. The latter is in response to internal stimuli such as thirst and nervousness, and to external stimuli including light and noise. The typical "furious" clinical symptoms then include: aerophobia, hydrophobia, fluctuating consciousness, spasms, and autonomic dysfunctions (hypersalivation and piloerection).

The initial clinical features of "paralytic" rabies are similar to those of "furious" rabies albeit later and milder. Inspiratory spasms occur in all patients with "paralytic" rabies during the preterminal phase. The bitten limb will usually present with weakness, which eventually spreads to all of the limbs, pharyngeal, facial, and respiratory muscles. Other symptoms

include hypersalivation and altered perception. In many cases, a fear of death is continually expressed leading to confusion, urinary incontinence, and atrial fibrillation followed by respiratory spasms, breathing difficulties, convulsions, profuse salivation, and ultimately cardiorespiratory arrest (Hemachuda and Phuapradit, 1997; Solomon et al., 2005). In contrast, an ascending paralysis, usually from the bitten limb, is characteristic of the paralytic or "dumb" form of the disease. The paralysis then spreads rapidly and symmetrically with a loss of sphincter control and paralysis of the muscles of deglutination and respiration. The latter occurs as a terminal event.

MORBIDITY AND MORTALITY

Rabies is almost always fatal, once symptoms appear (Hemachuda and Phuapradit, 1997; Rupprecht et al., 2002; Warrell and Warrell, 2004). It has been reported that five vaccinated patients with "atypical" rabies have survived as none of these patients showed the "usual" clinical symptoms of rabies (Hemachuda, 1997). In 2005, a single case of survival from rabies in a teenager from the US following rabies virus transmission from a bat bite was reported (Willoughby et al., 2005). In this case, the patient showed "typical" clinical symptoms of rabies and although she had not received pre or postexposure vaccination against rabies, her treatment consisted of an innovative and largely unproven regimen of drug-induced coma plus a combination of antiviral therapy. Although premature in understanding, the success in treating this patient, and the history of prior survivors, does suggest that the clinical course of rabies can be altered in a small number of cases. Attempts at duplicating the original achievement of the "Milwaukee protocol" from different laboratories in patients suffering rabies have been unsuccessful, leading to the supposition that additional fundamental studies and development of relevant animal models are still required before this protocol is universally accepted (Hemachudha et al., 2006; Jackson et al., 2007; Willoughby 2007). Therefore, until the treatment used is substantiated, once clinical symptoms develop rabies remains a fatal and not a curable disease.

DIAGNOSTIC METHODS

A diagnosis of rabies is usually made on clinical grounds in the first instance. In areas free of rabies, a history of travel to a rabies-endemic country and/or evidence of a bite wound support a rabies diagnosis. A preliminary diagnosis should be verified through the use of specific laboratory tests. Rabies is diagnosed in many laboratories following positive histological examination of brain tissue by the direct fluorescent antibody test (FAT), which employs the detection of the nucleocapsid protein (Goldwasser and Kissling, 1958; Dean et al., 1996). This is a rapid, sensitive, and specific test (2–3h) with a high specificity. Histopathological preparation on formalin fixed paraffin-embedded brain preparations, stained with Hemotoxylin and Eosin (H&E), can be performed as well, but take several hours longer than the FAT. Aggregates of viral protein ("Negri bodies") often accumulate within certain neurons (particularly in the brain stem, cerebellum, and hippocampus) and can be observed under the light microscope, however false-positive results have been reported due to nonspecific inclusion bodies. Although the older method of examination for Negri bodies may be rapid, it has a low specificity and sensitivity compared to other methods (Nietfeld et al., 1989). Virus isolation can be achieved by the mouse inoculation test (MIT). This is performed by preparing homogenized suspension of suspect tissue (normally brain tissue) that is administered to mice by intracranial injection (Koprowski, 1996). The mice are monitored up to 28 days postinfection. The rabies tissue culture infection test (RTCIT) is comparable to the MIT and the results are obtained within 2–4 days (Rudd and Trimarchi, 1987; Crick and King, 1988). Laboratories with access to highly specific monoclonal antibodies have the opportunity to employ immunohistochemical techniques in detecting antigen in fixed tissues. Rapid immunohistochemistry protocols are under development for enhanced field surveillance (Lembo et al., 2007). Molecular techniques including the reverse transcriptase-polymerase chain reaction (RT-PCR) can be used to identify the presence of viral RNA in a range of samples (Sacramento et al., 1991), including saliva, thus providing the ability to attempt antemortem diagnosis in humans (Johnson et al., 2002b; Smith et al., 2003). An advantage of molecular diagnostic techniques, especially RT-PCR, is the ability to amplify template in preparation for sequencing. This may be required if more than one lyssavirus genotype is present in the area when the infection occurred. In general, the highly variable regions of the genome are the most suitable for differentiating closely related isolates. In contrast, the conserved regions are suitable for typing distantly related lyssaviruses. Given the cost, time, and opportunity for both false positives from laboratory contamination, as well as false negatives from primer mismatches, these variables, among others, usually limit the diagnostic utility of PCR to national research laboratories.

TREATMENT

Although there is no proven treatment that exists for rabies once clinical signs have appeared in an animal, postexposure prophylaxis is highly effective in man before clinical symptoms are observed and is also likely to be effective in animals. For this reason the actions taken following a bite from a potentially rabid animal are critically important to ensure prevention of disease. In the event of clinical suspicion, it is advisable to isolate the suspect animal, and to euthanize it (Rupprecht and Gibbons, 2004). Previous studies have demonstrated that thorough cleansing of the wound or wounds, with copious amounts of soap and water can increase survival by 50% (Kaplan et al., 1962). Subsequently, medical advice should be sought and PEP initiated as soon as possible. This consists of administering several injections of an antirabies vaccine according to a protocol defined by the medical authorities, principally the WHO. Vaccine is supplemented by the administration of rabies immune globulins (RIGs) infiltrated around the wounds. In some exceptional circumstances, recovery from clinical rabies has been documented both in humans and animals (Hattwick et al., 1972; Porras et al., 1976; Willoughby et al., 2005) but as yet the reason for these recoveries has not been elucidated.

PHYSICAL RESISTANCE OF THE VIRUS

Lyssaviruses are regarded as relatively fragile and are susceptible to a range of physical agents: virions are rapidly destroyed by heat, and heating to 50°C for 15 min completely inactivates the virus. Lyssaviruses are also inactivated by light and ultraviolet rays, and by different chemical agents including lipid solvents (ether, chloroform), quaternary ammoniums, bleach, and soapy solutions (practical application to the washing of bite wounds and their disinfection) (Kaplan, 1996). Phenol, formaldehyde, β-propiolactone, acetylethyleneimine also destroy the virus (practical application for inactivation of the virus during vaccine manufacture). In addition, lyssaviruses are preserved by 50% glycerine (application to the preservation of samples for dispatch to the laboratory in the event of lengthy transport) and quite resistant to putrefaction under certain circumstances, and virus has been identified in the carcass of a rabid animal that had been buried for 9 days (Lewis and Thacker, 1974). Rabies virus has been shown to survive from naturally infected foxes, in the form of a suspension of salivary gland tissue in physiological saline containing 10% calf serum. At temperatures of 37 and 20°C there was a rapid decline in the amount of virus over the first 24 h with complete inactivation after 96 h. The effect of temperature was marked, with virus surviving 144 h at 5°C when exposed on a flat surface but being inactivated within 42 h at 20°C (Matouch et al., 1987). Solar radiation increased the rate of virus destruction; inactivation was complete after one and a half hours when exposed to intense sunshine at 30°C, but inactivation took 20 h at the same temperature in the absence of sunshine.

IMMUNOLOGY

Antigens Encoded by Agent

The *Lyssavirus* genome is composed of a single strand of negative-sense, nonsegmented RNA (around 12 kb) encoding for five separate proteins and comprising a vestigial intergenic region (psi) between the G and L cistrons. The genes are ordered from 3′ to 5′ end of the genome as follows: nucleoprotein (N), phosphoprotein (P, NS, or M1), matrix protein (M or M2), glycoprotein (G), and RNA-dependent RNA polymerase (L) (Fig. 33.5). Structurally, the virion is composed of a nucleocapsid incorporating the N, P, and L proteins in tight association with the genomic RNA. The M protein forms a capsid structure which is in turn surrounded by a host-derived envelope into which the G protein is inserted. As a result the G protein is the only surface exposed viral protein. The G- and N-gene products are the major stimuli involved in eliciting an immune response in vaccinated animals (Wunner et al., 1988; Rupprecht et al., 1991) and therefore have been the focus of much research.

The G-genes of fixed strains of RABV and that of wild-type strains are drastically different (Lafon, 2005) and as such suggest that the glycoprotein is responsible for degrees of virulence and plays a fundamental role in both pathogenicity and neuroinvasiveness in different hosts (Faber et al., 2007). Of critical importance to neurovirulence is the presence of an arginine at position 333 of the glycoprotein. A change of residue at this position severely attenuates the virus variant through a loss of neuroinvasiveness (Dietzschold et al., 1983). Differences in pathogenicity between lyssavirus strains might also be dependent on the length of the genomic region between the L-gene start methionine and the transcription termination and polyadenylation (TTP) motif, which might affect transcriptional activity and RNA stability. All available lyssavirus sequences to date, including the EBLVs, use the second TTP site with the exception being Pasteur Virus (PV) and PV-derived isolates (Marston et al., 2007).

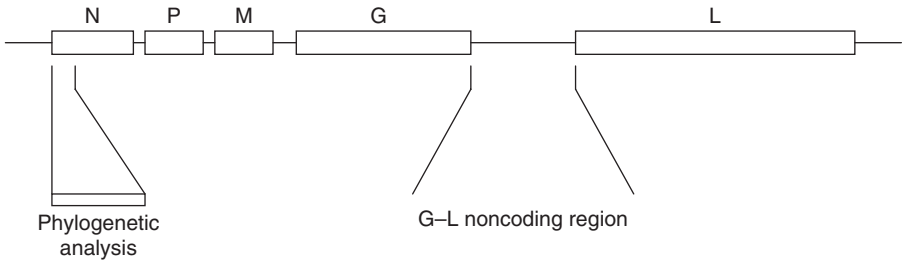

FIGURE 33.5 A schematic representation of the rabies virus genome showing the 5 coding regions for the nucleoprotein (N), phosphoprotein (P), matrix protein (M), glycoprotein (G), and the RNA polymerase (L). Also shown is the 400 base pair region of the nucleoprotein used for phylogenetic analysis of panels of rabies viruses (see Fig. 33.3) and the 500 bp G–L intergenic region with no known coding function.

PROTECTIVE IMMUNE RESPONSES

The principal property of RABV is its ability to infect neurons and gain access to the CNS, an immune-privileged site. If the virus can gain access to the CNS before an immune response is generated, the fate of the host is largely sealed. The principal correlate of protection against rabies is a strong virus neutralizing antibody response (Hemachuda, 1994). This response is used as a convenient marker to demonstrate the utility of vaccination in animals (Fooks et al., 2002). Antibodies directed to the viral glycoprotein are believed to provide the most effective immunological means as this is the only surface exposed antigen (Celis et al., 1986) possibly by the inhibition of cell-to-cell spread of infectious virus particles (Hooper et al., 1998). However, the glycoprotein of different RABV strains have different immunogenic properties, possibly related to the ability of certain strains to induce apoptosis (Morimoto et al., 1999). It is hypothesized that fixed, laboratory adapted strains of RABV overproduce glycoprotein and trigger the host cell to apoptose. This in turn makes the virus more immunogenic and reduces virulence. By contrast, the street or wild-type strains of RABV do not overproduce glycoprotein and maintain virulence for the host without apoptosis (Theerasurakarn and Ubol, 1998; Bahloul and Lafon, 2003).

The three-dimensional structure of the glycoprotein has not been fully elucidated, and as yet no crystal structure for this protein has been resolved. However, it is postulated to form trimeric structures within the virion envelope, which may have frustrated efforts to create recombinant vaccines against rabies. A number of epitopes have been identified using monoclonal antibody mapping. The principal epitopes are conformational (Seif et al., 1985; Prehaud et al., 1988) although many linear, nonconformational epitopes have been demonstrated (Dietzschold et al., 1990: Luo et al., 1997: Ni et al., 1995: Raux et al., 1995: Mansfield et al., 2004). However, it is unclear whether naturally infected or vaccinated individuals produce antibodies against these sites. Studies of RABV sequences encoding for the glycoprotein have not demonstrated great variation at suspected epitopes or for any selective pressure at particular glycoprotein sites driven either by the need to evade the host immune system or to adapt to new hosts (Holmes et al., 2002).

RABV-specific cell-mediated responses have been demonstrated (Celis et al., 1986; Cho et al., 1987) and may play a role in protection but this may be limited to assisting in the development of the antibody response. Gene knockout experiments in mice suggest that the loss of the cell-mediated arm of the immune system lowers but does not preclude resistance to rabies, whereas loss of antibody production invariably leads to fatal infection (Hooper, 2005).

Although the contribution of cell-mediated and innate immune responses to protection against rabies virus replication has not been fully defined, it is considered that they are not as important as the antibody response. As a result only a small number of studies have sought to identify T cell epitopes on particular virus-encoded proteins. Such epitopes have been mapped to the phosphoprotein (Celis et al., 1990), nucleoprotein (Ertl et al., 1991), and glycoprotein (Desmezieres et al., 1999). The entry of primed cytotoxic T cells into the CNS would lead to the destruction of virally infected cells, which in turn could contribute to the manifestations of disease (Sugamata et al., 1992). They may also play a role in the expression of proinflammatory cytokines, especially type 1 interferons. The expression of interferon-γ, TNF-α, IL-1α, and TLR3 are markedly increased following rabies infection and correlate with disease symptoms (Marquette et al., 1996; McKimmie et al., 2005). However, it is unclear if T cell infiltration is a common feature of late stage rabies virus infection (Wang et al., 2005). Indeed, RABV-specific cytotoxic T cells, in

association with the production of inflammatory cytokines such as tumor necrosis factor-α, may be detrimental to the host and induce paralytic disease. Human cases of infection do not always show evidence of an antibody response and although it is often used diagnostically, serological tests for rabies are often inconclusive (Crepin et al., 1998). In contrast, vaccination is highly effective either given before exposure or prophylactically.

VACCINES

The development of vaccination against rabies began early in the 19th century with the pioneering work of Louis Pasteur. Without the benefit of our current understanding of the pathogen or the immune system, he developed a vaccine that prevented the development of disease following exposure. The first vaccines used the desiccated spinal cord of rabbits infected with rabies and required a long course of injections (which Pasteur as a scientist, not a clinician, was unable to administer himself). Although nerve tissue-derived vaccines are still in use today, WHO (2005) does not recommend their use due to side effects induced by components of the vaccine preparation. A 20th century milestone has been the development of cell-culture derived vaccines. These vaccines, such as human-diploid cell vaccine (HDCV: Imovax®, Sanofi), are considerably safer but are more expensive to produce. However, they are now being superceded by the purified chick embryo cell vaccine (PCECV; Rabipur®, RabAvert, Chiron Behring Vaccines, USA), and Vero cell vaccines (PVRV; Verorab, Sanofi). Such vaccines can be used for both pre and postexposure prophylaxis. Preexposure vaccination is recommended for those at high risk, including research workers, veterinarians, animal handlers, and travelers to rabies-endemic areas. The vaccination schedule consists of three intramuscular injections at day 0, 7 and 21 or 28. Postexposure vaccination is more complex and its use may depend on the level of exposure. A number of regimens have been developed (Dreesen, 1997) that also include the use of RIG. The RIG is derived from equine or human sources, although the cost of its production has cast doubt on its future availability (WHO, 2005). There are little data on the persistence of protection although one study demonstrated that 14 of 22 vaccine recipients possessed neutralizing antibody levels above 0.5 IU/ml five years after immunization (Rodrigues et al., 1987). By current WHO recommendations, those that are at continuous risk of exposure to the virus are recommended to monitor serum antibody levels at 6 monthly intervals and to obtain a booster vaccination if the antibody level drops below 0.5 IU/ml.

Parenteral vaccination of animals against rabies is undertaken by the subcutaneous or intramuscular route at doses recommended by the vaccine manufacturer. The vaccines most frequently used in tropical countries until recently were modified live-virus vaccines obtained by passage in laboratory animals or in cell culture (ERA/SAD strains or derivatives) and in chicken embryos (Flury strain, high or low egg passages: HEP or LEP). These vaccines had the advantage of being easy to produce, were inexpensive, and provided protection for 2–3 years. They had the disadvantage, however, of being heat-sensitive and dangerous for some species (e.g., the LEP vaccine in the cat). These live-virus vaccines have therefore gradually been replaced by inactivated virus vaccines produced in cell culture, which had the advantage of lacking the potential threat of vaccine-induced rabies. The length of immunity conferred can also equal or exceed that offered by live-virus vaccines, especially when an adjuvant is added. Such vaccination should be given to companion animals in rabies-endemic areas and is a requirement for many animals being transferred from a rabies-endemic area to a rabies-free country (Fooks et al., 2002).

Japan is believed to be the first country to use canine vaccination on a large scale to control rabies. A Semple-type vaccine of rabbit brain origin was developed in the early 1920s, and its success aroused interest in the US, where research on methods to assess the potency of this type of vaccine, and on establishing the duration of immunity in vaccinated dogs, was undertaken.

A further development in the vaccination of animals has been the development of live-attenuated rabies vaccines that can be administered orally (Baer et al., 1971). This approach was pioneered in the field in Switzerland (Wandeler et al., 1988) and has been used extensively in Europe and North America. The three vaccines used most frequently are based on the ERA/SAD strain, the SAG2 strain, and recombinant vaccinia-rabies glycoprotein vaccine (VRG). These vaccines are usually offered in liquid form, 1–2 ml of which are placed in a vaccine container, such as a plastic capsule, which is encased in a meatmeal or fishmeal-based bait. Often the content and mode of presentation of the bait needs to be refined to target particular species and provide sufficient uptake to ensure a high level of vaccine coverage. These baits can either be distributed in the wild (manually or by aerial means) in the case of wild carnivores or stray dogs, or distributed individually by hand outs directly in the case of domestic dogs. In view of the potential

danger that these vaccines present to nontarget species (notably man), who could ingest them, the distribution of oral vaccines should be administered by authorized persons and must be undertaken within a regulated national vaccination program. This approach has led to the virtual elimination of rabies from the fox population in much of Europe and has contributed to the control of rabies in a range of wildlife species in North America.

Modern, cell culture-based rabies vaccines with their origin from genotype 1/serotype 1 strains, are composed of, and elicit protective immunity against, strains within phylogroup I. It is unclear, however, that vaccines based on genotype 1/serotype 1 strains will protect against infection with viruses from the other phylogroups. Studies to assess the ability of rabies vaccines to protect against the other lyssaviruses continue as results vary widely depending on the vaccine virus strain, challenge method, and host species. There are three main vaccine strains: PV, Pitman-Moore (PM), or Flury low egg passage (LEP). Hanlon and coworkers have shown that RABV-based vaccines provide little to no crossprotection against the recently identified lyssavirus, West Caucasian Bat virus. The inability of conventional preexposure immunization against rabies and postexposure prophylaxis against these newly emerging lyssaviruses has serious public health implications (Hanlon et al., 2005). As conventional prophylaxis does not exist for these new viruses, there is an urgent need for the development of a broad-spectrum vaccine and an appropriate immune globulin with cross-neutralizing ability against all of the viruses within the *Lyssavirus* genus.

Future DNA vaccines or recombinant viral vectors expressing immune-dominant regions may be able to confer protective immunity against all of the lyssaviruses. These prototype vaccines should be simple to produce, cost-effective, safe from genetic reassortment, and able to elicit a balanced Th1/Th2 immune response. In this respect, both the G- and N-proteins have been expressed in prokaryotic and eukaryotic expression systems and used as vaccine-delivery systems for both parenteral and oral application (Rupprecht et al., 1986; Prehaud et al., 1990; Yarosh et al., 1996). Despite numerous research studies, DNA vaccination against rabies has not proved sufficiently efficacious to warrant phase I clinical trials (Ertl, 2003). Edible plants expressing rabies virus proteins have also been considered for the large-scale production of antigens. Plant-derived proteins could provide an inexpensive delivery vehicle for subunit vaccines in developing countries to vaccinate both animals and man in mass vaccination campaigns (Yusibov et al., 1997; Ma et al., 2005). Transgenic tomatoes have been engineered to express the RABV glycoprotein, freeze-dried, and fed to mice resulting in the generation of G-specific antibodies (McGarvey et al., 1995). However, major issues about antigen concentration and delivery remain.

Although initially complex, the ability to produce recombinant negative-strand viruses is now very common. This has included the reverse genetics of rabies virus (Schnell et al., 1994) and has lead to a revolution in our understanding of the relationship between particular viral components and disease pathogenesis (Faber et al., 2004). This technology now offers a great many opportunities to design and develop a range of live-attenuated vaccine candidates tailored to the particular virus variant being targeted. For example, in the United States this could find many applications where current oral delivery vaccines have not proven effective at reducing rabies among a number of wildlife vectors (Dietzschold and Schnell, 2002). Indeed, the level of sophistication achieved by this approach has enabled rationally attenuated rabies viruses to be redesigned for use as a vaccine against other pathogens and also incorporating a beneficial cytokine gene (McGettigan et al., 2006).

PUBLIC HEALTH SIGNIFICANCE

WHO estimates that there are in excess of 50,000 rabies deaths in humans each year. The highest number of human rabies cases is reported in Africa and Asia, particularly the Indian sub-continent. These figures however, are considered to be conservative estimates due to underreporting of the disease in developing countries. This is largely a result of poor health care infrastructures and also because of insufficient control measures confronting significant reservoirs present in domestic animals and wildlife species. For these reasons, it is unlikely that rabies will be truly eradicated globally, especially considering the role of bats. Control efforts are focused on virus elimination in animals that might have frequent contact with man, particularly companion animals.

The Pan American Health Organization demonstrated in the late 1990s that human rabies could be effectively reduced through a program of parenteral vaccination of domestic animals in conjunction with rabies education campaigns, especially in rural rabies-endemic regions of developing countries of the Americas. In this way, the transmission cycle from animals to humans was disrupted, acutely limiting virus spread and reducing the public health risk. However, this approach does not yet address elimination or reduction of rabies in wildlife reservoirs. This provides

a compelling argument for an understanding of the epidemiological cycle of rabies in a specific region so that appropriate control policies can be used to target particular animal reservoirs. Furthermore, bat rabies has never been successfully eliminated, and it is not clear what strategies would be successful, so true eradication of the disease is not possible in many parts of the world. Population controls used to reduce transmission of RABV from vampire bats in Latin America using nonselective destructive methods are considered to be obsolete and offer only a short-term respite from the problem. In many cases, the problem can be exacerbated where habitat is destroyed or disrupted. Bats incubating the disease can travel up to 100 km and transmit rabies to new colonies resulting in further dissemination of the virus in geographical locations that may have been previously rabies-free.

Apart from infection by bites, exceptional cases of infection by aerosols have been reported (in caves inhabited by large colonies of infected bats) or by the ingestion of infected animal carcasses. However, these natural modes of infection are not considered to be of critical public health importance in epidemiological terms at the present time (Constantine, 1962).

PROSPECTS FOR THE FUTURE

With the advent and widespread use of molecular biology techniques, it is now possible to construct lyssaviruses from cloned cDNA (Schnell et al., 1994). This pivotal report has led to an explosion in "reverse genetics" allowing genome rearrangements and the selection and isolation of "rescued" viruses that do not occur naturally. Possible drawbacks in these technologies is their use in developing viruses with altered phenotypes that demonstrate a broader cell-tropism with enhanced targeting moieties. A genetically engineered strain of rabies virus could potentially be generated with a high neuroinvasiveness, the potential ability to change tropisms, to be airborne, and to evade immunity from current rabies vaccines. A more simplistic and less technologically challenging scenario would be a strain of virus that targeted feral cats in urban areas. This would also cause widespread disruption and risks to public health. Lastly, opportunistic scenarios and "timing" of an event could be utilized for terrorist acts. In 2004, a shortage in the supply of Imovax® rabies vaccine (Sanofi Pastuer) in Canada led a second vaccine, RabAvert® (Chiron), to be licensed for use in Canada in a relatively short time. In the US and Europe, manufacturing problems in the shortage of Imovax® rabies vaccine led to concerns over available vaccine for PEP. The global shortage of immune globulins for human use as part of a PEP regimen has led to numerous approaches, some coordinated by WHO, to provide an alternative product for use throughout the world. Additionally, the need for national strategic stockpiles of these orphan biologicals has received recent attention.

It is necessary for governments and international organizations to combat any terrorist use of biological agents, such as rabies, by implementing a global, integrated surveillance program that has an "early detection" signal with open communication channels for the free-flow of data and information between cooperating countries, before such events are documented.

KEY ISSUES

- Lyssaviruses are zoonotic.
- Lyssaviruses are present in all continents of the world.
- Lyssaviruses must be notifiable in all countries.
- Lyssaviruses should be considered as potential biothreat agents.
- Transmission of a lyssavirus from one host to another is principally by the dissemination of virus-laden saliva from a biting incident.
- Lyssaviruses are readily inactivated in the environment and are poorly transmitted by the airborne route.
- Detection of the virus in a previously "rabies-free region" would result in widespread disorder, especially if used for agroterrorism.
- Misconceptions concerning rabies still avail. It is largely the "notoriety" and "fear" of the disease, especially in countries that are free from terrestrial disease in animals, in which the disease would cause the most disruption.
- Efficacious animal (live-attenuated and recombinant viral-vectored) vaccines are available for both parenteral and oral use.
- The large-scale control of rabies in wildlife has been successfully demonstrated with the use of oral vaccines.
- Fully efficacious and safe (inactivated) cell-culture produced human vaccines are available.
- There is no reliable treatment for rabies once clinical symptoms appear.
- Postexposure prophylaxis against rabies is only effective in humans before the onset of clinical symptoms.
- Any PEP regimen must include both a course of vaccination and the administration of immune globulin to be fully effective.

- New vaccine candidates and alternative immune globulins are under development in order to neutralize and cross-protect against new and emerging lyssavirus strains.

As part of the emergency preparedness to deal rapidly with any deliberate release of rabies virus or a related lyssavirus, an incident report plan (IRP) has been prepared. The IRP will be coordinated from national veterinary/medical authorities in alliance with international organizations, especially the WHO and OIE and used to quickly identify an infected area and to galvanize a rapid response team comprised of designated experts involved with emergency planning in consultation with rabies experts representing the World Health Organization Communicable Disease Surveillance and Response Collaborating Centre network and the OIE rabies reference laboratory network. Additional support from international specialists in veterinary public health, epidemiologists, clinicians, and representatives from other government departments and nongovernmental organizations will be provided in such an emergency.

Ross River Virus: Epidemic Polyarthritis

John Aaskov
Institute of Health and Biomedical Innovation; World Health Organisation, Collaborating Centre for Arbovirus Reference and Research, Queensland University of Technology, Brisbane, Australia

OUTLINE

ABSTRACT

Ross River virus is a mosquito-borne Alphavirus which is endemic in Australia and Papua New Guinea and which causes approximately 5000 cases of a disease known as epidemic polyarthritis each year. Horses are the only hosts, other than humans, known to develop clinical signs or symptoms following a natural infection. The dramatic increase in the number of cases reported between 1980 and 1990, and thereafter, reflects the development and commercialization of ELISA-based tests to diagnose this disease and the requirement for it to be notified to health authorities. Patients develop arthritis in the small joints of the hands and feet and also may experience fever, rash, and a range of other nonspecific signs and symptoms. Disability lasts from a few weeks to a year or more. The disease has been estimated to cost Australia more than US$10 million each year in direct medical costs. The epidemic potential of the virus was demonstrated in 1979–1980 when it spread to Fiji, New Caledonia, Samoa, Tonga, and the Cook Islands causing thousands of clinical infections. Interestingly, this outbreak by-passed New Zealand. After an interval of 25 years, RRV transmission was detected again in Fiji in 2004. Isolated cases of epidemic polyarthritis also are diagnosed among visitors returning from Australia to Europe and to areas of the southern United States where there are mosquitoes which are able to transmit the virus. Vector control is

an expensive and inefficient mechanism for controlling this disease because of the wide range of mosquito and vertebrate hosts for RRV and the wide range of different habitats employed by these hosts. Natural infection in humans appears to provide lifelong immunity against a second clinical infection so this virus appears to be an ideal target for a vaccine. Experimental animals immunized with RRV inactivated with binary ethyleneimine or with formalin developed no adverse signs or symptoms and did not develop a viremia when challenged intravenously with large doses of virus. The titers of neutralizing antibody elicited by these killed vaccines in experimental animals were similar to those in humans following a natural infection.

INTRODUCTION

Ross River virus (RRV) causes approximately 5000 cases of epidemic polyarthritis in Australia and an unquantitated number in Papua New Guinea each year. While the emergence of epidemic polyarthritis in Australia is probably a reflection of the emergence of a capacity by laboratories in this country to diagnose RRV infection in a simple and reliable manner, the epidemic of RRV infection in the Pacific in 1979–1980 was a clear demonstration of the epidemic potential of this virus in nonimmune human populations. It remains to be seen whether the apparent absence of RRV from most areas of the Pacific involved in the 1979–1980 outbreak has allowed a large enough population of nonimmune hosts to develop for another outbreak to occur in this region. There also may be value in monitoring the return of epidemic polyarthritis patients to areas of the United States where the local mosquitoes are known to be competent to transmit the virus. RRV infection is difficult to prevent through vector control programs alone because of the large number of potential hosts and mosquito vectors. However, natural infection with this virus appears to elicit lifelong immunity against clinical disease.

HISTORY OF THE DISEASE

Shope and Anderson (1960) recognized that the outbreaks of polyarthritis that had been observed throughout eastern Australia since 1928 (Nimmo, 1928; Halliday and Horan, 1943; Harris, 1944; Sibree, 1944; Dowling, 1946; Goswell, 1946; Short, 1949; Anderson and French, 1957; Fuller and Warner, 1957; Wilson, 1957) resembled that in Tanganyika (Tanzania) in 1952 (Robinson, 1955) from which one of Casals' (Casals, 1957) Group A arboviruses (Chikungunya) had been isolated (see Chapter 32). Using a panel of Group A arboviruses (Semliki Forest, Mayaro, Chikungunya, Bebaru, and Getah) to test acute and convalescent sera from patients who developed rash and polyarthritis during an outbreak of "epidemic polyarthritis" in Mildura and surrounding towns in the Murray Valley (Fig. 34.1) in 1956, Shope and Anderson (1960) were able to show diagnostic rises in hemagglutination inhibiting (HI) antibody titers to Semliki Forest virus (three patients) and Bebaru virus (two additional patients). A diagnostic rise in neutralizing antibody titers against Bebaru virus also was detected in four of these five patients.

Anderson et al. (1961) then detected antibody that neutralized Bebaru virus in sera from humans from Queensland, Victoria, the Northern Territory, and Papua New Guinea and in horses, pigs, and cattle from throughout Queensland. Stanley and Choo (1964) also detected antibody that reacted with Bebaru virus in human sera from central and Western Australia and in horses from south-west Western Australia. Together, these studies suggested that epidemic polyarthritis was caused by a Group A arbovirus (Alphavirus) and that infection with this (these) agents was widespread in Australia.

Isolation of RRV by Doherty et al. (1963) enabled serological tests to be used to confirm that it, rather than Bebaru virus, was the causative agent of epidemic polyarthritis (Doherty et al., 1963, 1964).

FIGURE 34.1 Locations in Australia mentioned in the text.

Subsequent serological studies have found the subclinical infection rates with RRV in humans to vary from approximately 0.5% per annum in southern Australia (Echuca-Melbourne Collaborative Group, 1976; Fraser et al., 1986) to 1.5% per annum, and greater, in northern Australia (Doherty et al., 1966; Aaskov et al., 1981e).

ETIOLOGICAL AGENT

Classification

Family: Togaviridae. Genus: *Alphavirus* (Fig. 34.2).

Doherty et al. (1963) used suckling mice to isolate the prototype strain of RRV (T48) from a pool of 88 female *Aedes vigilax* mosquitoes which had been collected in a mangrove habitat near Ross River in Townsville in northeastern Australia between January 27 and February 6, 1959.

Although Doherty et al. (1972) recovered RRV from a child with headache, fever, and chills in 1971, using suckling mice, the first isolate of RRV from an epidemic polyarthritis patient was made, again using suckling mice, by Mataika and Miles during the outbreak of RRV infection in Fiji in 1979 (Aaskov et al., 1981c). Subsequently, Tesh et al. (1981) recovered a single isolate of RRV from epidemic polyarthritis patients in Samoa and Rosen et al. (1981) recovered 49 isolates of RRV from acute phase sera from epidemic polyarthritis patients in the Cook Islands and demonstrated viremia in these patients for up to a week following onset of symptoms. Despite more than two decades of attempts to isolate RRV from epidemic polyarthritis patients in Australia using a variety of avian and mammalian systems, the first isolates were not made until 1983—using C6-36 mosquito cells (Aaskov et al., 1985). Subsequent experience in Australia suggested that virus could be recovered from approximately 10% of acute phase seronegative serum samples from epidemic polyarthritis patients using cultures of C6-36 cells. This rate is lower than that reported by Rosen et al. (1981) in the Cook Islands but few Australian patients present as early after onset of symptoms as did those in the Cook Islands.

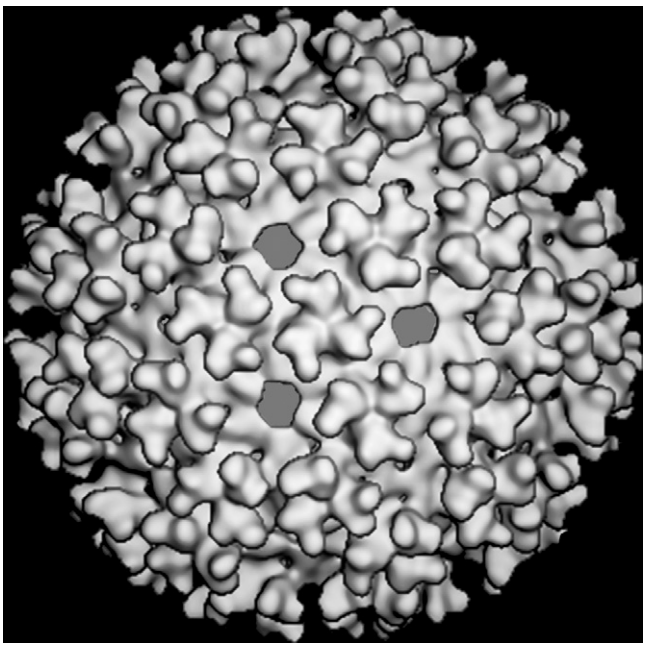

FIGURE 34.2 Cryo-EM reconstruction of RRV showing the clusters of trimeric E1-E2 heterodimers over the surface of the virion. The dark areas in the centre of the virion are regions in which the lipid envelope is exposed.

Shope and Anderson (1960) provided the first serological evidence that the causative agent of epidemic polyarthritis was a "Group A" arbovirus and the subsequent serological studies with RRV (Doherty et al., 1963, 1964) confirmed its classification in this family. However, it was not until the studies by Martin et al. (1979) and Richardson et al. (1980) and the limited nucleotide sequencing by Dalgarno et al. (1983) that there was biochemical evidence to support the subsequent classification of RRV as an *Alphavirus* in the family Togaviridae.

The genomes of the prototype strain of RRV (T48) and that of a mouse avirulent strain (NB5092) have been sequenced (Faragher et al., 1988).

By analogy with other alphaviruses, the genome of RRV (Faragher et al., 1988) is believed to code for four nonstructural proteins (nsP1-4) and five structural proteins (capsid [C], envelope protein 3 [E3], envelope protein 2 [E2], 6K protein, and envelope protein 1 [E1]) although only C, E2, and E1 can be detected in mature virions. RRV falls into the subgroup of Alphaviruses with an OPAL stop codon (UGA) at the 3′ end of the nsP3 protein. However, recent studies with O'nyong-nyong (Lanciotti et al., 1998) and RRVes (Aaskov, unpublished) suggest that Alphavirus populations may be polymorphic at this site having genomes with the OPAL codon and genomes with a codon for Arginine (CGA).

Cryo-electron microscopic reconstructions of the RRV virion (Cheng et al., 1995; Smith et al., 1995; Mukhopadhyay et al., 2002; Zhang et al., 2005) (Fig. 34.2) revealed a genome encased in a nucleocapsid composed of 240 copies of the capsid protein in a $T = 4$ icosahedral lattice and surrounded by an host cell-derived lipid bilayer approximately 40Å thick. Anchored in the lipid bilayer were 80 spikes each composed of three E1-E2 envelope protein heterodimers.

There are no reports of the E3 protein being detected in mature RRV virions. Amino acid residues around E218 of the E2 protein may play a role in attachment to host cells (Kerr et al., 1993; Heil et al., 2001) and the region ^{80}VYTGVUPFMWGGAYCFCD^{97} in the E1 glycoprotein of RRV shows extensive homology with the same region of other alphaviruses and with other viral proteins which are involved in fusion of virions with host cell membranes (Strauss and Strauss, 1994) and may play a similar role in the infection of cells by RRV.

Antigens Encoded by the Agent

While all the structural and nonstructural proteins of RRV are likely to be immunogenic, evidence of humans producing antibodies, or cell-mediated responses, against most of them is lacking.

Sera from epidemic polyarthritis patients and from experimental animals infected with RRV react with the E1 and E2 structural proteins (Kistner et al., 2007). IgG antibody in serum from epidemic polyarthritis patients reacts with both reduced and nonreduced RRV E1 and E2 proteins in western blots, albeit more strongly with the nonreduced proteins. IgM antibody from epidemic polyarthritis patients reacts with nonreduced E1 and E2 proteins in western blots, but rarely, if at all with reduced proteins. The reaction of human anti-RRV IgM with the E2 protein invariably is stronger than the reaction with E1 (unpublished observations). Sera from experimentally infected animals react with the C protein as well as E1 and E2 (Kistner et al., 2007) while that from patients has not been observed to react with C (unpublished observations). There have been no systematic studies of the reaction of sera from patients with nonstructural proteins.

As with other alphaviruses, many of the determinants involved in antibody-mediated neutralization, cell tropism, and mouse virulence have been identified in the E2 glycoprotein of RRV (Kerr et al., 1992, 1993; Meek et al., 1989; Vrati et al., 1986, 1988, 1996). Three, and possibly four, epitopes recognized by monoclonal antibodies which neutralized infection of RRV in vitro have been identified in the E2 glycoprotein of RRV. These involve amino acids at positions E4 (Kerr et al., 1993), E216, E232-234 and E246-251 (Vrati et al., 1988). However, polyclonal sera raised against peptides corresponding to the three putative epitopes between amino acids 216 and 251 of the RRV E2 protein failed to neutralize virus in vitro (Kerr et al., 1992). One possible explanation for these data was that the epitopes recognized by the neutralizing monoclonal antibodies in the RRV E2 protein were conformational or discontinuous and that the polyclonal sera raised against the linear peptides bound to virions with insufficient affinity to neutralize infection.

It is not known whether sera from humans recognize the same epitopes in the E2 protein as these neutralizing monoclonal antibodies but, in an epitope blocking ELISA, Oliveira et al. (2006) found sera from epidemic polyarthritis patients, which inhibits the binding of an anti-E2 mouse monoclonal antibody to Ross River virions. No serological epitopes have been identified in the E1 glycoprotein despite the extensive serological responses to this protein by both humans and experimentally infected animals.

Class switching of anti-RRV antibodies from IgM to IgG occurs readily in both humans and experimental animals indicating the virus is eliciting an effective T_H (CD4) response. Furthermore, Fraser and Becker (1984) observed predominantly CD4 lymphocytes in the synovial effusion of epidemic polyarthritis patients, although the role or function of these cells could not be identified. In contrast, these authors (Fraser et al., 1983) reported predominantly CD8 lymphocytes in the exanthem associated with many RRV infections. Again, neither the function nor the epitopes recognized by these cells could be determined.

An H-2K^d restricted T-cell epitope (QYSGGRFTI) has been identified in the capsid protein of RRV (Linn et al., 1998). Murine CD8 T-cells recognizing this epitope were able to destroy RAW264.7 cells (a murine macrophage cell line) infected with RRV in vitro but had no effect on viremia in mice.

PROTECTIVE IMMUNE RESPONSE

Epidemic polyarthritis patients do not develop a second clinical infection and in a prospective serological study (Aaskov et al., 1981e) a fourfold rise in preexisting anti-RRV antibody titers was observed in several participants suggesting they had experienced a subclinical anamnestic infection. While these observations suggest a natural infection elicits a lifelong immunity, they do not identify which arm(s) of the immune response are responsible for this protection. Also lacking are any data for the outcome of RRV infections in humans who are immunosuppressed or who have defined immunodeficiencies.

Early laboratory studies (Doherty et al., 1963) in which mixtures of RRV and antibody were injected into newborn mice demonstrated that antibody alone could prevent infection in vivo—at least in experimental animals. There have been no definitive studies which demonstrate that T cells (CD4 or CD8) alone can protect against an infection with RRV.

FIGURE 34.3 Geographic distribution of confirmed transmission of RRV.

EPIDEMIOLOGY

Although the rate of infection of humans with RRV at any given locality appears to be independent of age (Doherty et al., 1966; Echuca-Melbourne Collaborative Group, 1976), clinical disease in children is rare (Aaskov et al., 1981c) and when it does occur, arthritis is mild or nonexistent (Doherty et al., 1972; unpublished observations) (Fig. 34.3). The incidence of disease in those over 40 years of age decreases, presumably due to immunity elicited by previous subclinical and clinical infections. There have been no confirmed reports of an epidemic polyarthritis patient developing a second clinical infection and there is no other epidemiological evidence that the antibody-dependent enhancement of monocyte/macrophage cell lines by RRV observed in vitro (Linn et al., 1996; Lidbury and Mahalingam, 2000) plays any role the epidemiology of RRV infection.

While there was extensive serological evidence of human infection with RRV prior to 1979 (Doherty, 1972), disease appeared to occur as outbreaks in geographically discrete regions. In areas where epidemic polyarthritis was endemic, almost all cases were reported following the summer rains (December–April)—new cases in the July–October interval were rare (Doherty et al., 1971). Subsequent expansion of RRV diagnostic facilities and epidemic polyarthritis becoming a notifiable disease in 1990 showed this to be an incomplete picture of human disease (Fig. 34.4).

The detection of anti-RRV antibodies in a wide range of native and domestic animals raised the possibility of a zoonotic cycle of transmission of RRV with humans as an incidental host. RRV has been recovered from asymptomatic native birds (*Grallina cyanoleuca* and *Microeca fascinans*; Whitehead et al., 1968) and horses (Pascoe et al., 1978), and from horses with musculoskeletal disease (Azoulas et al., 2003). Horses and little corellas (*Cacatua sanguinea*) have been shown to develop viremias sufficient to infect *Culex annulirostris* mosquitoes (Kay et al., 1986). *Aedes aegypti* (Taylor and Marshall, 1975) and *Aedes polynesiensis* (Gubler, 1981) mosquitoes could be infected by feeding on viremic baby laboratory mice, and *Aedes vigilax* mosquitoes

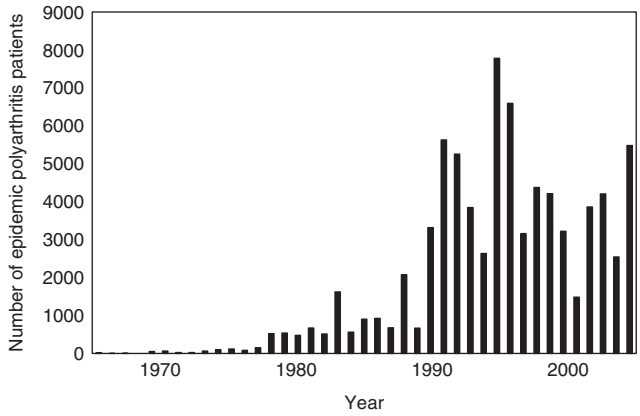

FIGURE 34.4 Number of cases of epidemic polyarthritis reported each year in Australia from 1966 to 2006. Notification became compulsory in 1990.

could be infected by feeding on viremic gray-headed flying foxes (*Pteropus poliocephalus*) (Ryan et al., 1997). A range of other native, domestic, and feral animals have been shown to develop viremia following experimental infection with RRV (Whitehead, 1969; Marshall and Miles, 1984; Kay and Aaskov, 1989) but they have not been assessed for their capacity to infect known vectors of RRV.

Although, RRV has been isolated from more than 30 species of mosquitoes (Russell, 1995, 2002), the competence of most to transmit this virus has not been assessed. The logistics of these studies are magnified by the need to assess the competence of mosquito species collected from different localities to transmit a range of RRV genotypes (Sammels et al., 1995).

Two events have directed attention to the possibility that RRV may be able to maintain itself in human–mosquito–human cycles. The first was the epidemic of RRV infection in the Pacific in 1979–1980 and the second was the realization, with the provision of comprehensive diagnostic RRV serology and national reporting of cases of epidemic polyarthritis that human infection occurred year round and that many patients were urban dwellers (Aaskov et al., 1981e) who lived nowhere near significant numbers of most of the native animals proposed as likely amplifying hosts for RRV.

Although there are anecdotal accounts of the first cases of epidemic polyarthritis appearing in the Murray Valley with the arrival, each year, of sugarcane cutters from north Queensland to pick stone fruit, the first definitive evidence of movement of RRV over significant distances came with the outbreak of RRV infection in the Pacific in 1979–1980. Evidence to support the concept that the virus was introduced into the Pacific with a viremic human came from the subsequent reports of tourists developing epidemic polyarthritis within days of returning to Australia from Fiji (Bennett et al., 1980).

The first cases of epidemic polyarthritis were recognized, in Fiji, in late April 1979 near Nadi International Airport. Cases then began to appear throughout the island of Viti Levu, peaking in late May or early June. Cases subsequently appeared on the second largest island, Vanua Levu, and continued for more than a year with virus being isolated from two patients from Labasa in January 1981 (Marshall and Miles, 1984). In August 1979, epidemic polyarthritis appeared in American Samoa and new cases continued to be recognized until at least January 1980 (Tesh et al., 1981). By November 1979, cases of epidemic polyarthritis were recognized in the Wallis and Futuna Islands (Fauran et al., 1984) and in January 1980 they were being reported from Tonga (Kay, 1981), the Cook Islands (Rosen et al., 1981), and New Caledonia (Fauran et al., 1984). Serological testing of preepidemic sera from Fiji (Aaskov et al., 1981c) suggested RRV transmission may have occurred there in the years preceding the outbreak but was not sustained. Similar testing of sera from Western Samoa suggested that RRV infection also may have occurred there prior to 1980 although no cases of epidemic polyarthritis were recognized (Marshall and Miles, 1984). However, in the absence of travel histories for the individuals involved, it is possible they were infected with RRV during a visit to Australia.

Taken together, these data suggested that RRV employs multiple host–vector cycles, each adapted to a particular ecological niche. The observation by Hawkes et al. (1985) that the incidence of epidemic polyarthritis could vary almost 10-fold between two very similar communities (237 per 10^5 residents in Forbes and 27 per 10^5 residents in Parkes), only 30 km apart, during the same outbreak, in the same geophysical region of New South Wales, suggested that these niches may be quite small. It seems possible that multiple niches could exist even within a single large metropolitan center. It also is likely that these niches are dynamic environments which constantly change in response to human (development, habitation, vector control programs) or natural (tides, temperature, rain, wind) intervention.

Significance as a Public Health Problem

Approximately 5000 cases of epidemic polyarthritis are reported in Australia each year (Fig. 34.4) and the direct medical costs of the disease have been estimated to be US$ 10 million annually (Aaskov et al., 1998). Given the scores of possible vertebrate hosts

and the scores of potential mosquito vectors, vector control programs can hope only to reduce the number of cases of epidemic polyarthritis in urban areas. Efforts to motivate individuals to take adequate personal protective measures have fallen, largely, on deaf ears.

The cost of vector control programs designed to limit this disease have not been quantitated and it is probably unreasonable to do so because a significant motivation for mosquito control programs in Australia is nuisance reduction rather than disease prevention. The social costs of epidemic polyarthritis have not been quantitated.

No estimate has been made of the cost of the epidemic of RRV infection in 1979–1980, which resulted in tens of thousands of cases of clinical disease across the Pacific (Aaskov et al., 1981c; Rosen et al., 1981; Tesh et al., 1981), or of the disease burden in Papua New Guinea (Scrimgeour et al., 1987). Each year small numbers of tourists from Europe and the US also develop epidemic polyarthritis after visiting Australia as do foreign military personnel who participate in exercises in northern Australia.

Potential as a Biothreat

While RRV would not appear to have potential as a conventional biological weapon, its remarkable capacity to cause epidemics, as demonstrated during the outbreak in the Pacific in 1979–1980 (Aaskov et al., 1981c; Rosen et al., 1981; Tesh et al., 1981; Kay, 1981), marks this virus as a biothreat. The recent reports of cases of epidemic polyarthritis originating in Fiji (Klapsing et al., 2005; and unpublished) point to the possibility of a repeat of the earlier epidemic in the Pacific. The ability of rapid air travel to put viremic humans into the southern states of the United States where mosquitoes have been shown to be competent to transmit this virus (Mitchell et al., 1987) suggest RRV also poses a threat to that region.

CLINICAL DISEASE

The term "epidemic polyarthritis" was coined by Dowling (1946) and now is used to describe the disease caused by RRV in humans. The recent use by some of the term "epidemic polyarthritis" to describe infections caused by other mosquito-borne viruses is without foundation and causes confusion.

The interval from infection with RRV to onset of symptoms has been estimated to be from 3 to 21 days (Anderson and French, 1957; Fraser and Cunningham, 1980; Rosen et al., 1981). Disease occurs most commonly in adults (Mudge and Aaskov, 1983; Hawkes et al., 1985; Curran et al., 1997) with symptoms being milder and of shorter duration in children. There is a decreasing incidence of disease with age, presumably due to many long-term residents being immune as a result of previous clinical or subclinical infections (Aaskov and Doherty, 1994). The ratio of subclinical to clinical RRV infections varies from approximately 20:1 in areas like Queensland where infection is endemic to 4:1 (in Fiji; Aaskov et al., 1981c) or even lower (1:2 in Griffith, New South Wales; Hawkes et al., 1985) during outbreaks of disease. Those with the HLA DR7 haplotype are 3.3 times more likely to develop clinical disease following an infection with RRV than those with other haplotypes, while HLA DR3 appeared to provide significant protection against clinical disease (Fraser et al., 1980).

Epidemic polyarthritis is characterized by arthritis, particularly in the knees and the small joints of the hands and feet and may be accompanied by a maculopapular rash and or fever/chills. Patients also may develop a range of other nonspecific signs and symptoms (e.g., paresthesia, lethargy, depression, headache, nausea; Aaskov et al., 1981c; Mudge and Aaskov, 1983; Hawkes et al., 1985; Fraser, 1986; Condon and Rouse, 1995; Seldon and Cameron, 1996; Harley et al., 2001; Mylonas et al., 2002).

The clinical presentation of what is believed to have been epidemic polyarthritis appears to have changed with both time and location (Keary et al., 1997). While to Nimmo (1928), Halliday and Horan (1943), Goswell (1946), and Shope and Anderson (1960) arthritis was the most noticeable feature of this disease, but to Dowling (1946), Weber (1946), Wilson (1957), and Fuller and Warner (1957) it was the rash. In a survey by Mudge and Aaskov (1983), rash was reported from 78% of epidemic polyarthritis patients from South Australia but from only 40% of patients from the remainder of the country. Even with careful observation, rash was detected in only 20% of Fijian patients (Aaskov et al., 1981c). Seglenieks and Moore (1974) reported that in the same area of South Australia rash was the most prominent feature of the 1956 outbreak of RRV infection while in 1971 it was arthritis. It is unclear whether the pathological processes leading to the rash are the same as those that lead to arthritis (see below). There is no evidence that different strains of RRV cause different symptoms, or symptoms of varying severity, in humans. Another feature of epidemic polyarthritis that appears to be changing is the duration of symptoms and, perhaps related to this, more frequent reports of lethargy and depression. It is difficult to quantitate these changes because of the differing methodology used to

obtain the data but they might be influenced by diagnosis and reporting of more patients with milder disease now that laboratory confirmation is more readily available. While two early studies (Sibree, 1944; Goswell, 1946) reported hospitalization of significant numbers of patients for from 1 to 4 weeks, there were few reports of long-term sequelae. In contrast, hospitalization of epidemic polyarthritis patients is now uncommon but long-term sequelae are being reported more often. More recent studies suggest epidemic polyarthritis patients are absent from work for an average of 2 days (Mylonas et al., 2002) and unable to perform normal duties for, on average, 2–6 weeks (Hawkes et al., 1985; Condon and Rouse, 1995; Seldon and Cameron, 1996; Westley-Wise et al., 1996). Symptoms usually resolve over 3–6 months (Aaskov et al., 1981b, 1987; Harley et al., 2002; Mylonas et al., 2002) but some patients may have symptoms lasting a year or more (Fraser, 1986).

There is a body of evidence suggesting that strains of RRV T48 and NB5092 vary in their tropism for cardiac and neurological tissue (Mims et al., 1973; Murphy et al., 1973) but the issue of the tissue tropism of virus populations that have not been passaged extensively in mice has not been explored, and not in human tissues.

There also are isolated reports of involvement of the renal and central nervous systems in RRV disease. Davies et al. (1982) postulated on the basis of retrospective serology that RRV might cause segmental necrotizing glomerulonephritis but it was not until two later studies (Fraser et al., 1988b; Anstey et al., 1991) that a clearer association between RRV infection and glomerulonephritis and hematuria was made. Changes observed in the renal biopsy made by Fraser et al. (1988b) were compatible with a serological or immune-complex mediated pathogenesis. However, no viral antigen was detected in this tissue.

RRV is highly neurotropic in young mice (Doherty et al., 1963; Mims et al., 1973; Murphy et al., 1973) and possibly in horses (Gard et al., 1977), but evidence for infection of the human central nervous system has been less convincing. Perhaps the first such report was that of the death of a soldier of encephalitis in Katherine (Northern Territory) in 1942 or 1943, several months after developing what was believed to be epidemic polyarthritis (Short, 1984). Other tenuous examples include two from Queensland (Aaskov, 1979), one from the Northern Territory (Lucas and Qiao, 1999), one from Papua New Guinea (Scrimgeour, 1999), and one of a focal encephalitis in a 58-year-old male German tourist on return from a visit to Queensland. This patient had developed a febrile illness and prolonged arthritis while in Australia where a RRV infection was confirmed by serology. Eight weeks after onset of symptoms, he presented to a hospital in Germany complaining of weakness, disturbed temperature sensation, and paresthesia in his left forearm. Cerebrospinal fluid was normal as were routine blood tests and blood chemistry. A cerebal magnetic resonance tomography with gadolinium IV showed three high-density subcortical plaques. It was felt that one of these, in the right hemisphere, could have explained the transient neurological symptoms (Aaskov, unpublished data). Perhaps the strongest evidence of meningitis following a RRV infection was provided by Penna and Irving (1993). A patient with symptoms (fever, arthralgia) and serology (HI titer 80; anti-RRV IgM positive) compatible with a diagnosis of epidemic polyarthritis presented with the additional symptoms of headache and neck stiffness during the 1993 outbreak of RRV infection in South Australia. Virus isolation could not be attempted but cerebrospinal fluid contained 100 leukocytes/μl consisting of 80% lymphocytes and 20% neutrophils. No fungal or bacterial pathogens could be cultured and no serological evidence of infection with other pathogens was obtained.

Just as RRV can be extremely neurotropic in young mice but rarely causes central nervous system symptoms in humans, it readily crosses the placenta of pregnant mice (Aaskov et al., 1981a; Milner and Marshall, 1984) but rarely does so in humans. Following the outbreak of RRV infection in Fiji in 1979, cord blood from approximately 5% (11/198) of children born to mothers who were 11–19 weeks pregnant when infected, contained anti-RRV IgM antibody suggesting in utero exposure to virus or viral antigen (Aaskov et al., 1981d). These children, with anti-RRV IgM in their cord blood, appeared normal at birth and following a physical examination several years later. In a smaller retrospective study of children born to women in the Cook Islands who were infected with RRV during the first 21–22 weeks of pregnancy (39 children), Aleck et al. (1983) found no evidence of in utero infection nor of increased rates of abnormalities in children born to infected mothers. However, the sample size (39 subjects) in the study by Aleck et al. (1983) was too small to detect an in utero infection, if the incidence of transplacental transmission of virus was similar to that reported by Aaskov et al. (1981d) in Fiji.

TREATMENT

The results of the only formal trial of treatment for epidemic polyarthritis suggested recovery was faster in patients taking corticosteroids (Mylonas et al., 2004). However, most clinicians employ symptomatic treatment with nonsteroidal anti-inflammatory

medication (Fraser, 1986). A number of patients with prolonged, severe, arthritis have gained relief when taking prednisolone.

PATHOGENESIS

Titers of anti-RRV antibodies and of autoantibodies do not correlate with the presence or duration of arthritic symptoms of epidemic polyarthritis and complement activation has not been detected in the joints of patients (Clarris et al., 1975; Aaskov et al., 1981b, 1981c; Fraser et al., 1981, 1987, 1988a). Together with the predominantly mononuclear nature of the inflammatory response in the arthritic joints of these patients (see below), these observations point to a cell-mediated rather than an antibody-mediated pathogenesis for this disease.

As outlined above, the feature common to all epidemic polyarthritis patients is arthritis in the small joints, particularly the hands and feet. Biopsies of joint synovium from a small number of patients revealed mild hyperplasia, mononuclear cell infiltration, and some fibrin deposition (Hazelton et al., 1985; Soden et al., 2000). The cell infiltrate consisted of approximately equal numbers of monocytes/macrophages and lymphocytes. Both B and T lymphocytes were detected with approximately 60% of the T lymphocytes being $CD4^+$. The cell exudate in the joints of epidemic polyarthritis patients consisted predominantly of mononuclear leukocytes with reports of the relative proportions of macrophages and lymphocytes in the exudate varying extensively (Halliday and Horan, 1943; Clarris et al., 1975; Fraser et al., 1981; Fraser and Becker, 1984; Hazelton et al., 1985). The lymphocyte populations in the exudate consisted of B lymphocytes, natural killer (NK) cells and $CD4^+$ and $CD8^+$ T lymphocytes (Fraser and Becker, 1984; Hazelton et al., 1985).

T lymphocytes from the peripheral blood of epidemic polyarthritis patients proliferated in a virus-specific manner when cultured with purified RRV in vitro (Aaskov et al., 1981b). However, the interval over which lymphocytes recovered from patients would proliferate when reexposed to virus in vitro did not correlate with the duration of symptoms. A better, but inverse, correlation was observed between peripheral blood NK cell activity and symptoms (Aaskov et al., 1987). NK cell activity was depressed soon after onset of symptoms and remained depressed for as long as arthritis persisted, months after virus could no longer be detected in joints or in the peripheral blood. Significant depression of NK cell activity also occurred when patients had severe relapses of arthritis. In the study reported by Hazelton et al. (1985), functional NK cells were recovered from the knee of an epidemic polyarthritis patient and subsequently Aaskov et al. (1987) were able to demonstrate killing of uninfected autologous synovial cells by NK cells.

Although there are no reports of recovery of live virus from the joints of epidemic polyarthritis patients, Fraser et al. (1981) were able to detect viral antigen in mononuclear leukocytes in the exudate from the joints (knee or ankle) of five patients for up to 7 days after onset of symptoms. This is the same interval over which it has been possible to isolate RRV from the peripheral blood of patients (Rosen et al., 1981; Aaskov et al., 1985). Soden et al. (2000) were able to detect viral RNA in inflamed synovial tissue from 2 of 12 patients for up to 5 weeks after onset of symptoms but could not recover live virus from the joints of any of these patients.

Journeaux et al. (1987) were able to establish prolonged (up to 5 weeks), but not persistent, infections with RRV in human synovial cells in vitro by lowering the temperature of the cultures from 37°C to 35°C—the approximate temperature of small peripheral joints. This interval correlates reasonably well with the duration of intense arthritis experienced by many patients early after onset of symptoms (Fraser, 1986a; Seldon and Cameron, 1996; Westley-Wise et al., 1996). At the end of this interval, only fibroblast-like (type B) synovial cells remained in the virus-infected cultures. Superficially, these data could be taken as suggesting that the macrophage-like (type A) synovial cells supported virus replication and that when these poorly replicating cells had been destroyed, the infection terminated. However, we, and others (Cunningham and Fraser, 1985) have shown human fibroblast-like synovial cells to be able to be infected with RRV in vitro so it is difficult to understand how they survived exposure to RRV in this system. The levels of extracellular RRV produced in vitro by the primary synovial cell cultures (Journeaux et al., 1987) was very low as evidenced by its detection with the highly sensitive C6-36 mosquito cell line but not with Vero cells. The earlier failure of Cunningham and Fraser (1985) to detect prolonged infection of human synovial cells with RRV in vitro may have been due to their use of relatively insensitive virus detection assays.

Linn et al. (1996) and Way et al. (2002) have been able to establish persistent RRV infections in murine macrophage cell lines—but not in human macrophage/monocyte cell lines or in human tissues. Way et al. (2002) were able to detect viral RNA in their cells when levels of extracellular virus were undetectable by conventional cell culture techniques. Furthermore, they were able to manipulate culture conditions to induce these cells to again produce infectious extracellular virus—mirroring the relapses reported by some epidemic polyarthritis patients.

Although not all epidemic polyarthritis patients develop a rash, many of the histological changes associated with the rash mirror those seen in joints. A perivascular infiltrate of mononuclear leukocytes (monocytes/macrophages and $CD8^+$ T-cells) was observed in the dermis adjacent to the rash. RRV antigen was detected in this region as well as in basal epidermal and eccrine duct cells. No immunoglobulin or complement (Clq, C3) deposition was detected (Fraser et al., 1983).

While these data point to a possible role for T lymphocytes in the pathogenesis of epidemic polyarthritis, only one T-lymphocyte clone ($CD4^+$) was recovered after more than 2 years work by a group with more than a decade of experience producing T-cell clones from patients with other viral infections (Suhrbier, unpublished observations).

There is an extensive literature describing the pathogenesis of RRV infection in mice beginning with that of Mims et al. (1973) (reviewed by Suhrbier and Linn 2004 and Rulli et al., 2005). This points to a central role for monocytes/macrophages and cytokines/chemokines in the pathogenesis of epidemic polyarthritis. However, many of these observations remain to be confirmed in humans or in human tissue (Mateo et al., 1999).

VACCINES

Epidemic polyarthritis is an ideal target for a vaccine. There are no confirmed reports of an epidemic polyarthritis patient ever having a second clinical infection (i.e., immunity appears to be lifelong) and the limited genetic analyses which have been performed suggest there is very little genetic variation between isolates of RRV (Faragher et al., 1985; Sammels et al., 1995).

In the absence of any markers of attenuation of virulence of RRV for humans, a decision was made to attempt to develop a killed vaccine. Irradiation with ultraviolet light had been used previously to inactivate RRV (Aaskov and Tucker, 1979) while retaining critical epitopes recognized by IgG and IgM antibodies in sera from epidemic polyarthritis patients (Oseni et al., 1983). However, at that time, there was no equipment or facilities available that would have enabled this procedure to be undertaken on an industrial scale. The inactivation of viruses by formalin or beta-propiolactone has nonlinear kinetics which makes determination of the time required for inactivation of all virions difficult (Harrison et al., 1971; Cole et al., 1974; Barrett et al., 1984; Klockmann et al., 1989; Barteling and Vreeswijk, 1991). Furthermore, both these agents affect the antigenic structure of proteins. Formalin cross-links adjacent proteins and beta-propiolactone alters the chemical structure of amino acids such as methionine, cysteine, histidine, praline, and lysine (Taubman and Atassi, 1968; Boutwell et al., 1969). Inactivation of RRV with beta-propiolactone resulted in a significant reduction of binding of anti-RRV IgM antibody to virions in indirect ELISAs but had less effect on the attachment of IgG (unpublished observations).

RRV recovered from a child with epidemic polyarthritis and who had no evidence of other infectious or chronic diseases (Yu and Aaskov, 1994) was inactivated with binary ethylenimine (BEI), purified by centrifugation on a sucrose gradient, and evaluated as a vaccine. This treatment had no detectable effect on the binding to the BEI-inactivated virions of human polyclonal anti-RRV IgM or IgG. It has been our experience that recognition of RRV virions by IgM antibodies is extremely sensitive to any change in the conformation of the E1 and E2 glycoproteins. Furthermore, RNA extracted from the BEI-inactivated virus was at least one thousand times less infectious than RNA extracted from live virus, i.e., 1.5 μg RNA from the vaccine caused neither morbidity nor mortality when injected intracerebally into newborn mice (Aaskov et al., 1997).

Neither vaccine nor vaccine with Alhydrogel adjuvant caused any adverse reactions when administered intramuscularly to mice. Biopsies of the sites of injection revealed a strong inflammatory response but no significant tissue damage (Yu and Aaskov, 1994).

Mice immunized with one dose of vaccine elicited lower total antibody titers (indirect ELISA) than mice immunized with vaccine plus Alhydrogel adjuvant, but the levels of anti-RRV neutralizing antibodies in mice immunized with vaccine alone were higher than in mice given vaccine plus adjuvant. Furthermore, the levels of protection against in vivo challenge with live virus were higher in mice given one dose of vaccine alone than in those given vaccine plus adjuvant. Mice given two doses of 0.2–30 μg vaccine or two doses of 0.2–30 μg vaccine with adjuvant produced no detectable viremia when challenged intravenously with 10^5 TCID of RRV 75 days after the second immunization (Yu and Aaskov, 1994).

Because of an observed association between HLA DR7 and clinical disease following human infection with RRV and a claimed increased prevalence of clinical RRV infections in females, the responses of male and female, inbred and outbred, mice were evaluated. Levels of neutralizing antibodies were similar in all groups 7 weeks after two injections with 2 μg vaccine. While sera from these animals neutralized a panel of contemporary strains of RRV to varying degrees ($\log_{10}$ neutralization indices from 2.0 to >3.5), these titers are similar to those of former epidemic polyarthritis patients who are immune to a second clinical infection (see below).

Despite the promise of a BEI-inactivated RRV vaccine in animal experiments, BEI has not been employed for the production of a human vaccine and so there are no protocols to satisfy regulatory authorities of its safety or at least convince them that the BEI could be completely removed or converted to a harmless metabolite. Prior to committing to these processes, studies were conducted to determine whether or not standard formalin-inactivation protocols could be employed to produce a safe immunogenic RRV vaccine (Kistner et al., 2007).

The strain of RRV used to prepare the BEI-inactivated vaccine was grown serum-free in vaccine-certified Vero cells in commercial-scale fermenters, inactivated with formalin and any contaminating Vero cell DNA destroyed with Pronase. The virus was filtered through 1.2 and 0.2 μm filters throughout the formalin treatment process and finally purified by centrifugation on a sucrose gradient. Examination of this material by electron microscopy revealed few examples of clumps of two or more virions. SDS-PAGE of the formalin-inactivated virus preparation revealed capsid (C) and envelope proteins (E1, E2) of anticipated sizes as well as several bands of protein of larger molecular weight which were recognized by polyclonal anti-RRV antisera. These were presumed to be oligomers of E1 and E2 cross-linked by formalin. Human anti-RRV IgM antibodies reacted as well with the E1 and E2 proteins from formalin-inactivated virus as they did with these proteins from native virus suggesting that the prolonged treatment with formalin had not damaged immunodominant epitopes. In contrast to the response to BEI-inactivated vaccine, formalin-inactivated RRV elicited both lower levels of antibody and lower levels of neutralization in vitro and in vivo than vaccine with $Al(OH)_3$ adjuvant.

Two doses of 0.625 μg formalin-inactivated virus with adjuvant elicited titers of neutralizing antibodies (log_{10} 2.7) similar to those in humans who were immune following a natural infection with RRV (log_{10} 1.1–3.5, median 2.4).

Two different inactivation protocols have produced killed RRV vaccines that, at clinically relevant doses, elicited strong neutralizing responses in experimental animals with no apparent adverse effects, even after challenge with live virus. The virus grows to high titer in serum-free cultures in industrial scale fermenters and can be purified using conventional industrial protocols. A clinical trial of a formalin-inactivated, U.V.-irradiated, RRV vaccine is in progress. It is likely to be a cost-effective alternative to the burden of 5000 cases of epidemic polyarthritis in Australia each year and it also could have a place as a "tourist vaccine" and for military personnel coming to Australia for joint exercises. It also would be a very useful tool in the event of the introduction of RRV into the southern United States or if there is another outbreak of RRV infection in the Pacific.

KEY ISSUES

- Ross River virus causes approximately 5000 cases of epidemic polyarthritis in Australia each year and caused a major outbreak in Pacific countries in 1979–1980. Patients commonly are symptomatic for up to 9 months and the health costs associated with this disease are estimated at US$10 million each year.
- Because so many different species of mosquitoes are potential vectors of Ross River virus and the virus has so many vertebrate hosts, mosquito control programs are not cost effective and will not be able to prevent this disease.
- The virus grows to high titer in cell culture and retains immunogenicity when inactivated by a number of methods. This makes Ross River virus an ideal candidate for an inactivated vaccine.

Rotavirus

Monica Malone McNeal and David I. Bernstein
Division of Infectious Diseases, Cincinnati Children's Hospital Medical Center, University of Cincinnati, Cincinnati, OH, USA

OUTLINE

ABSTRACT

The most common cause of severe diarrhea in children under 5 years of age is rotavirus. Rotavirus infections are responsible for over 600,000 deaths worldwide, representing 5% of all childhood deaths. Ninety percent of these deaths occur in developing countries. In addition, it is estimated that societal costs, including doctor's visits and hospitalizations, are approximately 1 billion dollars per year. Since the 1990s, The World Health Organization (WHO) has given priority to finding a safe and effective rotavirus vaccine. This quest has been going on for over 30 years. Natural infection with rotavirus has been shown to provide protection from subsequent severe disease, although the exact mechanism of protection is unclear. Both live and non live vaccines have been developed but only live oral rotavirus vaccines have progressed to human trials. One vaccine, Rotashield, was licensed in the United States in 1998 but was later withdrawn due to safety concerns because of its association with intussusception, a serious condition that causes bowel obstruction. After several years, and the completion of the largest vaccine trials ever conducted for a vaccine, two new live attenuated vaccines became available. Rotarix®,

an attenuated human strain became available in 2004 in Mexico and now is approved in over 100 countries. In 2006, another vaccine, RotaTeq™, a live five component bovine human reassortant was licensed in the United States. In 2006, the WHO issued a recommendation that the two vaccines could be introduced in regions where they had been evaluated in clinical trials. The licensure of these two vaccines should dramatically decrease the burden of disease in countries where it is approved but the true impact of the vaccines will not be realized until it is available in the countries with the highest disease burden.

INTRODUCTION

Rotaviruses are recognized as the single most important cause of severe infantile gastroenteritis worldwide and have been estimated to be responsible for >600,000 deaths annually (Parashar et al., 2003, 2006). Transmission of rotaviruses occurs primarily by the fecal–oral route, providing a highly efficient mechanism for universal exposure that circumvents differences in national cultural practices and public health standards (Kapikian et al., 2001). Nearly all children less than 5 years of age have experienced at least one rotavirus infection (Glass et al., 2006; Rodriguez et al., 1987; Kapikian, 1993).

The most common symptoms associated with rotavirus disease are diarrhea and vomiting accompanied by fever (Kapikian, 1993; Staat et al., 2002). Rotavirus illness can be mild and of short duration or produce severe dehydration leading to hospitalization and mortality if not treated. Severe disease occurs primarily in young children, most commonly between 6 and 24 months of age and treatment of rotavirus illness is limited to supportive measures such as oral or intravenous rehydration (Kapikian, 1993; Staat et al., 2002; Rodriguez et al., 1977). The only specific method to combat rotavirus disease is the development of a vaccine. Fortunately, between 2004 and 2006, two new rotavirus vaccine candidates have become available and their licensure is proceeding in countries around the world.

The reduced severity of illness, typically associated with sequential rotavirus infections, provide the basis for the development of rotavirus vaccines (Velazquez et al., 1996). Thus, a realistic goal for a rotavirus vaccine would be to protect against severe disease and hospitalization. The purpose of this review is to present a summary of the development of rotavirus vaccines including early vaccine candidates, the current licensed vaccines, and other vaccine candidates under development. In addition, the epidemiology, pathogenesis, molecular virology, and immunology of rotavirus will be briefly discussed.

DISEASE BURDEN

In the United States, nearly every child is infected with rotavirus by the age of 5 and rotavirus illness results in 20–70 deaths annually (Fischer et al., 2007; Glass et al., 1996). Infection with rotavirus often results in more severe illness than other pathogens and therefore rotavirus accounts for a higher percentage of gastroenteritis episodes requiring medical intervention (Clark and McKendrick, 2004; Wilhelmi et al., 2003). During peak rotavirus seasons, 70% of all gastrointestinal hospitalizations may be due to rotavirus-associated gastroenteritis (Parashar et al., 1998). It is estimated that 1 child in 7 will require a doctor's visit at a clinic or emergency room and 1 in 67 to 1 in 87 will be hospitalized because of a rotavirus illness (Malek et al., 2006; Fischer et al., 2007). Based on these estimates, rotaviruses are responsible for 5–10% of all gastroenteritis episodes in children under 5 years of age leading to over 50,000 hospitalizations. Depending on how hospital surveillance studies were conducted, these estimates may be lower than the actual numbers of rotavirus-related hospitalizations (Hsu et al., 2005). Similar estimates of the disease burden due to rotavirus were recently reported in a large study conducted in seven European countries (Van Damme et al., 2007a; Giaquinto et al., 2007a), demonstrating similar patterns of rotavirus disease in developed countries.

Globally, rotavirus disease has a much more dramatic and significant impact on infant health. Although rates of rotavirus illness among children are similar throughout the world, the resulting mortality differs substantially. It is estimated that rotavirus illness is responsible for over 600,000 deaths annually, representing 5% of all deaths in children younger than 5 years of age worldwide (Parashar et al., 2003, 2006). More than 90% of these deaths occur in Africa and Asia (Fig. 35.1). Greater than 100,000 deaths occur in India and sub-Saharan Africa and 35,000 occur in China (Parashar et al., 2003; Glass et al., 2005). Therefore, safe and effective rotavirus vaccines are urgently needed, especially in countries

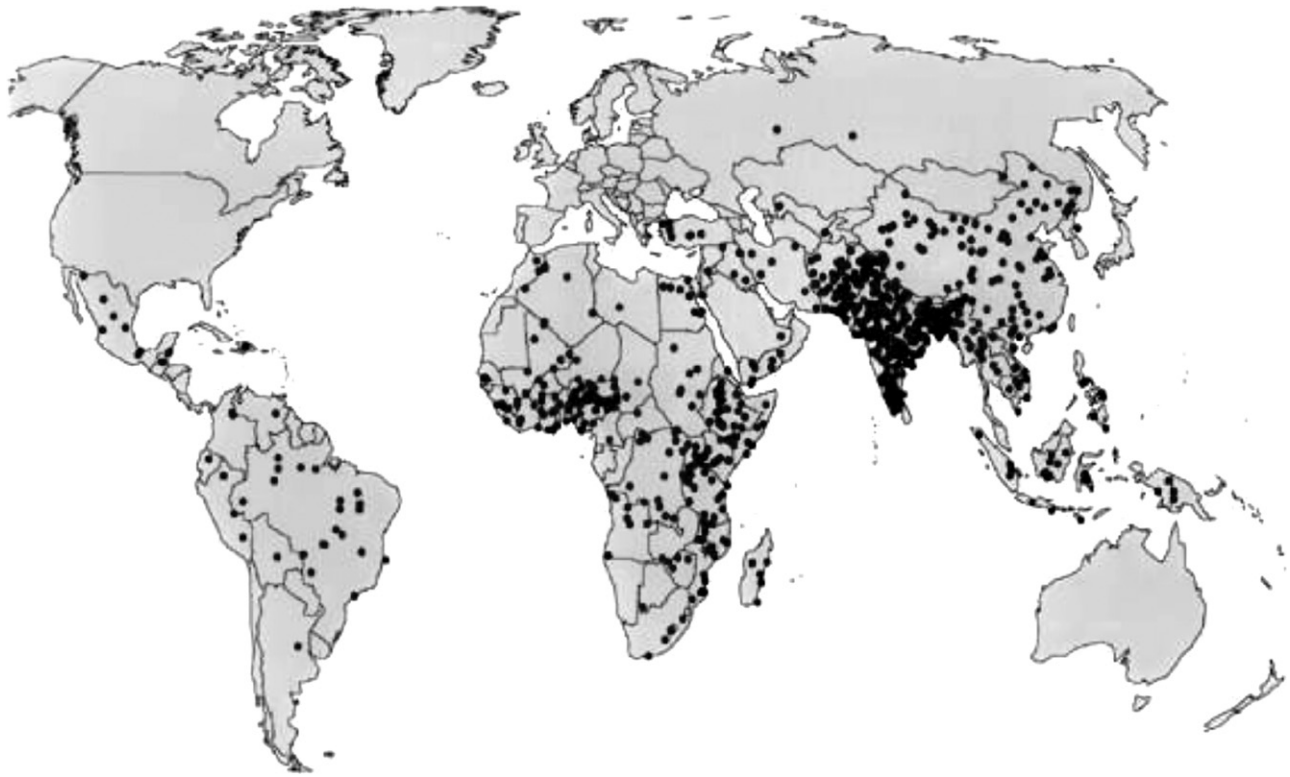

FIGURE 35.1 Distribution of deaths due to rotavirus. Each dot represents 1000 deaths. (Image courtesy of Umesh Parashar, Center for Disease Control and Prevention, Atlanta, GA.)

with the highest rotavirus mortality and the most limited resources available to treat diarrheal illnesses (Girard et al., 2006).

HISTORY OF ROTAVIRUS

The first rotaviruses to be described, based on pathology and epidemiology, were murine strains which were classified under the general description as the agents responsible for "epizootic diarrhea of infant mice," i.e., EDIM (Cheever and Mueller, 1947; Pappenheimer and Enders, 1947). Murine rotaviruses were also among the first to be visualized by electron microscopy (Adams and Kraft, 1963), along with viruses obtained from the rectal swabs of monkeys that contained viruses with comparable morphologic features (Malherbe and Harwin, 1963). These agents were described as 70-nm particles that had a wheel-like appearance and were later designated "rota" viruses from the Latin word for wheel (Flewett et al., 1974; Wyatt et al., 1978). Mebus et al. (1969) demonstrated the presence of these particles in stools of calves with diarrhea, thus associating these viruses with a diarrheal disease.

The correlation between these viruses and severe diarrhea in young children was reported first in 1973 by Bishop and colleagues, who used electron microscopy to examine biopsy specimens of duodenal mucosa from children with acute gastroenteritis (Bishop et al., 1973, 1974). Within a short time other investigators confirmed the association between the presence of rotavirus in feces and acute gastroenteritis.

In addition to their distinctive morphologic features, human rotaviruses along with their animal counterparts, share a group antigen (Kapikian et al., 1976; Woode et al., 1976) and are classified as members of the *Rotavirus* genus within the Reoviridae family (Matthews, 1979). In 1980, particles that were morphologically indistinguishable from established rotavirus strains but lacked the common group antigen were discovered in pigs (Bridger, 1980; Saif et al., 1980). This finding led to the identification of rotaviruses belonging to six additional groups (B–G) based on common group antigens, with the original rotavirus strains classified as group A (Saif and Jiang, 1994). Only groups A–C have been associated with human diseases, and most known cases of rotavirus gastroenteritis are caused by group A strains. Although, there have been large outbreaks reported in China and Japan associated with

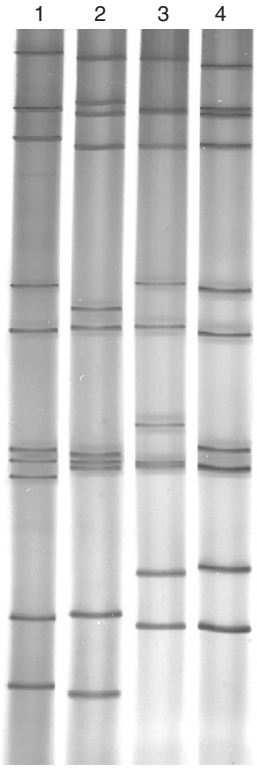

FIGURE 35.2 Polyacrylamide gel electrophoretic patterns of genomic RNAs obtained from group A human rotaviruses and visualized by silver staining. The patterns demonstrate the characteristic four size classes of RNA separated into groups of four, two, three, and two segments each. Human rotavirus strains included (from left to right) lane 1, Wa; lane 2, ST-3; lane 3, DS-1; lane 4, natural isolate containing a short pattern similar to DS-1.

nongroup A strains, particularly among adults (Hung, 1988; Kuzuya et al., 1998; Matsumoto et al., 1989), group A rotaviruses are the strains to which vaccine development has been directed.

PROPERTIES OF THE VIRUS

Rotavirus is a double-stranded RNA virus. The genome segments of rotavirus can be extracted from viral particles and separated by polyacrylamide gel electrophoresis into 11 bands visualized by ethidium bromide or silver staining as shown in Fig. 35.2. Each rotavirus strain has a characteristic RNA profile or electropherotype, a property that has been used extensively in epidemiologic studies of these viruses. The characteristic RNA electrophoretic pattern of group A rotaviruses consists of four size classes containing segments 1–4, 5 and 6, 7–9, and 10 and 11 (Kapikian et al., 2001). A short pattern is seen when the segment 11 runs slower than segment 10. RNA segments of strains belonging to less well characterized rotavirus groups (i.e., groups B–G) also can be separated into four size classes, but the distribution of segments within these classes differs from group to group (Saif, 1990).

The genome of rotavirus encodes the six structural proteins—VP1–VP4, VP6, and VP7—and six nonstructural proteins designated NSP1–NSP6 (Estes and Kapikian, 2007; Estes, 2001). Each segment encodes one known rotavirus protein except segment 11 which encodes both NSP5 and NSP6 using alternative open reading frames (Mattion et al., 1991). The genome segments range in size from approximately 660 to 3300 base pairs, and their encoded proteins, whose known functions are briefly described in Table 35.1, have molecular weights of approximately 12,000–125,000 (Estes and Kapikian, 2007).

Computer-generated images of rotavirus particles obtained by cryoelectron microscopy show it is ca. 100 nm in diameter and is composed of three concentric protein layers depicted in Fig. 35.3 (Pesavento et al., 2006; Prasad and Chiu, 1994; Shaw et al., 1993). The outer layer contains 780 molecules of the VP7 glycoprotein and 60 dimers or trimers of the VP4 protein (Dormitzer et al., 2004) which forms spike-like projections that extend through and 11–12 nm beyond the VP7 layer (Pesavento et al., 2006; Prasad and Chiu, 1994). The VP4 protein is anchored to the intermediate layer of the particle composed of 780 molecules of the VP6 protein. The innermost layer contains 120 molecules of the VP2 protein that interact with 12 molecules each of the viral transcriptase (VP1) and the guanylyltransferase (VP3) along with the 11 segments of the double-stranded RNA genome (Valenzuela et al., 1991; Estes, 2001; Liu et al., 1992; Estes and Kapikian, 2007).

Replication

Rotaviruses are activated by cleavage of the outer capsid VP4 protein by trypsin-like proteases into proteins termed VP5 and VP8 which remain associated with the virus (Lopez et al., 1985; Arias et al., 1996; Zarate et al., 2000; Estes et al., 1981). After attachment to receptors on the cytoplasmic membrane, through association with the VP8 protein, the activated virion either passes directly through this membrane or is taken into the cytoplasm within a vesicle (Hewish et al., 2000; Graham et al., 2005, 2006; Nava et al., 2004; Blanchard et al., 2007; Lopez and Arias, 2006). During membrane penetration or soon thereafter, the outer capsid proteins are removed (Cuadras et al., 1997). The RNA-dependent RNA polymerase (i.e., the VP1 transcriptase) associated with the inner shell is stimulated to synthesize the 11 viral mRNAs that are capped by VP3 (Patton, 1994; Patton and Spencer, 2000; Patton et al., 2006). The mRNAs are extruded from the virus cores through channels

TABLE 35.1 Rotavirus gene segments and properties of encoded proteins

RNA segment	No. of base pairs	Encoded protein	Molecular weight of protein (H 10^{-4})	Properties of proteins
1	3300	VP1	12.5	Inner core protein, RNA-dependent RNA polymerase, binds to ssRNA, complexes with VP3
2	2700	VP2	9.4	Inner core protein, RNA binding, needed for VP1 replicase activity
3	2600	VP3	8.8	Inner core protein, guanylyltransferase, methyltransferase, complexes with VP1
4	2360	VP4	8.7	Outer capsid protein, hemagglutinin, receptor binding, virulence, neutralization protein, fusogenic protein
5	1600	NSP1	5.9	Nonstructural protein, RNA binding, IRF regulatory protein
6	1360	VP6	4.5	Intermediate capsid protein, group and subgroup antigen, required for transcription
7	1100	NSP3	3.5	Nonstructural protein, mRNA binding, inhibits host translation
8	1060	NSP2	3.7	Nonstructural protein, RNA and NSP5 binding, virosome formation
9	1060	VP7	3.7	Outer capsid glycoprotein, neutralization protein
10	750	NSP4	2.0	Nonstructural glycoprotein, transmembrane protein, enterotoxin
11	660	NSP5	2.2	Nonstructural protein, phosphorylated, NSP2 binding, VP2 and NSP6 interaction
		NSP6	1.2	Nonstructural protein, NSP5 binding

in the VP2 and VP6 protein layers at the 12 vertices of the viral particles, and subsequently translated into viral proteins (Prasad et al., 1996; Lawton et al., 1997). Once viral proteins accumulate within the cytoplasm, large inclusions or viroplasms are formed in which the assembly of virion precursors is initiated (Patton et al., 2003, 2006; Fabbretti et al., 1999). Particle assembly may be initiated by the formation of complexes within the viroplasm that contain plus-strand RNAs from the 11 genome segments along with VP1 and VP3 and RNA-binding nonstructural proteins NSP2, NSP5, and NSP6 (Patton et al., 2003; Taraporewala et al., 2006; Taraporewala and Patton, 2004).

Although the mechanism is not completely defined, the virus assembles and packages one of each of the plus-strand RNAs within individual precursor viral complexes. These complexes eventually lose their nonstructural proteins, evolve into double-layered viral particles with the sequential addition of VP2 and VP6, and convert their single-stranded RNAs into double-stranded genome segments (Silvestri et al., 2004; Patton et al., 2004; Tortorici et al., 2006).

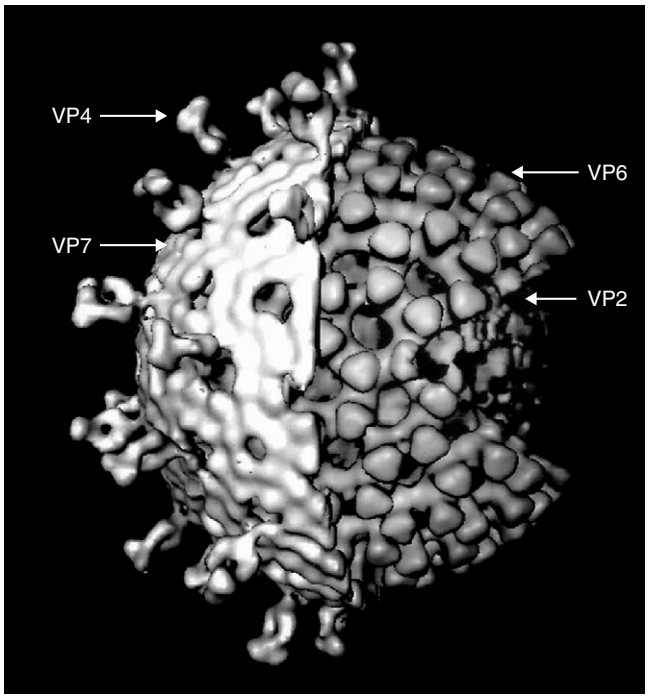

FIGURE 35.3 Image obtained by cryoelectron microscopy. (Image courtesy of B.V.V. Prasad, Baylor College of Medicine, Houston, TX.)

The double-layered particles then bud into the rough endoplasmic reticulum (ER) after their association with the NSP4 transmembrane glycoprotein. VP4 is either added prior to entry into the ER or sometime thereafter. The other rotavirus glycoprotein, VP7, which becomes sequestered within the rough ER, is added to complete the formation of mature viral particles (Estes, 2001; Patton et al., 2007). These mature viruses accumulate within the lumen of the rough ER until cell lysis occurs (Estes and Kapikian, 2007).

Serotypes

The two outer capsid proteins, VP7 and VP4, contain neutralization epitopes (Greenberg et al., 1983; Hoshino et al., 1984). Early studies using sera from hyperimmunized animals in cross-neutralization assays described a number of different serotypes found to infect humans and animals based on the VP7 protein (Hoshino et al., 1984; Wyatt et al., 1983). Viruses were given a G type referring to the glycosylated structure of this protein. Researchers later found that most of the neutralizing antibody induced when an animal was hyperimmunized, by injecting live preparations, was directed against the VP7, but that in some cases, i.e., after oral infection, VP4 could be the dominant neutralization protein (Clark et al., 1990; Perez-Schael et al., 1990; Ward et al., 1988, 1993). A dual serotyping scheme was therefore developed.

VP7 serotypes are determined by cross-neutralization and by using panels of monoclonal antibodies (Ward et al., 1991; Coulson et al., 1987; Taniguchi et al., 1987), VP4 serotype determination however, is more difficult (Mackow et al., 1988; Padilla-Noriega et al., 1992; Taniguchi et al., 1988). Two numeric systems were established to classify the VP4 protein, or P type referring to the protease sensitivity of this protein. The P serotype is based on neutralization assays using antisera against recombinant expressed VP4 proteins or viruses with specific VP4 genes (Gorziglia et al., 1990; Snodgrass et al., 1992). The second classification is based on comparative nucleic hybridization and sequence analyses or genotypes (Gentsch et al., 1992; Gouvea et al., 1994). The P serotype is indicated by an open number and the genotype is noted with a bracketed number. For example, the most common P type worldwide belongs to serotype P1A and genotype 8 and is therefore designated P1A[8]. Most recently, rotaviruses are often only classified by genotyping for the P protein. To date, 15 G types and 25 P types have been identified on the basis of sequence analyses from animal and human isolates (Estes and Cohen, 1989; Gentsch et al., 1996; Liprandi et al., 2003; McNeal et al., 2005; Rahman et al., 2005). However, as discussed below only a few G and P type combinations account for the vast majority of human infections.

Rotaviruses, similar to other viruses with segmented genomes, have the ability to form reassortants. During replication, if a coinfection has occurred, gene segments from each parent virus can be incorporated into new progeny viruses. The gene segments from different viruses can segregate independently and the new viruses produced can contain genes from either parent. Rotaviruses have an extremely wide host range, but natural cross-species infections, particularly between animals and humans, may be rare. Nevertheless, numerous human isolates appear to be animal strains or animal–human rotavirus reassortants as determined by sequence analyses (Cunliffe et al., 2000; Das et al., 1993a, 1993b, Matthijnssens et al., 2006). This property of reassortment has contributed to the diversity of G and P types found throughout the world. In addition, as will be discussed, a number of reassortant viruses have been used as vaccine candidates.

GLOBAL DISTRIBUTION OF HUMAN ROTAVIRUS SEROTYPES

Early studies using cross-neutralization assays and monoclonal antibodies to determine serotypes found

that four main G types (G1, G2, G3, and G4) accounted for 90% of the stains isolated from humans. However, it was common in these early studies to have a high percentage of strains that were not typed by these methods. With the development of surveillance studies using reverse-transcription polymerase chain reaction (RT-PCR) genotyping and automated nucleotide sequencing of VP7, for G type, and VP4, for P type, more strains have been identified and genotyped. Over 42 different P–G combinations of strains infecting humans have been described, containing 10 different G types and 11 different P types (Gentsch et al., 2005). The most common G types still remain G1 through G4 but now also include G5, G8, G9, G10, and G12 (especially G9) in various regions around the world. The most common types for the P protein are P[8] and P[4] in addition to the more recently described P[6].

The global distribution of G and P serotypes can vary greatly by location and time, or, as was found in some studies, vary little over sequential seasons (Ward et al., 1991; Pipittajan et al., 1991). A review by Santos and Hoshino (2005) has summarized rotavirus serotypes from 124 studies performed between 1989 and 2004 and included data on 45,571 isolates collected from 52 countries on 5 continents. The four common G types, G1, G2, G3, and G4, with either P[8] or P[4], represented over 88% of the strains identified worldwide during this period. Serotype G9, containing either P[8] or P[6], was found to be an emerging strain in a number of different locations. Overall, the most common strains responsible for rotavirus illness have been found to be G1P[8] strains (Gentsch et al., 1996; Santos and Hoshino, 2005). In North America, Europe, and Australia the G1P[8] strain was responsible for over 70% of rotavirus infections. In South America and Asia the incidence was only 30% while in Africa it was only 23%. Africa has a G8 frequency as high as that of G3 or G4, and P[6] was found in a third of all isolates. In addition, in Africa, 27% of the strains identified had unusual combinations, such as G8 with P[4] or P[6]. Viruses containing G5 have been shown to be increasing in South America (Santos and Hoshino, 2005).

In another study by Gentsch et al. (2005), data on studies conducted in 35 countries, involving over 20,000 isolates were analyzed. The four common strains, G1P[8], G2P[4], G3P[8], and G4P[8] again represented 72% of all strains with G9 containing either P[6] or P[8] identified in over 2% of the isolates. Although P[6] was first identified in combination with G9 strains, recent studies have found that the G9P[8] strain may be more predominant (Iturriza-Gomara et al., 2000; Kirkwood et al., 2003, 2006a; Montenegro et al., 2007). It was also found that G types including G5, G6, G8, and G10 in various combinations with P[4], P[6], P[8], P[9], and P[14] were found in approximately 1.2% of the total strains identified. Latin America, Africa, and Asia also had a higher incidence of P[6] stains than Europe or North America and developing countries were found to have a higher incidence of unusual strains (Santos and Hoshino, 2005; Gentsch et al., 2005). In European countries, G1, G2, G3, G4, and G9 were the predominant G serotypes found, although the incidence varied by country (Van Damme et al., 2007b). Similar findings were reported from Central and South-Eastern Europe (Tcheremenskaia et al., 2007). A review of studies from China showed that G1 was the overall predominate strain but that G3 viruses were becoming more common in recent studies (Orenstein et al., 2007; Wang et al., 2007). G12 viruses, either with P[6] or P[8], appear to be the new emerging strains in India (Ramani et al., 2007) and Australia (Kirkwood et al., 2006b). The diversity of rotavirus serotypes, especially in developing countries where mortality due to rotavirus is greatest, has had an effect on vaccine development, although the extent of cross protection remains unclear as discussed below.

EPIDEMIOLOGY OF ROTAVIRUS

Severe human rotavirus disease occurs most commonly between 6 and 24 months of age (Kapikian and Chanock, 1990; Rodriguez et al., 1987; Ward et al., 1991), but the age may be lower in less developed countries (Haffejee and Moosa, 1990; Raul Velazquez et al., 1993). Neonatal rotavirus infections, which are often asymptomatic, are common and appear to be endemic in some newborn nurseries (Bishop et al., 1983; Perez-Schael et al., 1984). The asymptomatic nature of neonatal rotavirus infections may be due, at least partially, to protection from transplacental antibody that can persist for the first months of life (Bernstein et al., 1990). The onset of rotavirus disease in infants has been reported to coincide with the decline of maternal IgG antibody (Zheng et al., 1989).

Older children and adults, including elderly patients, are susceptible to reinfections with rotavirus, which can cause mild but rarely severe disease (Nakajima et al., 2001; Griffin et al., 2002; Marshall et al., 2003; Iijima et al., 2006). The reduced severity of rotavirus disease in older children and adults is due primarily to the immunity induced by previous rotavirus infections.

As with other respiratory and enteric viruses, distinct seasonality is associated with rotavirus disease (Estes and Kapikian, 2007; Cook et al., 1990; Haffejee, 1995; Kapikian et al., 1974; Turcios et al., 2006). This

seasonality is particularly evident in temperate climates, where rotaviruses are responsible for the large increase in hospitalizations and deaths due to diarrheal diseases found during the winter season (Parashar et al., 1998). The seasonality of rotavirus disease is less apparent in tropical climates but disease is still more prevalent in the drier, cooler months (Haffejee, 1995). The cause for the seasonality of rotavirus disease remains unknown.

PATHOGENESIS

The incubation period for rotavirus is approximately 1–3 days (Kapikian et al., 1983). In children with symptoms, the onset is often abrupt, with fever and vomiting followed by explosive, watery diarrhea. Vomiting may precede the diarrhea in approximately half the cases (Haffejee, 1991). Fever occurs commonly during rotavirus illness, with estimates of between 45 and 84% of patients (Rodriguez et al., 1977; Uhnoo et al., 1986). The disease is usually self-limited, lasting 4–8 days, although the duration of symptoms ranged between 2 and 22 days in a Guatemalan study (Wyatt et al., 1979). In a study conducted in the United States, 63% of hospitalized children with rotavirus infection had fever, vomiting, and diarrhea at presentation, but children also presented with combinations of only one or two of these symptoms (Staat et al., 2002).

After fecal–oral transmission of rotavirus, infection is initiated in the upper intestine and typically leads to a series of histologic and physiologic changes. Studies in calves revealed that rotavirus infection caused the villus epithelium to change from columnar to cuboidal, which resulted in a shortening and stunting of the villi. The cells at the villus tips became denuded, while in the underlying lamina propria, the numbers of reticulum-like cells increased and mononuclear cell infiltration was observed. The infection started at the proximal end of the small intestine and advanced distally (Mebus et al., 1974; Mebus, 1976). From the few studies examining the pathologic changes in the intestines of humans, the resulted changes appeared to be similar to those found in animals (Holmes et al., 1975; Suzuki and Konno, 1975).

Although rotaviruses cause severe diarrhea in numerous species, including humans, the mechanisms responsible for the illness have not been completely determined and may be due to multiple factors. From various studies in animals, malabsorption of carbohydrates, sodium and calcium fluxes, retarded differentiation of uninfected enterocytes, or crypt cell secretions have been found to be involved in causing diarrhea in specific animal studies (Davidson et al., 1977; Graham et al., 1984; Collins et al., 1988). Diarrhea also has been induced in infant mice and rats by intraperitoneal inoculation with the rotavirus NSP4 protein as well as with a 22 amino acid peptide derived from this protein (Ball et al., 1996; Morris et al., 1999). Investigators observed that this protein and its peptide increased the levels of intracellular calcium by activating a calcium-dependent signal transduction pathway that mobilizes transport of this ion from the ER (Tian et al., 1994, 1995). Further reports suggest that NSP4 possesses membrane destabilization activity that may result from increased intracellular calcium concentrations, resulting in cytoskeleton disorganization and cell death (Tian et al., 1996; Browne et al., 2000; Brunet et al., 2000a, 2000b). Thus, binding NSP4 to intestinal epithelium after its release from infected cells may contribute to altered ion transport and diarrhea. Another factor that may have a role in rotavirus-induced diarrhea is the enteric nervous system which lies under the villus epithelium. It has been reported that rotavirus infection can activate this system in mice and drugs that block nerve activity attenuate rotavirus-induced fluid secretion in vitro and attenuate diarrhea in vivo (Lundgren et al., 2000). Whether this is a major mechanism of diarrhea occurring after rotavirus infection in humans remains to be determined.

The tissue tropism of rotavirus infection in humans was thought initially to be restricted to the villi of the small intestine. Because no consistent evidence of extraintestinal replication of rotavirus had been shown, the general assumption was that rotavirus pathology is strictly intestinal. However, instances of nongastrointestinal rotavirus-associated disease, including the association with abnormal liver function, as well as respiratory and nervous system involvement were reported (Lewis et al., 1979; Matsuno et al., 1983; Hongou et al., 1998; Nigro, 1991; Honeyman et al., 2000; Hattori et al., 1992). This spread was explained when it was reported that both antigenemia (presence of rotavirus protein in the blood) and viremia (presence of live rotavirus in the blood) were found during rotavirus infection in several strains of animals and in humans (Blutt et al., 2003). Since that time, this observation has been confirmed by a number of studies in humans (Chiappini et al., 2005, 2006; Fischer et al., 2005; Blutt et al., 2006, 2007; Ray et al., 2006).

IMMUNITY

After over 30 years of research involving studies of natural rotavirus infection, vaccine studies, and animal studies, the mechanisms of immunity to rotavirus infection remain unclear. Humoral antibody responses include an early IgM response followed by the

production of rotavirus IgG and IgA (Riepenhoff-Talty et al., 1981; Grimwood et al., 1988). Infection also induces local, intestinal antibodies that are predominantly IgA (Bernstein et al., 1989; Coulson et al., 1990; Matson et al., 1993; Brown et al., 2000). T cell responses have been difficult to measure in humans, but several rotavirus proteins have been identified that contain T cell epitopes and have been used to measure T cell responses after rotavirus infection (Offit et al., 1993; Jaimes et al., 2002; Franco et al., 1994).

As stated before, virus neutralization epitopes are found on VP4 and VP7 proteins located on the surface of the virion, and neutralizing antibody to the infecting virus can be detected after infection or vaccination. However, VP6 appears to be the most immunogenic protein and antibody made against VP6 is not neutralizing. One of the most controversial questions concerning the development of immunity to rotavirus infection is whether or not neutralizing or serotype-specific antibody is necessary for protection. As will be discussed, this has had a dramatic effect on vaccine development.

Studies dealing with natural rotavirus infections were used initially to understand rotavirus immunity and the role of serotype specific antibodies. Many investigators reported that natural rotavirus infections produce incomplete protection, but many studies have shown that previous infections protect against severe disease associated with reinfection (O'Ryan et al., 1990; Bernstein et al., 1991; Clemens et al., 1992, Ward and Bernstein, 1994; Velazquez et al., 1996; Franco et al., 2006). In a large study conducted in Mexico, protection from both rotavirus reinfection and rotavirus diarrhea increased with each new infection (Velazquez et al., 1996). However, sequential infections even with the same serotype have been reported. In an early study reporting rotavirus disease with reinfection by the same serotype, the investigators noted that protection of young children in a Japanese orphanage lasted 6 months then declined after 1 year. This study noted a close correlation between titers of serotype-specific antibody and protection (Chiba et al., 1986). This study is often cited to support the idea that neutralizing antibody is necessary for protection. While it is generally accepted that if present at a sufficient titer, neutralizing antibody will protect, it is still unclear whether only neutralizing antibody is necessary for protection.

Although, reinfections with rotavirus can be common, other studies have shown that protection lasts at least 1 year. Neonates infected within the first 2 weeks of life were protected against severe disease but not against reinfection in one study (Bishop et al., 1983). In another study, infants who developed a symptomatic or an asymptomatic rotavirus infection during the first year of the study were protected against contracting a subsequent rotavirus illness or even an asymptomatic reinfection during the following year (Bernstein et al., 1991). Similarly, in another study, a natural rotavirus infection in the first year was found to be 93% protective against a symptomatic reinfection in the second year. This protection occurred even though the G1 strains that circulated during the first year were responsible for only 66% of rotavirus disease in the second year (Ward and Bernstein, 1994).

Correlations of serotype-specific neutralizing antibody and protection have not been supported in other larger studies. In the largest study, conducted in Bangladesh during a 2-year period when the four major G serotypes circulated, the titers of both preexisting homologous and heterologous neutralizing antibody were significantly lower in patients with acute rotavirus disease than in matched control subjects. Further analysis, however, could not find a correlation with serotype-specific neutralizing antibody, and protection seemed to correlate better with the magnitude of the response rather than with specific neutralizing responses (Ward et al., 1992). Differences in these studies evaluating the role of serotype specific antibody and the protection provided by natural infection may be due to the variation in circulating strains, the inoculum size, or the duration of protection.

Due to the difficulties associated with human studies, animal models using mice, rabbits, and gnotobiotic pigs have been developed (Ward et al., 1990; Conner et al., 1988; Saif et al., 1996). But again results from these studies have not completely identified the mechanisms of protection against rotavirus illness or infection possibly due to the use of different species. Questions remain regarding the relevance of these animal models to human rotavirus disease. Early studies in mice showed that while CD8 T cells are involved in resolution of an infection, antibody is necessary for protection against reinfection (McNeal et al., 1995; Franco and Greenberg, 1995; Franco et al., 1997). In a recent study, mice given an oral immunization of a fully heterotypic rotavirus were almost completely protected from shedding when later challenged, and this protection was dependent on the ability of rotavirus-specific IgA to be transported through intestinal epithelial cells or be present at the intestinal mucosa (VanCott et al., 2006). If these studies mirror what is needed in humans, then local antibody may be the effector of protection and non-neutralzing antibody that is not serotype-specific can also be involved in protection. Thus, serum levels of rotavirus-specific IgA may be a good correlate of protection, because it appears to parallel antibody levels in the gut (Brown

et al., 2000; Jiang et al., 2002). Our understanding of protective immune responses will improve with further animal evaluations and should be aided by studies of the two new vaccines. The absence of a reliable immunologic marker of protection, however, continues to render vaccine trials more difficult.

ROTAVIRUS VACCINES

Public health institutions around the world have given the development of an effective rotavirus vaccine a high priority (Parashar and Glass, 2006). Numerous cost-effectiveness analyses in many countries have evaluated the need and benefit of a rotavirus vaccine. Although studies in the United States have shown mixed results, rotavirus vaccination is considered a cost-effective intervention (Widdowson et al., 2007) and a recent study has indicated pediatricians in this country are willing to implement the recently licensed vaccine (Kempe et al., 2007). Studies in other countries, especially countries that have high mortality due to rotavirus disease, clearly have shown that a rotavirus immunization program would be cost-effective from the perspective of society and the health care system (Glass et al., 2005; Podewils et al., 2005; Giaquinto et al., 2007b; Lorgelly et al., 2007). Because natural rotavirus infections can induce excellent protection, at least against severe rotavirus disease, vaccine efforts have been directed mostly at the development of live attenuated rotavirus vaccines given orally.

Early efforts concentrated on the use of animal rotavirus strains, labeled the Jennerian approach because it relies on the natural attenuation of animal viruses in humans for safety and largely heterotypic immune responses for protection. The initial efforts with animal rotavirus vaccines yielded inconsistent results. Therefore, in an attempt to make the vaccines more closely related to human strains, human rotavirus genes coding for the proteins that induce neutralizing antibody, VP4 and VP7, were introduced into these animal strains by creating reassortant viruses as described earlier. This approach is often labeled the modified Jennerian approach. Another approach has been to use human rotaviruses, either isolated from asymptomatic infections in human neonates or isolated from a child with rotavirus illness and attenuated by cell culture adaptation and passage.

Animal Strains

The first vaccine trial was conducted 10 years after the identification of rotavirus as an agent of severe diarrhea. This vaccine candidate was based on an animal strain, a bovine rotavirus termed RIT4237 that was derived from the Lincoln isolate, NCDV, and was a G6P[1] virus (Hoshino and Kapikian, 1994). The initial studies of the RIT4237 vaccine produced variable results. The vaccine was safe and effective in Finland, providing a protective efficacy of approximately 50% against all disease and greater than 80% protection against severe disease. This trial, thus supported the hypothesis that heterotypic protection was possible since this virus shared neither G nor P serotypes with the predominant human types. Antibody responses after vaccination showed a seroconversion rate of 53% as measured by serum IgG (IgA antibody was not determined in these early studies) but protection against severe diarrhea was detected even in vaccinees who did not seroconvert, suggesting that IgG was not a good measurement of vaccine take (Vesikari et al., 1983, 1984, 1985). However, later studies in developing countries were disappointing, showing little or no efficacy (DeMol et al., 1986; Hanlon et al., 1987; Lanata et al., 1989). Similarly, the vaccine failed to provide protection in a study performed on a Navajo reservation in Arizona (Santosham et al., 1991) and ultimately development of this vaccine was discontinued.

Another bovine rotavirus based vaccine, WC3, also appeared to be safe but replicated poorly in humans with between 5 and 17% of vaccinees shedding detectable vaccine virus (Clark et al., 1988). Immunized infants developed a neutralizing antibody response to WC3 in addition to rotavirus IgA and IgG antibody responses (Bernstein et al., 1990). The initial studies conducted in Philadelphia using one dose of the vaccine appeared promising, showing a protection rate of 76% against rotavirus diarrhea and 100% protection against more severe cases during a season that had predominantly G1 strains (Clark et al., 1986). Unfortunately, later trials in Cincinnati (Bernstein et al., 1990) and in less developed countries (Georges-Courbot et al., 1991) showed no significant protection. As will be discussed, WC3 was later used to develop reassortant vaccines and is indeed the backbone of the RotaTeq™ vaccine now licensed in the USA (Merck Research Company).

The next major vaccine candidate was a simian rotavirus isolated from the diarrheal stool of a rhesus monkey and termed MMU18006 or more commonly known as RRV. This vaccine was a G3P[3] strain and thus shared the G type with a strain that is common in humans. This strain replicated better in humans than the bovine strains, perhaps because of the sharing of the G3 serotype. RRV vaccination was associated with mild side effects, including low-grade fever and mild diarrhea, especially when it was given to older children who had lost maternal antibodies (Vesikari et al., 1986; Perez-Schael et al., 1987; Losonsky et al.,

1986). RRV was found to induce serum rotavirus IgG and IgA, intestinal rotavirus IgA, and RRV neutralizing antibody responses, but no neutralizing antibody against non-G3 human rotaviruses could be detected (Losonsky et al., 1986). Protection with this vaccine was inconsistent, ranging from greater than 50%, even in developing countries, to moderate (20–50%) to nonexistent (Midthun and Kapikian, 1996). Some evidence suggested that protection was more effective in G3 than G1 outbreaks but the evidence was not conclusive (Flores et al., 1990; Conner et al., 1994). This virus was later used to make the reassortants containing human rotavirus VP7 genes that became Rotashield™ vaccine (Wyeth).

One additional animal strain that has been developed into a vaccine is a G10P[12] strain isolated from a lamb, designated LLR. In 2000 and 2001, a vaccine based on this strain and produced by the Lanzhou Institute of Biological Products was introduced in China (Ling-Qiao, 2001). The vaccine was not tested in a controlled trial against a placebo group, therefore the efficacy is not known.

A summary of the various vaccines based on animal strains is presented in Table 35.2.

Reassortant Vaccines

Because of the belief that homotypic immunity, or the development of serotype-specific antibody responses, might increase the protection seen with rotavirus vaccines and because of a lack of consistent protection after vaccination with heterotypic animal strains, the next vaccines developed were reassortant vaccines (Table 35.3). These vaccines contained the genes encoding VP7 or the VP7 and VP4 proteins of human rotavirus strains, with the remainder of the genes from an animal strain. As discussed earlier, these proteins were chosen because they induce neutralizing antibody. One goal of this strategy was to create a multivalent vaccine containing viruses with human rotavirus genes representing the main human serotypes, initially G1–4.

Rotashield™

The simian strain, RRV, was used as the background to make three different reassortant viruses containing the VP7 gene from human strains D (G1 serotype), DS-1 (G2 serotype), and ST-3 (G4 serotype) with the

TABLE 35.2 Animal rotavirus strains used as vaccine candidates

Candidate	Origin	G and P type	Comments
RIT4237	Bovine	G6P[1]	In small trials, safe but variable results; no efficacy in developing countries; discontinued development
WC3	Bovine	G6P[5]	Safe but variable results; virus used to make reassortants containing human genes
MU18006 (RRV)	Simian	G3P[3]	Some incidence of fever in vaccinees; inconsistent protection; virus used to make reassortants containing human genes
LLR	Lamb	G10P[12]	Used in China, efficacy not known

TABLE 35.3 Animal human reassortant rotavirus strains used as vaccine candidates

Candidate	Virus background	Human gene substitutions	Comments
RRV-TV (Rotashield)	RRV G3P[3]	G1, G2, G4	Some fever in vaccinees; 49–64% protective against rotavirus; 80% protective against severe disease; licensed in United States in 1998; withdrawn due to association with intussusception
RotaTeq™	WC3 G6P[5]	G1, G2, G3, G4, P[8]	Safe, no association with intussusception after trials involving over 60,000 infants; highly protective, especially against severe disease; three doses given to infants starting at 6–12 weeks of age; licensed in the United States in 2006
UK reassortants	UK G6P[5]	G1, G2, G3, G4	In small studies, safe and protective; under development in several countries; may add more reassortants, possibly for G9 and G8

G3 serotype represented by RRV itself. The reassortant viruses were initially tested individually in various trials for safety, immunogenicity, reactogenicity, and efficacy. Each RRV reassortant had a safety profile comparable to RRV, with low-grade fevers occurring in about 20% of the vaccinees. Protection rates varied with the different monovalent viruses depending on the study, but generally heterotypic and homotypic protection were measured (Midthun and Kapikian, 1996). Therefore, all four strains were incorporated into a tetravalent vaccine, RRV-TV which later was licensed as Rotashield™.

Vaccination with RRV-TV produced a rotavirus IgG and IgA serum antibody response, but neutralizing antibodies were produced predominantly to RRV rather than to the human serotypes (Bernstein et al., 1995; Rennels et al., 1996). This finding appears to be consistent with data suggesting that VP4 rather than VP7 is more immunogenic after live oral infection (Ward et al., 1988, 1993). Extensive evaluations of the RRV-TV were completed before licensure. In two large trials conducted at centers across the United States, the RRV-TV vaccine was found to be safe, with the subjects developing a slight increase in temperature after the first dose. The efficacy of the vaccine against any rotavirus disease for the first year was 49–64%, whereas during a 2-year follow-up, it was 57%. Protection against severe disease was 80% (Bernstein et al., 1995; Rennels et al., 1996). Vaccination also significantly decreased the number of medical office visits for rotavirus gastroenteritis or dehydration. In a postlicensure vaccine effectiveness study, it was determined that three doses of the vaccine were 100% effective in preventing hospitalization due to rotavirus (Staat et al., 2006). Vaccination appeared to provide protection against both G1 and G3 serotypes (Rennels et al., 1996; Bernstein, 2000). Similar results were reported from Finnish studies except that fever occurred somewhat more commonly and efficacy was somewhat enhanced (Joensuu et al., 1997). Protection similar to that seen in the US studies was also provided by the vaccine when it was evaluated in a less developed country, Venezuela (Perez-Schael et al., 1997).

As a result of these studies, RRV-TV or Rotashield™, was licensed in the United States in 1998 and recommended for general use in all infants (American Academy of Pediatrics, 1998). However, less than 1 year after licensing, 15 cases of intussusception that occurred shortly after vaccination were reported to the Vaccine Adverse Events Reporting System (VAERS). Intussusception is a form of intestinal blockage caused when a segment of the bowel prolapses into a more distal segment of the intestine (Centers for Disease Control, 1999a). Further analysis by the Advisory Committee on Immunization Practices led to the conclusion that an association existed between receipt of the vaccine and development of intussusception. Their recommendation for the use of Rotashield™ was withdrawn and the vaccine was withdrawn by the manufacturer (Centers for Disease Control, 1999b).

Much debate and controversy occurred after the use of Rotashield™ was halted. Initial publications describing the association reported an increased risk of the development of intussusception from 3 to 14 days after receipt of the first dose of Rotashield™ (adjusted odds ratio 21.7) and a smaller risk after administration of the second dose of vaccine (Murphy et al., 2001). The initial estimate was that one case of intussusception attributable to vaccination with RRV would occur for every 4670–9474 infants vaccinated. Therefore, the decision was made to discontinue the use of Rotashield™ (Murphy et al., 2001, 2002, 2003). In more recent analysis, the consensus was that the risk was approximately 1 in 10,000 (Peter and Myers, 2002). Further, when the data were further analyzed, it appeared that the risk of intussusception was age related and increased substantially in children greater than 90 days of age, leading some researchers to suggest that vaccination with any live rotavirus vaccine should be restricted to younger children (Simonsen et al., 2005; Rothman et al., 2006). The Food and Drug Administration (FDA) also recommended that future trials using live oral rotavirus vaccines should be conducted with more than 60,000 children to ensure that the risk of intussusception from a new vaccine would be less than was attributed to Rotashield™ (Glass et al., 2004).

The pathogenic mechanism underlying the association of the Rotasheild™ vaccine and intussusception has not been defined (Lynch et al., 2006). Several studies have investigated the possible infectious etiology of intussusception, but these studies have had a small sample size and several different pathogens, including adenoviruses, have been identified (Bhisitkul et al., 1992; Hsu et al., 1998). It does not appear that wild-type rotavirus causes intussusception as there is a lack of seasonal variation for intussusception that would be expected to occur if rotavirus was a major cause of intussusception (Rennels et al., 1998; Parashar et al., 2000; Chang et al., 2002).

RotaTeq™

After the bovine WC3 vaccine, discussed previously, was shown to be safe but not consistently effective, a monovalent vaccine containing the VP7 gene of a human G1 rotavirus (WI79-9) and the remainder

of the genes from WC3, was developed. This vaccine was reported to be effective especially against more severe disease during a predominantly serotype G1 outbreak in Rochester (Clark et al., 1990). Next, because of the idea that serotype-specific protection was necessary, a WC3-based reassortant quadrivalent vaccine containing three viruses with gene substitutions of the VP7 gene with human G1, G2, or G3, and one virus containing a VP4 gene substitution with a human P[8] on a WC3 background was evaluated. In studies conducted at multiple centers in the United States, it was shown to be safe and effective against all cases of rotavirus gastroenteritis (75%) and especially against severe cases (100%) (Clark et al., 2004). Finally by adding a reassortant virus containing a human G4 VP7 to the above four viruses, a pentavalent vaccine, RotaTeq™, was developed by Merck Research Laboratories (Clark et al., 2006).

Because of the association of Rotashield™ with intussusception, the large pivotal trial of RotaTeq™ included over 70,000 infants from 11 countries. The vaccine was shown to be safe and, unlike Rotashield™, it did not induce fever (Vesikari et al., 2006d). Most importantly there was no association with intussusception. Intussusception occurred in 12 vaccine recipients and 15 placebo recipients within 1 year after the first dose of vaccine including six vaccine recipients and five placebo recipients within 42 days after any dose (relative risk, 1.6; 95% confidence interval, 0.4–6.4). The vaccine was also highly effective, reducing all G1–G4 rotavirus gastroenteritis by 74.0%, severe gastroenteritis by 98.0%, and hospitalizations and emergency room visits by 94.5% (Vesikari et al., 2006d). On February 3, 2006 RotaTeq™ was licensed by the US FDA for use in infants. The American Academy of Pediatrics recommended the vaccine which is administered in a three-dose schedule between 6 and 32 weeks of age, with a first dose administered between 6 and 12 weeks of age and all three doses administered by 32 weeks of age (American Academy of Pediatrics, C.O.I.D., 2007a, 2007b). In the United States, postmarketing safety of RotaTeq™ is being monitored by the CDC and the FDA. As of February, 2007 there was no suggestion of an association of RotaTeq™ vaccination with intussusception and CDC reaffirmed its recommendation for routine vaccination of infants with RotaTeq™ (Centers for Disease Control, 2007).

Bovine UK Reassortant Vaccine

The bovine UK strain, which is also a G6P[5] similar to WC3, has also been used to develop a reassortant tetravalent vaccine. The bovine UK reassortant vaccine was developed in the laboratory of Albert Kapikian of the National Institutes of Health in Bethesda, MD where RRV-TV was also developed. The tetravalent UK reassortant vaccine contains single VP7 gene substitutions from G1, G2, G3, or G4 human rotaviruses on a 10-gene UK background. Initially, monoreassortants were developed and evaluated. They were found to be safe and immunogenic in infants under 6 months of age and also did not induce fever (Clements-Mann et al., 1999). The tetravalent UK vaccine was then evaluated for safety and immunogenicity in the USA and later for safety/immunogenicity/efficacy in Finland. Although the studies were small, protection was significant (60% against any rotavirus disease and 90% against severe rotavirus disease; $P < 0.02$) (Vesikari et al., 2006c). In order to facilitate the production and commercialization of this vaccine, the NIH Office of Technology Transfer has granted licenses to at least eight groups throughout the world, seven of which are in developing nations, including vaccine manufacturers in Brazil, China, and India. There has been additional work done to develop UK-based reassortants containing additional VP7 genes for some of the emerging viruses such as G8 or G9 strains, thereby, proposing a hexavalent reassortant vaccine (Kapikian et al., 2005).

Human Strains

The use of human strains for vaccine candidates is based on the data that show that natural infection can provide protection against subsequent infection or disease. The human strains considered as vaccine candidates are either naturally attenuated, as thought to be the case with neonatal strains, or attenuated by culture adaptation and multiple passage. The candidates discussed below and listed in Table 35.4 are each composed of one strain and therefore, rely on homotypic and heterotypic mechanisms of protection.

Neonatal Strains

The first natural history study showed that asymptomatically infected neonates had a subsequent reduction in the frequency and severity of rotavirus diarrhea, thereby, generating interest in the use of neonatal strains as vaccine candidates (Bishop et al., 1983) Therefore, one of the first human strains to be tested as a rotavirus vaccine was a neonatal strain isolated from an asymptomatic newborn infant in Venezula. The strain, M37 is a G1P[6]. Several small studies with this candidate showed that the vaccine was safe but only moderately immunogenic, inducing neutralizing antibody responses to the

TABLE 35.4 Human strains developed as vaccine candidates

Candidate	Origin	G and P type	Comments
M37	Neonatal	G1P[6]	Isolated in Venezuela; safe but not very immunogenic; no protection in small trials; discontinued
RV3	Neonatal	G3P[6]	Isolated in Australia; safe, and small trials showed limited protection at low dose; plans for Phase II and III trials at higher doses
116E	Neonatal	G9P[11]	Isolated in India; natural bovine human reassortant; small trials have shown immune responses; development continues in India
I321	Neonatal	G10P[11]	Isolated in India; natural bovine human reassortant; small trials have shown very poor immune responses; development discontinued
Rotarix®	Child with gastroenteritis	G1P[8]	Isolated in Cincinnati, OH; safe, no association with intussusception after trials involving over 63,000 infants; highly protective, especially against severe disease; given in two doses; licensed in Mexico in 2004 and in over 90 countries worldwide to date

M37 strain and not to other G1 strains such as Wa (Midthun et al., 1991). In an efficacy study of 203 Finnish infants, there was no protection against predominantly G1 strains and this vaccine candidate was not pursued (Vesikari et al., 1991).

RV3, another vaccine candidate, is a G3P[6] human rotavirus that was isolated in an obstetric nursery in Melbourne, Australia, where it caused endemic, asymptomatic infections in newborn infants in the 1970s. As stated above, neonates infected with this virus were 100% protected against severe rotavirus disease, caused primarily by heterotypic G2P[4] strains, for their first 3 years of life (Bishop et al., 1983). Once RV3 was developed into a vaccine candidate, Phase I and early Phase II trials were conducted. Although an immune response to the vaccine (6.5×10^5 ffu) was detected in only 46% of subjects, protection in the responders against primarily serotype G1 circulating rotaviruses was 54% ($P = 0.08$) (Barnes et al., 1997, 2002). Future evaluations will utilize a higher dose of vaccine to improve the immune response and protection.

Two other, more recent vaccine candidates, were derived from two neonatal strains isolated from asymptomatically infected neonates in India in the mid-1980s, one from New Delhi and the other from the Bangalore region of India. Both of these strains are natural reassortants between bovine and human strains. The strain from New Delhi, 116E, a G9P[11] strain, contains a VP4 gene segment from a bovine rotavirus and the other 10 genes are from a human strain (Das et al., 1993a). The other strain I321, is a G10P[11] strain and contains nine genes of bovine origin and only gene segments for two nonstructural proteins from a human strain (Dunn et al., 1993). Early studies suggested that neonates infected with viruses similar to these two strains were protected against subsequent rotavirus illness (Bhan et al., 1993; Aijaz et al., 1996), but a recent report by another group suggests otherwise for G10P[11] or I321-like viruses (Banerjee et al., 2007). Both I321 and 116E vaccine candidates were tested in a small, placebo-controlled trial, that showed only the 116E strain elicited significant immune responses (Bhandari et al., 2006). Therefore, only the 116E strain is being pursued as a vaccine candidate in India under a consortium with partners from the United States including the Children's Vaccine Program at PATH (Dennehy, 2007).

Rotarix®

The second marketed vaccine, Rotarix, was first licensed in Mexico in 2005 and has since been approved in over 100 countries worldwide including developed, less developed, and developing nations (Bernstein, 2006). This vaccine is based on the attenuated human strain, 89-12. This strain was obtained from an infant with rotavirus gastroenteritis in Cincinnati, OH and is a G1P[8] strain, representing the most common strain worldwide (Santos and Hoshino, 2005). The isolate was attenuated by multiple passages in tissue culture and then developed into a vaccine. Early studies with 89-12 showed that it was safe but

a low-grade fever did develop in 19% of recipients. Results of a multicenter efficacy trial showed that two doses of this vaccine provided 89% protection against any rotavirus disease and 100% protection from severe disease (Bernstein et al., 1999).

The 89-12 strain was further purified by limiting dilution and passage in tissue culture by GlaxoSmithKline. The final product was called RIX4414 and is now marketed as Rotarix (GlaxoSmithKline), a two dose oral vaccine. Initial safety testing in Finland showed that the vaccine was safe and more attenuated than the parent vaccine strain as it did not produce the fevers that had been detected with the parent 89-12 (Vesikari et al., 2004a). Subsequent studies in Singapore, Finland, Latin America, and the US confirmed that it was safe, not associated with fever and still remained highly immunogenic (Phua et al., 2005; Salinas et al., 2005). Other studies showed the vaccine did not interfere with other concomitantly administered childhood vaccines (Dennehy et al., 2005; Ruiz-Palacios et al., 2007). In the initial efficacy trial of RIX4414 conducted in Finland over two rotavirus seasons, the vaccine was 73% protective against all rotavirus gastroenteritis and 90% protective against severe illness even though a relatively low dose was used (Vesikari et al., 2004b).

Similar to RotaTeq™, and because of the concerns about intussusception, the pivotal vaccine trial with RIX4414 also involved large numbers. Over 63,000 infants from several countries in Latin America and Finland were enrolled in a safety trial. The RIX4414 vaccine ($10^{6.5}$ median cell culture infective dose) was given in a two dose schedule at approximately 2 and 4 months of age (compared to the three dose schedule of RotaTeq™). This large study showed the vaccine was safe, did not induce fever and again, most importantly, was not associated with intussusception. During the 31-day period after each dose, six vaccine recipients and seven placebo recipients had confirmed intussusception with no evidence of clustering (difference in risk, −0.32 per 10,000 infants, 95% confidence interval, −2.91 to 2.18; $P = 0.78$). During the entire study, there were 25 cases of intussusception, 16 in the placebo group and 9 in the vaccine group (Ruiz-Palacios et al., 2006).

Efficacy data from a subset of 20,000 infants from this trial showed 85% protection against severe rotavirus diarrhea and hospitalization. Protection against more severe gastroenteritis was 100%. It was also demonstrated that protection was high (86%) not only against severe rotavirus diarrhea caused by G1P[8] strains but also against G3P[8], G4P[8] and G9P[8] strains which all shared the VP4 P[8] genotype. Efficacy against G2P[4] strains (strains that are not matched for either VP4 or VP7) was 41%. However, in a meta-analysis efficacy was calculated to be 67–71%, indicating that the vaccine will provide substantial protection even against strains that do not have either G1 or P[8] specificity (Ruiz-Palacios et al., 2006).

In a more recent trial, conducted in six European countries, in a population more similar to that used in trials for RotaTeq™ over 4000 infants were evaluated. Protection in this study was 87% against any rotavirus gastroenteritis, 96% against severe disease and 100% against hospitalization due to rotavirus. In this study, efficacy against G3, G4, and G9 strains was similar to that against G1 strains and was over 95%. Efficacy against the unrelated G2 strains was 75%, suggesting that heterotypic or non-neutralizing antibody responses are also involved in protection (Vesikari et al., 2006a, 2006b). Of importance, protection against hospitalization for gastroenteritis of any etiology was 75%, demonstrating the importance of rotavirus as a pathogen of severe gastroenteritis in these countries.

One of the best correlations between rotavirus antibody induced by vaccination and protection was shown in studies using Rotarix. If a vaccinee did not develop a measurable serum rotavirus IgA response after two doses of Rotarix, they were significantly more likely to develop rotavirus disease when compared to subjects that did develop an IgA response (De Vos et al., 2004). However, protection rates against severe rotavirus illness were higher than the rate of vaccinees who had a measurable IgA response after Rotarix immunization (Salinas et al., 2005).

Similar to RotaTeq™, postlicensure safety of Rotarix is being monitored in the countries where use has begun. Additional trials are ongoing in developing countries in Asia and Africa to determine safety and efficacy in these areas where rotavirus disease burden is greatest. In addition, an application for licensure in the United States was accepted for review by the FDA in August, 2007.

NONLIVING ROTAVIRUS VACCINE CANDIDATES

In addition to live oral rotavirus vaccines, a number of nonliving vaccine candidates have been developed and evaluated in animal models. Nonliving vaccine candidates were developed in attempt to formulate a vaccine that would be more effective than live oral vaccines, since even natural infection does not always result in 100% protection from reinfection. In addition, these candidates were often studied in an attempt to better define mechanisms of protection, including

determinations regarding the protective efficacy of various viral proteins. Finally after the association of Rotashield with intussusception, possible safety concerns with live virus vaccines added to the possible need for nonliving vaccine candidates. The nonliving candidates studied include DNA vaccines (Chen et al., 1997; Choi et al., 2007), inactivated purified triple and double-layered virus particles (McNeal et al., 1998, 1999), recombinant virus-like particles (VLPs) containing VP2 and VP6, with or without VP4 and VP7 (O'Neal et al., 1998), and recombinant expressed VP6 protein (Choi et al., 2002a). To date none of these candidates have been tested in humans.

Using animal models, each of the above candidates have shown significant levels of protection, especially in the adult mouse model which uses reduction of viral shedding as its measure of protection. Of note, VLPs did not induce protection from illness when used in the gnotobiotic pig model, currently the only illness animal model (Yuan et al., 2000). Except for DNA-based vaccines, the other candidates often require the use of an effective adjuvant, usually recombinant formulations of bacterial toxins, to induce protection (Choi et al., 2002b; Bertolotti-Ciarlet et al., 2003). However, the use of this type of adjuvant in humans greatly increases the safety concerns associated with these vaccine approaches. If the present licensed live oral vaccines, RotaTeq™ and Rotarix, or other live oral rotavirus vaccines prove to be ineffective or have safety issues, the present nonliving vaccines may be further developed.

CONCLUSIONS

Worldwide, rotavirus infections are responsible for over 600,000 deaths, representing 5% of all childhood deaths in children less than 5 years of age. A safe and effective rotavirus vaccine is the best hope of combating this disease. After the largest vaccine trials in history, two live oral vaccines, RotaTeq™ and Rotarix, have been licensed or will soon be licensed in many countries around the world. Both vaccines were shown to be safe and effective, decreasing severe disease and hospitalization due to rotavirus by 85–100%. In addition, neither vaccine has been associated with intussusception in either the large trials or postmarketing surveillance. However, neither vaccine has been evaluated, to date, in the poorest countries where it is most needed. Assuming the vaccines are also effective in these countries, the next hurdle will be to make the vaccines available to these populations. The GAVI Alliance, formerly known as the Global Alliance for Vaccines and Immunization, has committed to helping with the financial cost of the vaccine in countries which qualify for support. In addition, in February, 2007, Rotarix was granted WHO prequalification status, an important first step in getting a rotavirus vaccine to poor countries.

KEY ISSUES

- Rotavirus is the most common cause of gastroenteritis in young children in all parts of the world. It is responsible for over 600,000 deaths around the world, and over 50,000 hospitalizations in the US.
- Rotavirus is a segmented double-stranded RNA virus. Serotyping is based on the two outer capsid proteins that induce neutralizing antibodies VP7 (G type) and VP4 (P type).
- The mechanism of protection against rotavirus is not completely clear but neutralizing antibodies play a role. The role of non-neutralizing antibodies and T cells are less clear but are probably important.
- Rotavirus vaccine development has largely concentrated on the use of live attenuated vaccines administered by the oral route in order to generate local, intestinal immunity.
- The initial approach of using animal rotavirus strains that were naturally attenuated for humans was replaced by the use of reassorted strains, i.e., replacement of animal rotavirus genes with human genes (most commonly encoding VP7 or VP7 and VP4 proteins) or using an attenuated human strain.
- The first licensed rotavirus vaccine Rotashield™ used a rhesus monkey rotavirus strain as the backbone for a quadrivalent vaccine. This vaccine was associated with intussusception and was quickly withdrawn from the market.
- There are now two rotavirus vaccines available in the US, EU, Latin America as well as many other countries. Rotateq™ is a pentavalent vaccine based on reassortants of a bovine rotavirus while Rotarix™ is an attenuated human strain.
- Both vaccine have undergone rigorous testing in large human trials of over 60,000 infants and appear safe with neither being associated with intussusception.
- Both vaccines also appear to protect infants from the most common human serotypes.

- The remaining challenge for both vaccines is to show they can impact disease in the poorest countries of the world where mortality is the highest.

CHAPTER

36

SARS

Bart L. Haagmans and Albert D.M.E. Osterhaus
Department of Virology, Erasmus MC, Rotterdam, The Netherlands

OUTLINE

ABSTRACT

Five years after the first severe acute respiratory syndrome (SARS) outbreak, several candidate SARS-coronavirus (CoV) vaccines are at various stages of preclinical and clinical development. Based on the observation that SARS-CoV infection is efficiently controlled upon passive transfer of antibodies directed against the spike (S) protein of SARS-CoV, vaccines containing the S protein have been formulated. Animals immunized with inactivated whole virus vaccines or live-recombinant vaccines expressing the SARS-CoV S protein (e.g., using rabies virus, vesicular stomatitis virus, bovine parainfluenza virus type 3, adenovirus, or attenuated vaccinia virus MVA as a vector), as well as mice immunized with DNA vaccines expressing the S protein gene all developed neutralizing antibodies to SARS-CoV and were protected against SARS-CoV challenge.

Although much effort has been focused on developing a SARS vaccine, the commercial viability of such a vaccine for SARS-CoV will ultimately depend on whether the virus re-emerges in the near future. This vaccine

should induce highly cross-reactive neutralizing antibodies to protect against newly emerging viruses related to SARS-CoV and protect both the gastrointestinal and respiratory tract in the absence of significant side effects. Given the fact that in the previous outbreak mainly the elderly succumbed to the infection, special attention should be given to vaccines that are able to efficiently protect aged individuals.

INTRODUCTION

Severe acute respiratory syndrome coronavirus (SARS-CoV) first emerged in the human population in November 2002. Phylogenetic analysis of SARS-CoV isolates from animals indicated that this virus most probably originated from bats, was transmitted first to palm civets and subsequently to humans at the wet markets in southern China. Subsequent outbreaks occurred early 2003 in Hong Kong, Hanoi, Toronto, and Singapore, and could be directly traced back to one index patient who acquired the infection in Guangdong and traveled to Hong Kong. A worldwide epidemic was halted through the efforts of the World Health Organization, which responded rapidly to this threat by issuing a global alert, rigorous local containment efforts, warning against unnecessary travel to affected areas, and by creating a network of international experts to combat this virus. In the end only 8096 people became ill, and 774 people died in this first SARS epidemic. Because SARS-CoV could re-emerge and cause another epidemic at any time, development of effective vaccines remains of vital importance.

ETIOLOGIC AGENT

Although several infectious agents, including chlamydia, influenza A subtype H5N1, and human metapneumovirus, were considered as a possible cause of SARS, three groups independently reported the isolation of a previously unrecognized CoV from clinical specimens of SARS patients (Peiris et al., 2003; Rota et al., 2003; Drosten et al., 2003).

Through electron microscopy, serology, and reverse-transcription PCR with consensus- and random-primers, and subsequent sequencing of the replicase gene, its identity could be revealed and consistently demonstrated in clinical specimens from patients with the disease but not in healthy controls. To conclusively establish a causal role for this CoV, cynomolgous macaques were inoculated with a SARS-CoV isolate. Because the disease in macaques caused by SARS-CoV infection was pathologically similar to that seen in human patients with SARS, and since the virus was successfully re-isolated from the nasal swabs and lung lesions of these animals, and a specific antibody response to the virus was shown in the infected animals, SARS-CoV proved to be the causative agent of this infectious disease (Fouchier et al., 2003; Kuiken et al., 2003).

CLASSIFICATION AND ANTIGENS ENCODED

SARS-CoV is a single-stranded, positive-sense RNA virus, phylogentically related to coronaviruses from group 2 despite the fact that it does not encode a hemagglutinin-esterase protein (Snijder et al., 2003). The genome is packaged together with the nucleocapsid protein, at least five membrane proteins (M, E, 3a, 7a, and 7b) and the spike (S) protein (Fig. 36.1). The S1 region within the S protein, and more specifically a 193-amino acid fragment of the S protein (corresponding to residues 318–510), has been identified as the region that interacts with the cell receptor, angiotensin-converting enzyme 2 (Li et al., 2005a). The majority of neutralizing antibodies are directed against this region of the S protein. Antibodies raised against the N-terminal region of 3a protein or the M

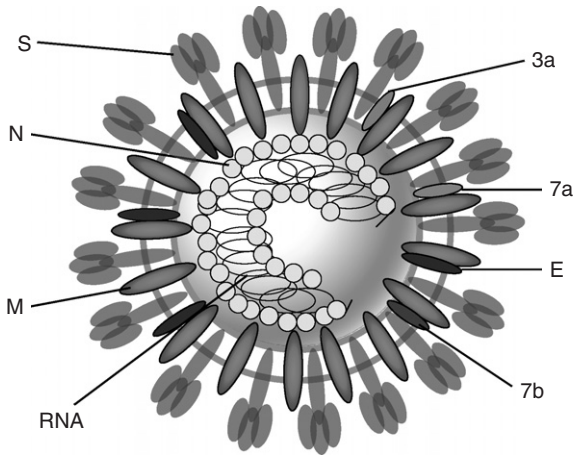

FIGURE 36.1 Schematic diagram of the SARS-CoV particle. S, spike protein; M, membrane protein, E, envelope protein; N, nucleocapsid protein; 3a, 7a, and 7b; structural proteins of SARS-CoV.

protein also inhibit SARS-CoV replication in vitro but their relevance in protection remains unclear. The genome also encodes two large poly-proteins with diverse enzymatic activities needed for efficient replication and several accessory proteins with unknown function (3b, 6, 8a, 8b, and 9b).

EPIDEMIOLOGY

At the end of 2004, 30 countries reported a total of 8096 probable cases of SARS (Fig. 36.2). Pathogenic SARS-CoVs do not circulate in the human population at the moment, but their re-emergence from animal reservoirs may likely occur in the future. Because many of the early SARS patients in Guandong had epidemiological links to the live-animal market trade, different animal species were tested for the presence of SARS-like viruses. Soon after the outbreak, a SARS-like coronavirus, which had more than 99% homology with human SARS-CoV, was detected by RT-PCR in the nasal and fecal swabs of palm civets (*Paguma larvata*) and a raccoon dog (*Nyctereutes procyonoides*) (Guan et al., 2003). More recent studies indicate that bats may potentially act as natural reservoirs for SARS-like CoVs (Li et al., 2005b; Lau et al., 2005). However, sequence comparison of the S protein genes from bat SARS-like CoV and palm civet SARS-like CoV revealed only 64% genetic homology. Subsequent studies by Tang et al. (2006) have demonstrated that approximately 6% of bats sampled in China were positive for CoVs. Interestingly, these CoVs are genetically diverse and many bat CoVs clustered with existing group 1 viruses, while others formed a separate lineage that included only viruses from bats (putative group 5). Other SARS-CoV like viruses clustered in a putative group 4 consisting of two subgroups, one of bat CoVs and another of SARS-CoVs from humans and other mammalian hosts. However, from these studies the direct progenitor of the SARS-CoV isolated from palm civets has not been identified. Major genetic variations in the S protein gene of these viruses from civet cats, seemed essential for the transition from animal-to-human transmission

FIGURE 36.2 Reported suspected SARS cases from November 1, 2002 to July 31, 2003 (data from the World Health Organization, http://www.who.int/csr/sars/country/table2004_04_21/en/index.html). Countries with >5 suspected cases are indicated.

to human-to-human transmission, which eventually caused the SARS outbreak of 2002–2003.

SIGNIFICANCE AS PUBLIC HEALTH PROBLEM AND POTENTIAL AS BIOTHREAT AGENT

There is at present no evidence for the virus persisting in the human population. Possible options for the re-emergence of SARS include the escape of the virus from laboratories, which has already occurred on three occasions. The re-emergence of the virus from its animal reservoir remains possible, given that the virus is detectable in the feces and respiratory secretions of some animals. Indeed, SARS-CoV re-emerged in four patients in Guangdong in December 2003, although these SARS-like CoVs caused milder clinical disease (Liang et al., 2004). The US National Institute of Allergy and Infectious Diseases Biodefense Network classified SARS-CoV as a category C priority pathogen pointing out that SARS-CoV could be a potential biothreat agent.

CLINICAL DISEASE

The clinical symptoms of SARS-CoV infection are those of lower respiratory tract disease and include fever, malaise, peripheral T cell lymphocytopenia, decreased platelet counts, prolonged coagulation profiles, and mildly elevated serum hepatic enzymes (Peiris et al., 2004; Li et al., 2004). Chest radiography reveals infiltrates with subpleural consolidation or "ground glass" changes compatible with viral pneumonitis. Around 20–30% of individuals with SARS require management in intensive care units and the overall case:fatality rate reached approximately 10%.

Although the main clinical symptoms are those of severe respiratory illness, SARS-CoV actually also causes a gastrointestinal and urinary tract infection; SARS-CoV can be detected in the feces and urine of patients, and electron microscopic studies of biopsies of the upper and lower intestinal mucosae of patients with SARS confirmed the presence of the virus in these tissues (Peiris et al., 2004). Fecal transmission proved to be important in at least one major community outbreak in Hong Kong (Amoy Gardens), in which over 300 patients were infected within a few days.

Three features of SARS may be relevant for intervention strategies. First, progressive age dependence in mortality and disease severity is observed in SARS patients. In fact, none of the SARS-CoV-infected children aged below 12 years in Hong Kong required intensive care or mechanical ventilation (Ng et al., 2004). This is not totally explained by comorbid factors but similar age dependence in mortality is seen in patients with other (nonviral) causes of acute respiratory stress syndrome (Rubenfeld et al., 2005). Second, virus transmission is low in the first days of illness and peaks around day 10 after disease onset (Chu et al., 2004). Finally, several studies revealed that high viral load in the nasopharyngeal aspirate was found to be an independent predictor of mortality (Hung et al., 2004; Chu et al., 2004). Therefore, vaccine strategies aimed at reducing the viral load may suffice to provide clinical benefit.

TREATMENT

The first efforts to treat SARS patients were mainly based on the use of ribavirin and corticosteroids. Ribavirin, which targets IMP dehydrogenase, has been known a long time as a broad-spectrum antiviral agent. However, current data do not support the use of ribavirin for SARS treatment; in vitro studies did not show significant antiviral activity (Cinatl et al., 2003) and ribavirin enhanced the infectivity of SARS-CoV in mice (Barnard et al., 2006). On the other hand, a protective effect of interferon (IFN)-α has been observed in a preliminary study during the SARS outbreak (Loutfy et al., 2003). These results are in concordance with several studies that noted antiviral activity in vitro (Cinatl et al., 2003; Hensley et al., 2004) and animal studies showing that pegylated IFN-α effectively reduced SARS-CoV replication and excretion, viral antigen expression by type 1 pneumocytes and the pulmonary damage in cynomolgous macaques that were infected experimentally with SARS-CoV (Haagmans et al., 2004). However, despite an extensive literature reporting on SARS treatments, it is not possible to determine whether treatments benefited patients during the SARS outbreak. Because of variation in treatment regimens—particularly the wide range in doses, duration of therapy, and route of administration of ribavirin and corticosteroids, no clear conclusion can be drawn regarding the efficacy of the drugs tested (Stockman et al., 2006). In the event of a future outbreak of SARS-CoV or another novel agent, attempts should be made to develop treatment protocols, organize randomized trials and to collect and contribute information for a standardized minimum dataset that could facilitate analysis of treatment outcomes among different settings (Stockman et al., 2006).

PATHOGENESIS

The major sources of transmission in humans are droplets that deposit on the respiratory epithelium. Unlike the situation in several other respiratory viral infections, viral load of SARS-CoV in the upper respiratory tract peaked around day 10 after disease onset (Peiris et al., 2004). Therefore, virus transmission may be less efficient in the first days of illness, a finding supported by epidemiological observations. Real-time PCR assays detect SARS-CoV during the first week in specimens of the lower respiratory tract (e.g., bronchoalveolar lavage, sputum, endotracheal aspirates), nasopharyngeal aspirate, throat swabs, and/or serum (Chan et al., 2004), whereas fecal samples may show very high viral loads toward the end of the first week and second week of illness. In typical cases, which were largely confined to adult and elderly individuals, SARS presented with acute respiratory distress syndrome, characterized by the presence of diffuse alveolar damage and multiorgan dysfunction upon autopsy (Nicholls et al., 2003). The pathological changes in lung alveoli most likely follow a common pathway characterized by an acute phase of protein-rich alveolar fluid influx into the alveolar lumina as a consequence of the injury to the alveolar wall. Subsequently type-2 pneumocyte hyperplasia takes place to replace the loss of infected type-1 pneumocytes and to cover the denuded epithelial basement membrane, resulting in restoration of the normal alveolar architecture. Severe alveolar injury may lead to fibrosis with loss of alveolar function in more protracted cases (Fig. 36.3).

INNATE IMMUNE RESPONSE TO INFECTION

It has been hypothesized that the pathological changes observed in the lungs are initiated by a disproportional innate immune response, illustrated by elevated levels of inflammatory cytokines and chemokines, such as CXCL10 (IP-10), CCL2 (MCP-1), IL-6, IL-8, IL-12, IL-1β, and IFN-γ (Huang et al., 2005; Wong et al., 2004). These in vivo data have been confirmed in vitro, demonstrating that SARS-CoV infection induces a range of cytokines and chemokines in diverse cell types (Cheung et al., 2005; Law et al., 2005). Although in vitro studies argued that production of type I IFNs is inhibited or delayed by SARS-CoV, in SARS-CoV-infected macaques, and also early during SARS in humans, type I IFNs can be readily demonstrated (De Lang et al., 2007). Because prophylactic treatment of macaques with pegylated IFN-α reduces SARS-CoV replication in the lungs, regulation of the production of IFNs may be important in controlling SARS (Haagmans et al., 2004).

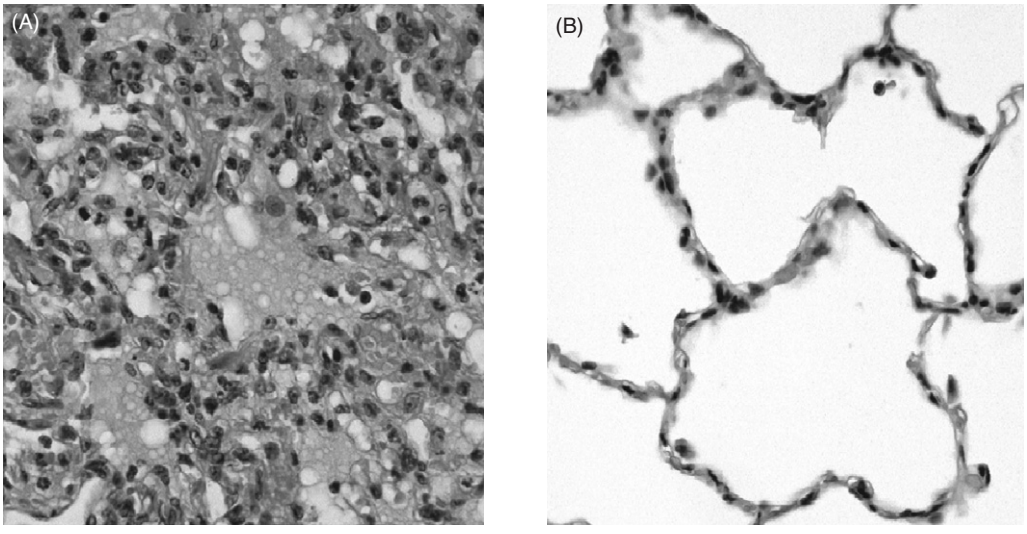

FIGURE 36.3 Acute lung injury after experimental infection of nonhuman primates with SARS-CoV. Shown are the histological changes in the lungs after SARS-CoV infection (A) as compared to the normal lung tissue (B). Viral infection of bronchiolar epithelial cells, type 1 and type 2 pneumocytes results in the influx of macrophages and neutrophils (A). The subsequent loss of type 1 cells may cause flooding of the alveolus by edema fluid (A) and in later stages fibrosis of the alveolar wall (deposition of collagen and influx of fibroblasts).

HUMORAL IMMUNE RESPONSE

Seroconversion usually occurs in weeks 2 or 3 of illness and virus-neutralizing antibodies can be detected in convalescent human serum. In patients who had recovered from SARS-neutralizing antibody titers peaked at month 4 but were undetectable in 16% of patients at month 36 (Cao et al., 2007). Neutralizing antibodies may be directed against different regions of the S protein (S1 and S2) as monoclonal antibodies against these epitopes exert potent neutralization of SARS-CoV in vitro (Sui et al., 2004; Lip et al., 2006). Conversely, peptides which are located in these regions were able to induce neutralizing antibodies (Bisht et al., 2005; Keng et al., 2005; Zhang et al., 2004).

Although experiments in diverse animal models have revealed that relatively low levels of neutralizing antibodies exert potent protection against lower respiratory tract infection, the neutralizing antibody titer necessary to achieve protection in humans exposed to SARS-CoV is not known. A concern in case of re-emergence of SARS is the possible absence of cross protection against these viruses. However, recent studies by He et al. (2006) have shown that the some neutralizing epitopes of SARS-CoV have been maintained during cross-species transmission, suggesting that receptor binding domain-based vaccines may induce broad protection against both human and animal SARS-CoV variants.

CELLULAR IMMUNE RESPONSE

In most SARS autopsies, extensive necrosis of the spleen and atrophy of the white pulp with severe lymphocyte depletion have been observed. On the other hand, rapid phase in peripheral lymphocyte recovery usually coincided with improved clinical conditions of SARS patients (Peiris et al., 2004). Long-lived memory T cell responses against SARS-CoV nucleocapsid and S protein have been demonstrated in recovered SARS patients, although their relevance in antiviral protection is not well understood (Yang et al., 2006; Peng et al., 2006; Li et al., 2006). However, despite potent immune responses and clinical recovery, peripheral lymphocyte counts in the recovered patients were not restored to normal levels (Li et al., 2006).

Interestingly, mice that lack NK-T cells, or NK cells, or T and B cells all cleared the virus by day 9 after infection (Glass et al., 2004). These data argue that cell-mediated immune responses are not essential to control virus clearance.

VACCINES

Based on the observation that SARS-CoV infection is efficiently controlled upon passive transfer of antibodies directed against the S protein of SARS-CoV, a range of vaccines containing the S protein/gene has been developed. Animals immunized with inactivated whole virus vaccines or live-recombinant vaccines expressing the SARS-CoV S protein (e.g., using rabies virus, vesicular stomatitis virus, bovine parainfluenza virus type 3, adenovirus, or attenuated vaccinia virus MVA as a vector), as well as mice immunized with DNA vaccines expressing the S protein gene all developed neutralizing antibodies to SARS-CoV and were protected against SARS-CoV challenge. Table 36.1 displays an overview of vaccines that have been tested for efficacy in animal models.

Inactivated Whole Virus and Subunit Vaccines

Inactivated SARS vaccines have been reported to elicit high titers of S protein-specific neutralizing antibodies. Few studies, however, have addressed whether inactivated whole SARS-CoV virions confer protection from virus challenge. Mice that were immunized twice with a candidate SARS-CoV vaccine, produced through a two-step inactivation procedure involving sequential formaldehyde and U.V. inactivation developed high-antibody titers against the SARS-CoV S protein and high levels of neutralizing antibodies (Spruth et al., 2006) (see Chapter 11). Moreover, the vaccine conferred protective immunity as demonstrated by prevention of SARS-CoV replication in the respiratory tract of mice after intranasal challenge with SARS-CoV. Protection of mice was correlated to the antibody titer against the SARS-CoV S protein and neutralizing antibody titer. Similar results have been obtained using a beta-propiolactone inactivated SARS-CoV vaccine in mice (Stadler et al., 2005). In addition, two Chinese groups have demonstrated protective efficacy of inactivated SARS vaccines in rhesus monkeys (Qin et al., 2006; Zhou et al., 2005). A soluble recombinant polypeptide containing the N-terminal segment of the S glycoprotein may suffice to induce neutralizing antibodies and protective immunity in mice (Bisht et al., 2005). In addition, a trimeric recombinant S protein was able to elicit an efficacious protective immune response in hamsters (Kam et al., 2007).

One of the most promising vaccine candidates is based on the combination of recombinant S protein with the Protollin adjuvant. In both young and aged mice, an intranasal Protollin-formulated S protein

vaccine elicited high levels of antigen-specific IgG in serum and significant levels of antigen-specific lung IgA (Hu et al., 2007). In contrast, mice immunized intramuscularly with Alum absorbed S protein did not develop detectable IgA responses. Following virus challenge of the aged mice, no virus was detected in the lungs of mice vaccinated intranasally, whereas intramuscularly immunized mice did not show significant control of virus replication compared to controls (Hu et al., 2007).

Vectored Vaccines

A DNA vaccine encoding the S glycoprotein of the SARS-CoV induces T cell, neutralizing antibody responses, and protective immunity in a mouse model (Yang et al., 2004). These authors also demonstrated that antibody responses in mice vaccinated with an expression vector encoding a form of S protein that includes its transmembrane domain elicited neutralizing antibodies. Viral replication was reduced by more than six orders of magnitude in the lungs of mice vaccinated with these S protein plasmid DNA expression vectors, and protection was mediated by a humoral, but not a T-cell-dependent, immune mechanism. Subsequent studies using a prime-boost combination of DNA and whole killed SARS-CoV vaccines elicited higher antibody responses than DNA or whole killed virus vaccines alone (Kong et al., 2005). Apart from this study, several other groups have analyzed the immunogenicity of SARS DNA vaccines but none of these challenged the vaccinated animals with SARS-CoV.

Adenovirus-vector based vaccination strategies against SARS-CoV were employed early on after the SARS outbreak to demonstrate that vaccinated rhesus macaques developed virus-neutralizing antibody responses against fragment S1 of the S protein and T cell responses against the nucleocapsid (Gao et al., 2003). More recently, See et al. (2006) demonstrated that vaccination of C57B/L6 mice with adenovirus type 5-expressing S and nucleocapsid administered intranasally, but not intramuscularly, significantly limited SARS-CoV replication in the lungs.

The highly attenuated modified vaccinia virus Ankara (MVA) has been used to express the S glycoprotein of SARS-CoV in vaccination experiments using mouse, ferret, and rhesus monkey models (Bisht et al., 2004; Chen et al., 2005; Weingartl et al., 2004). Intranasal and intramuscular administration of MVA encoding the SARS-CoV S protein led to the induction of a humoral immune response in BALB/c mice, as well as reduced viral titers in the respiratory tract (Bisht et al., 2005).

Recombinant bovine-human parainfluenza virus type 3 vector (BHPIV3) is being developed as a live attenuated, intranasal pediatric vaccine against human parainfluenza virus type 3. Immunization of African green monkeys with a single dose of BHPIV3 expressing SARS-CoV S protein administered via the respiratory tract induced the production of SARS-CoV neutralizing antibodies (Bukreyev et al., 2004). A recombinant BHPIV3 expressing SARS-CoV structural protein (S, M, and N) individually or in combination has been evaluated for immunogenicity and protective efficacy in hamsters (Buchholz et al., 2004). In the absence of S protein, expression of M, N, or E did not induce a detectable serum SARS-CoV-neutralizing antibody response and no protection against SARS-CoV challenge in the respiratory tract, whereas the vectors expressing the S protein induced neutralizing antibody responses and protection.

Recombinant rabies virus expressing the S protein of SARS-CoV induced a neutralizing antibody response in mice (Faber et al., 2005). Similarly, an attenuated vesicular stomatitis virus vector that encodes the SARS-CoV S protein may be used to induce neutralizing antibody responses (Kapadia et al., 2005). Mice vaccinated with recombinant vesicular stomatitis virus expressing S protein developed SARS-CoV-neutralizing antibody and were able to control a challenge with SARS-CoV performed at either 1 month or 4 months after a single vaccination. In addition, by passive antibody transfer experiments these authors demonstrated that the antibody response induced by the vaccine was sufficient to control SARS-CoV infection.

The efficacy of these vectors was further demonstrated in studies using aged mice. In aged mice, vaccinated with recombinant vesicular stomatitis virus expressing S protein, antibody titers induced were sufficient to protect them against subsequent challenge with SARS-CoV (Vogel et al., 2007).

African green monkeys immunized via the respiratory tract with two doses of a recombinant Newcastle disease virus encoding the S protein developed a relatively high titer of SARS-CoV neutralizing antibodies and upon challenge demonstrated a 1000-fold reduction in pulmonary SARS-CoV titer compared with control animals (DiNapoli et al., 2007).

Finally, Venezuelan equine encephalitis virus based vaccines have been tested extensively in young and aged mice. Most importantly, different recombinant SARS-CoV bearing epidemic and zoonotic S protein variants were used to challenge the vaccinated mice. Venezuelan equine encephalitis virus replicon particles expressing the 2003 epidemic Urbani SARS-CoV strain S glycoprotein but not particles containing the nucleocapsid protein from the same strain provided complete short- and long-term protection against homologous strain challenge in young and senescent mice (Deming et al., 2006). Although the S protein encoding vaccine provided complete short-term protection against heterologous (strain GD03) challenge in young mice, only limited protection was seen in vaccinated senescent animals. Interestingly, nucleocapsid-encoding vaccines not only failed to protect from homologous or heterologous challenge but also resulted in enhanced immunopathology with eosinophilic infiltrates within the lungs of SARS-CoV-challenged mice (Deming et al., 2006).

BASIC SCIENCE AND RATIONALE OF NEW GENERATION VACCINES

A new generation of vaccines may be obtained from manipulating the full-length infectious cDNA clone of SARS-CoV. One approach would be to delete the ORFs 3a, 3b, 6, 7a, 7b, 8a, 8b, or 9b similar to other coronavirus mutants generated previously; some mouse hepatitis or feline infectious peritonitis deletion viruses replicate to the same extent as wild-type viruses in vitro but are severely attenuated in vivo making them potential vaccine candidates. However, SARS-CoV deletion mutants lacking ORFs 3a, 3b, 6, 7a, or 7b, grew similar to that of the parental wild-type virus in the mouse model (Yount et al., 2005). On the other hand, a recombinant SARS-CoV that lacks the E gene was attenuated both in vitro and in vivo (DeDiego et al., 2007). Viable recombinant virus with the E gene deleted was recovered in Vero cells with a titer around 10^6 pfu/ml but titers in the respiratory tract of hamsters were 100–1000-fold reduced compared to wild-type SARS-CoV replication, suggesting that this mutant is attenuated. Multiplication of these viruses in packaging cell lines would provide the missing protein in trans and would make a promising SARS-CoV vaccine candidate that has the E gene deleted.

Live attenuated virus vaccines may revert to wild-type and recombine with other circulating human or

zoonotic coronaviruses. In order to prevent this, it has been proposed to delete an essential gene, located in a position distant from gene E, and the relocation of the deleted gene to the position previously occupied by gene E (Enjuanes et al., 2008). A potential recombination leading to the rescue of gene E would lead to the loss of the essential gene. Alternatively, the transcriptional regulatory sequences (TRS) of a vaccine virus could be genetically manipulated to a sequence incompatible with the TRS of any known circulating coronavirus as described by Yount et al. (2006). This virus could be further modified by building attenuating mutations on the genetic backbone of the recombination resistant TRS rewired virus either for use as a safe high titer seed stock for making killed vaccines or as a live virus vaccine. One such attenuating mutation could be targeted to the nonstructural protein 1. Recombinant Mouse Hepatitis Virus (MHV) encoding a deletion in the nsp1-coding sequence grew normally in tissue culture but was severely attenuated in vivo (Züst et al., 2007). Low doses of nsp1 mutant MHV elicited potent cytotoxic T cell responses and protected mice against homologous and heterologous virus challenge. This attenuation strategy provides a new paradigm for the development of highly efficient coronavirus vaccines.

PRECLINICAL DEVELOPMENT, INCLUDING RELEVANT ANIMAL MODELS

Although several types of vectored vaccines have been developed, several companies favored the classical approach using inactivated whole virus to develop a vaccine to be used for preclinical testing (see Chapter 11). Methods in place for the production of available vaccines could be easily used using well-established technologies. In the preclinical development stage, it is preferable that different animal species are used to evaluate the safety and efficacy of candidate vaccines.

Overall, a wide range of animal species, including rodents (mice and hamsters), carnivores (ferrets and cats), and nonhuman primates (cynomolgus and rhesus macaques, common marmosets, and African green monkeys) can be experimentally infected with SARS-CoV (Subbarao et al., 2004; Roberts et al., 2005b; Martina et al., 2003; Kuiken et al., 2003; McAuliffe et al., 2004; Haagmans and Osterhaus, 2006). Most species show no clinical signs of disease, although the virus replicates efficiently in respiratory tissues. Aged mice and ferrets on the other hand, show signs of clinical disease, albeit in the absence of the typical lung lesions seen in humans with SARS (Roberts et al., 2005a). In contrast, inoculation of SARS-CoV in the respiratory tract of cynomolgus macaques causes infection of bronchial epithelial cells and type-1 pneumocytes 1–4 days postinfection, followed by extensive type-2 pneumocyte hyperplasia in the lungs at 4–6 days postinfection (Kuiken et al., 2003; Haagmans and Osterhaus, 2006). The lesions, consisting of multiple foci of acute diffuse alveolar damage and characterized by flooding of alveoli with protein-rich edema fluid mixed with variable numbers of neutrophils, are quite similar to those observed in humans in the acute stages of SARS.

Remarkably, vaccine candidates tested in ferrets showed reduced efficacy. Vaccination with MVA encoding the S protein induced only moderate antibody responses and consequently did not protect against intranasal SARS-CoV infection and even resulted in an inflammatory response in the livers of the vaccinated ferrets (Weingartl et al., 2004). Whether these aberrant responses resulted from immunopathological mechanisms, like antibody-dependent enhancement of infection, or represented recall responses to viral antigen in the liver is not clear at the moment but deserves further investigation. In addition, limited protection from SARS-CoV challenge was observed in ferrets vaccinated with inactivated whole virus (Darnell et al., 2007). Two out of four ferrets showed little or no neutralizing antibody even after the second immunization and none of the vaccinated ferrets were able to reduce virus excretion at day 2 after challenge but subsequently cleared the virus more rapidly compared to control animals. Adenovirus-based vaccines tested in ferrets seemed more powerful as they protected the lower respiratory tract efficiently but had less effect on virus excretion in the upper respiratory tract (Kobinger et al., 2007).

CLINICAL TRIALS

Five years after the first SARS outbreak a range of candidate vaccines have been developed. Early in 2006 some companies in China and the US initiated phase 1 trials. The first clinical trial has been initiated by a Chinese company, Sinovac Biotech of Beijing in collaboration with the Chinese academy of Medical Sciences using an inactivated whole virus vaccine. To evaluate the safety and immunogenicity of this vaccine, 36 subjects received two doses of vaccine or placebo control. On day 42, all individuals showed seroconversion and peak titers of neutralizing antibodies were reached 2 weeks after the second vaccination followed

by a significant decline 4 weeks later (Lin et al., 2007). Several other candidate SARS vaccines are at various stages of preclinical and clinical development.

POSTEXPOSURE IMMUNOPROPHYLAXIS

In SARS patients who recover, high levels of neutralizing antibody responses are observed, suggesting that antibody responses play a role in determining the ultimate disease outcome of SARS-CoV-infected patients (Zhang et al., 2006). Although attempts have been made to test the efficacy of serum preparations from seroconvalescent SARS patients in the acute phase of SARS, no conclusive evidence has been obtained regarding their efficacy. In mice, on the other hand, SARS-CoV infection is efficiently controlled upon passive transfer of convalescent immunoglobulines (Subbarao et al., 2004). The concept that antibodies protect against SARS has been further explored through the generation of human monoclonal antibodies against SARS-CoV. Prophylactic administration of a human monoclonal antibody reduced replication of SARS-CoV in the lungs of infected ferrets by 1000-fold, completely prevented the development of SARS-CoV-induced macroscopic lung pathology, and abolished shedding of virus in pharyngeal secretions (Ter Meulen et al., 2004). In subsequent studies, several other monoclonal antibodies were evaluated for their efficacy in mouse and hamster models (Sui et al., 2005; Traggiai et al., 2004).

PROSPECTS FOR THE FUTURE

The importance of assessing immunogenicity of candidate SARS-CoV vaccines using virus neutralization assays is well acknowledged, but the variety of these tests in use is a significant problem since there is at this time no consensus on the most sensitive, specific, and reproducible assay system. To compare data from each of the candidate vaccines requires international standardization of the immunological assays and the availability of an antibody standard used for the evaluation of these vaccines. To test cross reactivity of antibodies generated by vaccination, murine leukemia virus was used to generate infectious particles containing different S proteins (Giroglou et al., 2004).

Enhanced disease and mortality have been observed in kittens immunized against or infected with a type I coronavirus, feline infectious peritonitis virus (FIPV), when subsequently exposed to FIPV infection (Weiss and Scott, 1981). Macrophages are able to take up feline coronavirus-antibody complexes more efficiently causing the virus to replicate to higher titers. Interestingly, one study also demonstrated that antibodies against human SARS-CoV isolates enhance entry of pseudo-typed viruses expressing the civet cat SARS-like CoV S protein into cells, but not replication (Yang et al., 2005). To date, there is no evidence for enhanced replication following SARS-CoV challenge in previously immunized animals.

One other problem which may arise after vaccination with whole inactivated virus when absorbed with certain adjuvants such as alum, could relate to the induction of skewed Th2 recall responses similar to what has been observed in children vaccinated with inactivated respiratory syncytial and measles virus vaccines.

Although much effort has been focused on developing a SARS vaccine, the commercial viability of developing a vaccine for SARS-CoV will ultimately depend on whether the virus re-emerges in the near future. It is questionable whether possible future outbreaks will cause major outbreaks but vaccines, antivirals, or passive immunization would be relevant in the context of protecting high-risk individuals such as laboratory and health-care workers.

KEY ISSUES

- Five years after the first SARS outbreak, several candidate SARS-CoV vaccines are at various stages of preclinical and clinical development.
- Based on the observation that SARS-CoV infection is efficiently controlled upon passive transfer of antibodies directed against the S protein of SARS-CoV, vaccines encoding this protein have been developed.
- Animals immunized with diverse vaccines containing the S protein or S protein gene developed SARS-CoV-neutralizing antibodies and were protected against SARS-CoV challenge.
- Future challenges for the development of SARS-CoV vaccines are linked to the potential re-emergence of this virus. Vaccines able to induce highly cross-reactive antibodies which efficiently protect the gastrointestinal and respiratory tract are needed. Given the fact that in the previous outbreak mainly elderly humans succumbed to the infection, special attention should be given to protect specifically these individuals.

OUTLINE

ABSTRACT

Throughout history mankind has been ravaged by smallpox, a devastating disease which touched every corner of the earth and was capable of destroying entire civilizations. Through repeated epidemics and pandemics smallpox altered the course of history and is thought to have killed more people than any other infectious disease. Although attempts to control and mitigate the disease had been practiced for thousands of years, it still took nearly two centuries after Jenner's initial experiments with cowpox and vaccination before smallpox was brought under control. The eventual eradication of smallpox in 1980 is undoubtedly one of mankind's greatest medical

achievements. It is a sad commentary on human nature that, only a few decades after this dreadful scourge was eradicated, smallpox is once again a subject of international concern, due to its potential as a biological weapon. Smallpox has been used as a biological weapon in the past and history has clearly and repeatedly shown that whether intentional or not, outbreaks of this disease in a susceptible population are devastating. Given the morbidity and mortality of this disease it is not surprising that the early part of the 21st century has seen millions of dollars being spent on preparedness, prevention, and therapeutic measures to combat the smallpox threat.

INTRODUCTION

Smallpox, a deadly disease with telltale clinical symptoms and signs, has plagued mankind for millennia. Before its eradication it was endemic (with the exception of Australia) throughout the world and claimed hundreds of millions of lives (Table 37.1). In the last century alone, it is estimated to have killed 500 million people (Fenner, 1988). It has wiped out entire civilizations and altered the course of empires and yet its origin remains obscure (Dixon, 1962; Hopkins, 1983; Hays, 2005).

Smallpox has been eradicated world-wide and variola-virus is currently found only in secure repositories in the US and Russia.

This chapter deals with not only the history of the disease and the organism that causes it, but will also focus on the vaccines and other strategies used to control the disease. This is especially important in the context of being the only infectious disease which has been successfully eradicated, and yet remains capable of inordinate morbidity, mortality, and societal disruption. This chapter will also discuss current issues as well as future prospects concerning smallpox and related poxviruses.

TABLE 37.1 Smallpox epidemics throughout history

Year	Location	Details
BC		
1000–2000	Egypt	Smallpox signs found in several Egyptian mummies
1350	Egypt	Epidemic among the Hittites thought to be smallpox
568	Mecca	Ethiopian army suffer outbreak during the "Elephant War"
430	Athens	Plague of Athens likely caused by smallpox
395	Sicily	Plague among Carthaginian army thought to be smallpox
165	Rome	Antonine Plague thought to be caused by smallpox
AD		
710–731	Europe	Islamic armies bring smallpox to Spain, Portugal, France
735	Japan	Epidemic in Nara kills thousands
1241	Iceland	First epidemic in Iceland
1368	Siam	Smallpox outbreak kills the king of Burma
1507	Caribbean	Epidemic wipes out entire tribes on Hispaniola
1519	Mexico	Cortez brings smallpox to Aztecs, death toll ~3.5 million
1524	Peru	Smallpox follows Pizarro to the Incan empire
1617–1619	Massachusetts	Severe outbreak eliminates many of the indigenous tribes
1623	Russia	First recorded occurrences of smallpox in Russia
1636–1697	Massachusetts	Boston suffers major epidemics about once every 10 years
1702	Canada	A severe outbreak in Quebec kills 1/4 of the inhabitants
1713	South Africa	Epidemic in Cape Town started by contaminated clothing
1763	Ottawa	Deliberate infection of Indians with smallpox by the British
1776	Quebec	An epidemic wipes out a portion of the Continental Army
1789	Australia	Severe outbreak among aborigines
1795	Germany	Epidemic in Berlin caused by variolation
1804–1810	Russia	Severe epidemics kill ~1 million Russians
1824	Europe	European smallpox pandemic
1868–1884	India	Five major outbreaks in India kill over 2.5 million people
1870	Europe	Pandemic during Franco-Prussian war kills over 500,000
1896/1904	US/Africa	Variola minor occurs in Florida and South Africa

EARLY HISTORY

The causative agent of the disease, variola major (Latin for mottled (*varius*) or pimple (*varus*)), is likely to have evolved by adaptation to humans from a virus which infected animals who lived in close proximity to the human populations. It appears to have developed in concert with civilizations reaching sufficient density to support a disease which only infected humans and required face-to-face contact for reliable transmission. Well-settled and thriving agricultural societies provided the close proximity and numbers of susceptible victims necessary for smallpox to establish itself. It is thought that smallpox originated between 5000 and 10,000 BC in the Nile river valley and Fertile Crescent areas of the Near East (Fenner, 1988). Perhaps the best early evidence of smallpox comes from ancient mummies, such as that of Rhamses V (died 1157 BC) shown in Fig. 37.1. These mummies bear scars characteristic of smallpox (Fenner, 1988; Dixon, 1962). From this base, the disease spread to Asia, Europe, and northern Africa. The earliest definitive mention of smallpox in India is by the physician Vagbhata in the 7th century AD and in China there are unmistakable descriptions of smallpox by the physician Ko Hung in 340 AD (Dixon, 1962). Europe likely had intermittent importations of smallpox throughout the early part of the first millennium AD until its population reached sufficient size to support endemic disease. Smallpox was periodically reintroduced to Europe by Muslim Armies in the 6th and 7th centuries and by knights returning from the Crusades of the 11th and 12th centuries (Dixon, 1962).

In Africa, smallpox spread across the Mediterranean coast with the expansion of Islam in the 8th century. Exploration and trade brought the disease to the coastal towns and then into the interior of Africa where it remained endemic until the 1970s.

The Western hemisphere remained free of smallpox until the European explorations and conquests in the 15th–18th centuries (Patterson and Runge, 2002; Eyler, 2003). In 1519 Cortez's army brought the disease into central Mexico where it killed millions of Aztec Indians. Less than a decade later, smallpox infected the Incan empire 2000 miles to the south, killing hundreds of thousands of individuals. Early settlers

FIGURE 37.1 The mummified head of Rhamses V with typical scarring from variola infection.

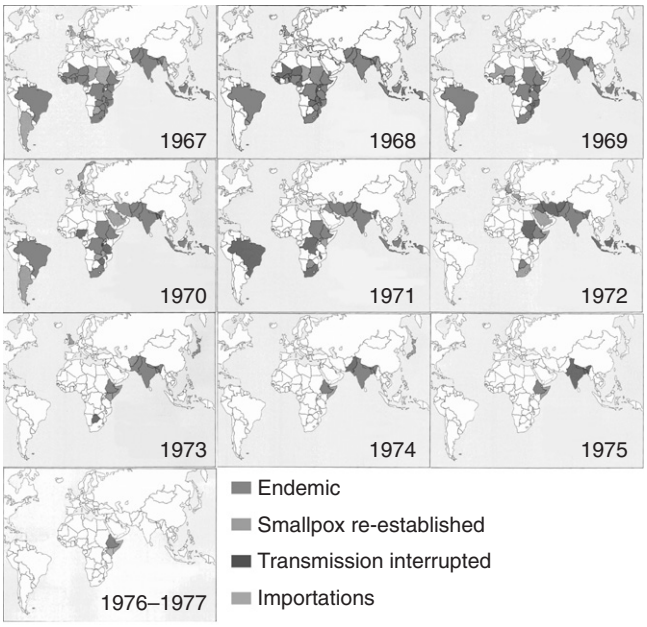

FIGURE 37.2 Worldwide smallpox prevalence during the Intensified Eradication Effort (1967–1977). Reproduced with permission from Fenner et al. (1980).

on the eastern coast of North America brought smallpox into contact with the local Indian tribes with the same tragic consequences.

In the 17th and 18th centuries, smallpox was endemic throughout the world with periodic deadly epidemics. Smallpox is estimated to have killed 400,000 people per year and to have caused more than one-third of all blindness in Europe during this period (Fenner, 1988). Smallpox never became established in Australia but it did cause major epidemics with massive numbers of casualties, mainly among the aborigines.

In the 1890s a milder version of smallpox was identified in South Africa and at about the same time in the southeastern USA. This disease, called variola minor, amaas, or alastrim, was considerably less severe than variola major, with a mortality rate of ~1% (Fenner, 1988; Shchelkunov et al., 2000; Bray and Buller, 2004). By the 1930s alastrim had replaced variola major in the US, Canada, the United Kingdom, and parts of Central America (Bray and Buller, 2004) while variola major continued to circulate in Asia and Africa.

ERADICATION

In spite of having achieved local control, smallpox remained a significant public health issue worldwide, even in countries without endemic cases. The World Health Organization (WHO) officially adopted the smallpox eradication program in 1959, but little progress was made until the Intensified Smallpox Eradication Program began in 1967. At this time smallpox was endemic in 31 countries in South America, Africa, India, and Asia. The eradication program consisted of a twofold strategy (Behbehani, 1980; Fenner, 1988). (1) Massive vaccination campaigns in areas with endemic smallpox and in the neighboring countries were quickly implemented. It was hoped that by achieving 80% vaccine coverage, sufficient herd immunity would be obtained to disrupt transmission and halt the spread of the disease. (2) Sophisticated disease surveillance systems were developed to allow early detection and containment of outbreaks. Once an outbreak was detected, all known or possible contacts with infected victims were vaccinated (Eichner, 2003).

Figure 37.2 tracks the worldwide reduction in endemic smallpox areas from 1967 to 1977. Within 3 years South America and most of Africa had been cleared of the disease. By 1975 clearance of smallpox from Asia occurred as well as the end of variola major infections. Two years later, on October 26, 1977, the last natural case of smallpox occurred in Somalia. The victim was Ali Maow Maalin a hospital worker who, ironically, was afraid to receive the vaccine.

On May 8, 1980 the 33rd World Health Assembly declared that smallpox had been eradicated from the world. During the eradication effort the WHO had spent approximately $112 million and enlisted hundreds of workers, while the international community

at large had donated vast amounts of vaccine, supplies, cash, and volunteer work. It is estimated that eradication of smallpox directly saved over $1 billion in global health care costs annually (Behbehani, 1983). While it is hard to put a price on a single case of a disease, a Pakistani traveler introduced smallpox to Great Britain in 1961. The resulting epidemic involved 67 smallpox cases, the vaccination of 5.5 million people, and cost $3.6 million (Behbehani, 1983).

During the Intensified Eradication Program, it was also decided that all samples of the virus would be destroyed or sent to one of the two approved repositories, the Centers for Disease Control and Prevention in Atlanta, GA, and the Research Institute of Viral Preparations in Moscow (virus specimens were subsequently moved to the Russian State Research Center of Virology and Biotechnology in Koltsovo) (Alibek, 2004). A fatal laboratory-acquired case of smallpox occurred in 1978 in Birmingham, England and no doubt spurred many of the remaining smallpox laboratories to destroy or transfer their samples to the two official repositories.

For the next 30 years smallpox was no longer a public health problem and the only attention paid to the disease were the efforts to comply with the WHO recommendations regarding vaccine stockpiles and the limited research on variola conducted at the two reference laboratories. This research initially focused on gene sequencing and later moved into developing animal models and diagnostic and detection assays (Massung et al., 1992, 1994; Antoine et al., 1998; Shchelkunov et al., 2000, 2001; Esposito et al., 2006; Li et al., 2006, 2007). Most basic research into variola virus and smallpox disease stopped, although work with other poxviruses, particularly vaccinia virus continued. In fact, shortly after the eradication, vaccinia began to show great promise as a vector for other vaccines.

There remains considerable debate over the fate of the last remaining variola specimens (Roizman et al., 1994; Henderson and Fenner, 2001; Breman et al., 2003) which are slated to be destroyed in 2011 (WHO, 2006). Arguments both for and against the destruction of the variola stocks center on whether or not continued research and testing is necessary in order to prepare for possible future biological attacks or outbreaks of emerging poxviruses.

POXVIRUS BIOLOGY

The etiologic agents responsible for smallpox are variola major and variola minor. Both are members of the Poxviridae family which are large, complex, DNA viruses that replicate in the cytoplasm of the host cell (Fields et al., 1996). Two subfamilies exist: Entomopoxvirinae, which infect insects and Chordopoxvirinae, which infect vertebrate animals (Table 37.2).

TABLE 37.2 Poxvirus families and representative species

Genus	Example	Reservoir	Zoonotic hosts
Avipoxvirus	Fowlpox virus	Birds, arthropods	
Capripoxvirus	Goatpox	Ungulates, arthropods	
	Lumpy skin disease virus	Ungulates, arthropods	
Leporipoxvirus	Myxoma	Rabbits, squirrels	
	Shope fibroma virus	Rabbits, squirrels	
Molluscipoxvirus	Molluscum contagiosum	Humans	
Orthopoxvirus	Buffalopox virus	Unknown	Buffaloes, humans
	Camelpox virus	Camels	Camels, humans
	Cowpox virus	Rodents	Wide host range
	Ectromelia virus	Rodents	
	Monkeypox virus	Rodents, squirrels	Monkeys, humans
	Uasin Gishu disease virus	Unknown	Horses
	Vaccinia virus	Unknown	Wide host range
	Variola virus	Humans	None
Parapoxvirus	Bovine papular stomatitis virus	Cattle	Humans
	Orf	Ungulates	Humans, cats
Suipoxvirus	Swinepox virus	Swine	
Tanapoxvirus	Yaba monkey tumor virus	Monkeys	Humans
Yatapoxvirus	Tanapox virus	Rodents, insects	Humans, monkeys

As shown in Fig. 37.3, Poxviruses have linear, double-stranded, DNA genomes 130–300 kb pairs in size (Fields et al., 1996). At each end of the genome is a hairpin loop and inverted terminal repeats which covalently join the two strands into one continuous chain (Gubser et al., 2004). Orthopoxvirus genomes contain 200–250 open reading frames (ORF), with most of the essential conserved genes located in the central region of the genome (Wittek, 1982; McCraith et al., 2000; Upton et al., 2003; Randall et al., 2004). An excellent

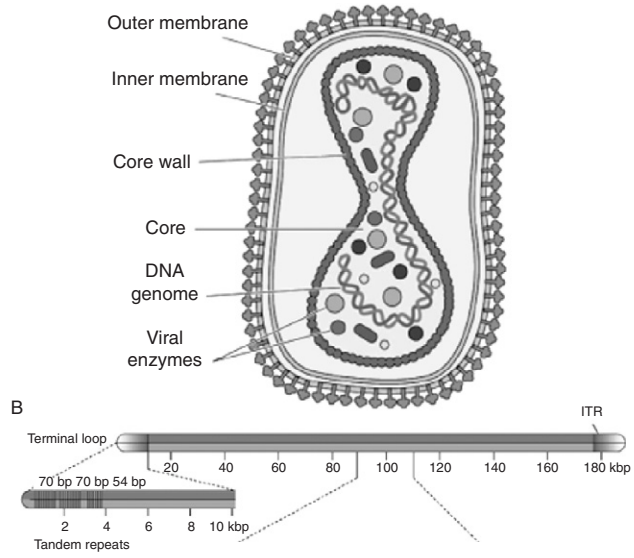

FIGURE 37.3 Diagram of (A) poxvirus virion and (B) genome structure. Reproduced with permission from Harrison et al. (2004).

online database with regularly updated genomic and proteomic information can be found at http://www.poxvirus.org.

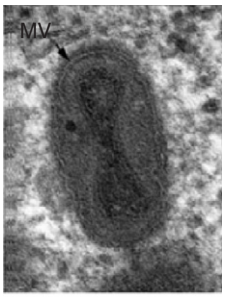
Figure 37.3 also shows the brick shaped, or rounded, rectangular virions about 350 × 270 nm. The outer lipid membrane is studded with protein tubule structures as well as cellular antigens (Krauss et al., 2002). Enclosed within this membrane is a dumbbell shaped nucleoprotein core and two lateral bodies. This virion, consisting of the core, lateral bodies, and membrane is fully infectious. Many strains of poxviruses can exist in other forms containing additional lipid bilayers (Fig. 37.4) which likely play distinct roles in viral spreading within the host (Buller and Palumbo, 1991; Smith et al., 2002; McFadden, 2005b; Moss, 2006).

The viral life cycle is shown in Fig. 37.5 and can be divided into several discrete stages. The timeframe for one complete viral life cycle (Entry→Assembly→Release of progeny virus) depends heavily on the viral strain and the type of host cell infected. For vaccinia virus, maximal yields are obtained 12–24 h after infection, although progeny virus can be seen in just 4–6 h postinfection (Buller and Palumbo, 1991).

Like most viruses poxviruses are able to quickly shutdown and/or control critical cellular processes such as DNA translation and transcription, protein synthesis, cell cycle, apoptosis, intracellular transport, and cytoskeletal machinery. Poxviruses also possess a large number of genes aimed at subverting a wide variety of key host defense mechanisms (Palumbo et al., 1994; Alcami et al., 1999, 2000; Bowie et al., 2000; Moss and Shisler, 2001; Seet et al., 2001; Shisler

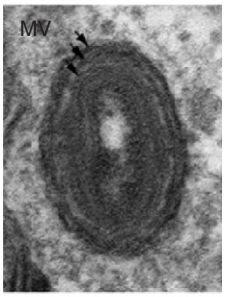
Mature Virion (MV)
Previously called the Intracellular mature virion (IMV)

Description: Consists of the DNA-Protein core and associated enzymes surrounded by a lipid membrane with over 12 embedded viral proteins. It is the most abundant infectious form.



Wrapped virion (WV)
Previously called the Intracellular enveloped virion (IEV)

Description: This form of the virus is identical to the MV with two additional membranes.



Extracellular virion (EV)
Previously called the Extracellular enveloped virion (EEV) and the cell associated virion (CEV)

Description: The MV surrounded by one additional membrane. It can be both cell associated or extracellular. The cell associated form is responsible for cell-to-cell spread by actin tails.

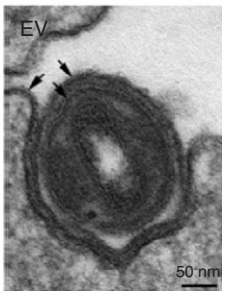


FIGURE 37.4 Infectious forms of poxviruses. Used with permission from Moss (2006).

and Moss, 2001; Fruh et al., 2002; Katze et al., 2002; Symons et al., 2002; Dunlop et al., 2003; Reading et al., 2003; Seet et al., 2003a, 2003b; Li et al., 2004a, 2005; McFadden, 2004; Haga and Bowie, 2005; Stack et al., 2005; Alejo et al., 2006; Taylor and Barry, 2006; Webb et al., 2006; Humrich et al., 2007; Nuara et al., 2007).

Both vaccinia and variola viruses are stable for several days at room temperature and for months at 4°C, however they are inactivated relatively quickly at temperatures above 50°C (Harper, 1961). Viral suspensions in most liquids are more labile than dried virus such as scabs or freeze-dried vaccine (Cardone, 1953, 1956; Ferrier et al., 2004), in fact variola major has been recovered from scabs kept in a laboratory cupboard for over 13 years. Both variola and vaccinia are sensitive to ultraviolet light, and most common cleaning and disinfecting agents such as alcohols, bleach, ordinary

detergents, and quaternary ammonium compounds (Tanabe and Hotta, 1976; Ferrier et al., 2004).

THE IMMUNE RESPONSE TO POXVIRUSES

Smallpox was eradicated well before the advent of modern immunologic techniques for assaying cell-mediated immunity; consequently much of what we know about the immune response to variola major is confined to humoral immunity (Fenner, 1988). In ordinary cases of smallpox antibody titers rose 6–10 days after illness (approximately 3 weeks after infection) and persisted for several years following infection. The magnitude and speed with which the humoral immune response developed correlated with both disease severity and survival. Infection left survivors with lifelong immunity. Prominent physicians in the 19th and 20th centuries estimated that only 1 in 1000 subjects would suffer a second attack, and field reports from the Intensified Eradication Effort revealed that rarely would one see a case of variola major in a pockmarked person (Dixon, 1962; Fenner, 1988).

Immune responses to vaccination show a slightly different picture. Vaccination produces robust antibody responses far more quickly than infection (~10 days after immunization) and is likely the reason that early postexposure vaccination reduced or even eliminated the clinical symptoms of smallpox. Historically, protection from disease was thought to wane 3–10 years after vaccination (Behbehani, 1983) and the CDC recommends revaccination every 10 years for those working with vaccinia and every 3 years for those working with pathogenic Orthopoxviruses such as monkeypox.

More recent work shows clear and distinct roles for both humoral and cellular immune responses as well as innate effector mechanisms such as $\gamma\delta$ T cells, NK cells, complement, and defensins (Haga and Bowie, 2005; Stack et al., 2005). Like antibody levels both CD4 and CD8T cell responses also rise dramatically in the few weeks following vaccination. CD8 responses steadily decline with a half-life of 8–15 years, while antibodies and CD4 responses persist for decades (Hammarlund et al., 2003; Kan et al., 2007; Sivapalasingam et al., 2007) but it is not known how much protection against disease this residual immunity may provide (Nishiura and Eichner, 2006).

Subjects with T or B cell deficiencies are at increased risk of serious adverse events following immunization with vaccinia virus, and may have had higher rates of severe smallpox disease (Fulginiti, 2003; Fulginiti et al., 2003b; Wollenberg and Engler, 2004). In some animal studies, the adoptive transfer of immune serum or virus-specific T cells confers full protection against subsequent vaccinia challenge indicating that either arm of the immune response is sufficient (Ramirez et al., 2002; Snyder et al., 2004; Chaudhri et al., 2006), whereas other studies show that while humoral responses provide protection against disease, $CD8^+$ T cell responses prolong survival but do not offer protection against death (Edghill-Smith et al., 2005; Fang and Sigal, 2005). The emerging picture is that during primary infection cellular immune responses function early to limit viral spreading while antibody responses function at later time points to clear the pathogen and provide protection from subsequent reinfection (Panchanathan et al., 2006).

Following the events of September 11 and renewed interest in smallpox, a number of researchers focused

on the identification of immunogenic proteins, peptides, and epitopes from vaccinia. The first CD8+ T cell epitopes were described in 2003, and a few years later, vaccinia-specific MHC I epitopes numbered in the hundreds (Drexler et al., 2003; Terajima et al., 2003, 2006; Snyder et al., 2004; Dong and Denny, 2006; Moutaftsi et al., 2006; Terajima and Ennis, 2006; Kennedy and Poland, 2007). MHC II restricted epitopes are also beginning to be identified (Tang et al., 2006; Jing et al., 2007; Mitra-Kaushik et al., 2007; Moutaftsi et al., 2007). The identification of numerous B cell epitopes has also been accomplished, and unlike T cells, B cells preferentially target structural and membrane proteins (Bell et al., 2004; Davies et al., 2005a, 2005b; Jones-Trower et al., 2005).

EPIDEMIOLOGY

Smallpox is a human disease for which there are no known animal or insect vectors (Fenner, 1988). In spite of the fact that viral particles are relatively resistant to environmental conditions, transmission almost always occurs via close physical contact with an infected subject who has the characteristic rash or with infected bedding or clothing (Breman and Henderson, 2002). Although rare, airborne transmission did occur under certain conditions (Meiklejohn et al., 1961; Downie et al., 1965; Wehrle et al., 1970). Outbreaks spread slowly and were easy to trace given that: (1) transmission required prolonged, close physical contact, (2) the incubation period was long, and (3) patients were infectious only when bedridden with a highly visible rash. Infection conferred lifelong immunity to the survivors, and there was no evidence of latent infection, recurrences, or a carrier state. Subclinical infections occurred but were rare and confined to vaccinated individuals. These subjects rarely shed virus and had little impact on disease transmission (Fenner, 1988).

Historical accounts indicate that there were two separate epidemiological patterns to the disease. When smallpox was introduced into a naive population it spread rapidly, infecting nearly every susceptible individual. These outbreaks affected all age groups and had very high mortality rates. The introduction of the disease to the Native Americans and Australian aborigines are the best documented examples of smallpox's destructive power, however there is no reason to believe that it was any less deadly among the naive populations in China, India, or Europe hundreds or thousands of years earlier.

In geographical areas with endemic smallpox the disease continually circulated through the community with seasonal outbreaks mostly in winter and spring when conditions (i.e., temperature and humidity) allowed the virus to persist longer in the environment. These larger outbreaks would occur when sufficient numbers of uninfected people accumulated in a town or city to allow a full-fledged epidemic. Most of the adults in the affected region were survivors of previous attacks and were immune to the disease, consequently disease outbreaks in these areas primarily affected children.

SMALLPOX AS A BIOLOGICAL WEAPON

Smallpox has a long history of use as a biological weapon, with most of the documented incidents coming from the Western Hemisphere (Hopkins, 1983; Bhalla and Warheit, 2004; Frischknecht, 2003) (Table 37.3). After the eradication it was thought that the likelihood of smallpox being intentionally reintroduced as a biological weapon was remote. That viewpoint changed in the 21st century (Henderson et al., 1999) after details came to light about the extensive nature of the Soviet and Iraqi biological weapons programs (Alibek, 2004; Roffey et al., 2002). The anthrax attacks in the US in 2001, as well as the large number of conventional terrorist attacks shortly thereafter

TABLE 37.3 Historical uses of smallpox as a biological weapon

Date	Description
1500s	Spanish conquistadors give Native Americans contaminated clothing. Resulting outbreaks contribute to the downfall of the Aztec and Inca empires.
1760s	French and Indian war—The British army gives Indians tribes loyal to the French contaminated blankets. Outbreaks estimated to have ~50% mortality.
1776	Revolutionary war—British send infected civilians out of Boston in hope of infecting continental Army. Washington institutes mandatory vaccination of soldiers.
1800s	Blankets from smallpox victims deliberately given to Native Americans causing widespread epidemics.
1860s	Civil War—Former Kentucky Governor sells contaminated clothing to Union troops.
1980s–?	The Soviet Union develops a bioweapons program which includes large quantities of smallpox. Iraqi biological weapons program attempts to develop camelpox as a biological weapon. International concern that other countries are also involved in biological weapons development and testing.

were grim reminders that individuals and groups were willing to use such weapons. The CDC created a categorized list of potential biological agents with variola listed as one of the most likely pathogens to be used as a biological weapon (Henderson et al., 1999; Bhalla and Warheit, 2004). Smallpox has several key features which make it an excellent choice for a biological weapon (Fig. 37.6) (Tegnell et al., 2002; Blendon et al., 2003; Mahy, 2003; Pennington, 2003; Whitley, 2003; Cleri et al., 2006).

- Deadly, disfiguring illness
- Extremely low infectious dose
- High mortality rate
- Contagious pathogen
- Long incubation time allows for the perpetrator to escape
- Would cause widespread panic and disruption
- Modern populations largely susceptible
- No effective treatment
- Insufficient vaccine to deal with large epidemics
- Odorless and tasteless, making it difficult to detect

FIGURE 37.6 Characteristics of smallpox which make it an ideal biological weapon.

CLINICAL DISEASE

The clinical course of the disease can be divided into several discrete phases (Fenner, 1988; Breman and Henderson, 2002) shown in Fig. 37.7. The average incubation period is 12–14 days (range: 7–17 days) during which time the subject is asymptomatic and noninfectious. This is followed by a prodromal phase accompanied by the abrupt onset of severe headache, backache, high fever (>40°C), prostration, and sometimes vomiting. Symptoms may last for 2–4 days. The rash begins with an enanthema involving the mouth and oropharynx followed a day later by small reddish macules which develop into papules over a period of 1–2 days. One to two days later the papules become vesicles 2–5 mm in size. The lesions initially occur on the face and extremities and gradually cover the entire body. Round, hard, fluid-filled pustules soon develop and over the next 5–8 days begin to crust over. All of the lesions typically progress with the same kinetics.

FIGURE 37.7 Smallpox disease progression and characteristics. Used with permission from Dr. David Heymann, World Health Organization and Breman and Henderson (2002).

Recovery occurs as the scabs fall off, leaving 65–80% of the victims with extensive scarring typically concentrated on the face (Fenner, 1988). Blindness from viral keratitis or secondary infection occurs in 1% of cases (Behbehani, 1983). Encephalitis is rare but can occur (1% of cases) (Dixon, 1962). Rarely, disease occurring in children can lead to arthritis due to infection and disruption of the growing bone and joint tissues (Fenner, 1988). Variola minor cases resemble mild cases of ordinary type smallpox while disease caused by variola major can be classified into five main types based on clinical severity (Table 37.4).

TABLE 37.4 Classification of smallpox

Designation	Symptoms	Mortality
Ordinary	Fever, backache, malaise, headache, delirium	~30%
	The extent of the rash can vary	
	Discrete pocks	<10%
	Semiconfluent	25–50%
	Confluent	50–75%
Less severe (far more common in vaccinated individuals)		
Modified type	Rash has discrete, smaller lesions which rapidly resolve	Rare
Variola sine eruptione	Asymptomatic or brief fever, influenza like symptoms; patients may or may not present with rash	0%
More severe (account for ~10% of all cases)		
Flat type	Lesions are flat, evolve slowly, and eventually coalesce; rash may be discrete or confluent	80% immune 99% naive
Hemorrhagic	Prolonged, severe prodrome; dusky rash, bleeding from mucosal membranes	97%
Variola minor		
Alastrim or amaas	Similar to ordinary type variola major but far more mild symptoms	1–2%

Adapted from: Fenner (1988), Breman and Henderson (2002), and Cleri et al. (2006).

The two milder forms are called modified type and variola sine eruptione and are more commonly seen in vaccinated individuals as they have preexisting immunity which lessens the severity of disease symptoms. Ten percent of the cases are much more severe: flat type or hemorrhagic smallpox. Death rates are extremely high for both of these classes of disease. In addition, victims of hemorrhagic smallpox act as "super-spreaders" of disease by virtue of the higher viral titers, prolonged prodrome, and profuse bleeding. It was noted early on that the extent and distribution of the lesions correlated with mortality. Patients with fewer discrete lesions were more likely to recover, while victims with dense or confluent lesions typically had a poor prognosis (Fenner, 1988; Breman and Henderson, 2002).

TREATMENT

There remains no effective treatment for smallpox. In the past, patients were typically isolated and then provided with supportive care such as intravenous (IV) fluids, antibiotics to reduce secondary infections, and medications for pain relief. If an outbreak were to occur today our options would be essentially unchanged.

Data from numerous outbreaks during the 20th century indicate that postexposure immunization can reduce the severity of symptoms. Immunization within 3–4 days of smallpox infection is thought to provide nearly complete protection from disease, while immunization later than this may provide partial protection and reduce the disease severity (Breman and Henderson, 2002; Massoudi et al., 2003; Mortimer, 2003a; Nishiura and Eichner, 2007). This is likely due to the long incubation period of variola virus which allows time for the crossprotective antivaccinia responses to develop. Consistent with this data, the CDC recommends vaccination within 3 days of exposure.

Historically, numerous drugs were tried and although initial reports of thiosemicarbazones and arabinoside derivatives showed therapeutic effects, further studies could not confirm these results and showed high levels of toxicity (Neyts and De Clercq, 2003; Sliva and Schnierle, 2007). Cidofovir, a nucleoside analog DNA polymerase inhibitor has shown antiviral activity in vitro and in animal models with several poxviruses (Smee et al., 2001b; De Clercq, 2002; De Clercq and Neyts, 2004; Neyts et al., 2004; Quenelle et al., 2004a; Knorr et al., 2006). Although it may be used to treat smallpox or vaccine complications under an investigational new drug application its utility is limited by its severe renal toxicity

(Bray and Roy, 2004). Several groups have focused on modifications of cidofovir which enhance its oral availability, activity against poxviruses, and reduced nephrotoxicity with promising results (Smee et al., 2001a; Bray et al., 2000; Buller et al., 2004; Painter and Hostetler, 2004; Quenelle et al., 2004b). Other drugs showing promising activity against poxviruses include: ribivirin, trifluridine, a variety of tetrapyrrole compounds (Chen-Collins et al., 2003), and small molecule inhibitors of essential viral enzymes (Byrd et al., 2004; McFadden, 2005a; Reeves et al., 2005; De Clercq, 2001) with limited homology to human enzymes (Smee and Sidwell, 2003; Yang et al., 2005; Sliva and Schnierle, 2007).

Vaccinia immune globulin (VIG) is concentrated gamma-globulin from pooled plasma of recently vaccinated individuals. It was initially developed in the 1950s to combat vaccine-related complications (Fenner, 1988; Bray, 2004). There is extensive literature attesting to its efficacy in treating disease and vaccine complications and while there are no controlled therapeutic trials, the United States and other countries have once again begun making and stockpiling VIG (Goldsmith et al., 2004; Hopkins and Lane, 2004; Hopkins et al., 2004).

Yet another area of exploration is the use of immunotherapeutics to combat smallpox infections (Atrasheuskaya et al., 2004; Liu et al., 2004; Law et al., 2005). There are a few reports indicating that combined vaccination and VIG administration is more effective than postexposure vaccination alone. One avenue of current research is to develop humanized monoclonal antibodies with similar or enhanced efficacy compared to VIG (Casadevall, 2002; Chen et al., 2006). Along a similar vein, one can envision the use of agents which block viral virulence factors, or molecules such as TNFα antagonists to reduce immunopathology, or even the use of adjuvants to redirect and shape a developing immune response to increase protective immunity while decreasing inflammation and its associated side effects (Ahmed et al., 2005; Staib et al., 2005).

In summary, there is currently no treatment for smallpox infection other than immediate postexposure vaccination and perhaps VIG. This picture is likely to change in the future, especially given the research impetus and the results in this field so far.

PATHOGENESIS

Much of our understanding of smallpox pathogenesis comes from studies using related poxviruses such as mousepox, rabbitpox, and monkeypox (Fenner et al., 1957; Marshall and Fenner, 1960, 2000; Wallace and Buller, 1985; Esteban and Buller, 2005; Levine et al., 2007). The virus enters the respiratory tract and rapidly enters the local lymph nodes. Within a few days, a brief, low-level viremia deposits the virus into the liver and spleen, where it grows to extremely high titers over the next 4–14 days (Breman and Henderson, 2002). A secondary viremia marks the beginning of the prodromal phase when large quantities of the virus enter the bloodstream and infects the mucous membranes of the mouth and pharynx followed by infection of the dermal layer of the skin. The characteristic lesions form on the mouth and tongue 24h before the rash appears on the skin. All of the lesions contain large quantities of virus (Fenner, 1988). The virus is also present in the urine, blood, and other body fluids as well as internal organs such as the liver, spleen, lymph nodes, kidneys, and bone marrow (Sarkar et al., 1973a, 1973b). Virus is present in respiratory secretions and can be found on clothing, linen, and bedding. Viral shedding is greatest during the first 10 days of the rash however patients remain infectious until all scabs and crusts are shed (Mitra et al., 1974; Sarkar et al., 1974; Breman and Henderson, 2002).

The immune response develops within a week of the first symptoms of disease and consists of both humoral and cellular responses. Survival depends on the ability of both arms of the immune system to curb viral replication and eliminate virally infected cells. These immune responses are a two-edged sword as deaths after infection were frequently due to immunopathology.

In addition to variola virus there are a number of other poxviruses which can cause human disease. These are shown in Table 37.5. Of particular concern for public health officials is monkeypox, which has been associated with sporadic outbreaks in Africa (Ligon, 2004; Levine et al., 2007), and a 2003 outbreak in the Midwestern United States (Kile et al., 2005) related to the unregulated importation of exotic pets. There are also recent reports from South America describing outbreaks of novel poxviruses in cattle with documented transmission to humans (Damaso et al., 2000; Schatzmayr et al., 2000; da Fonseca et al., 2002; de Souza Trindade et al., 2003; Nagasse-Sugahara et al., 2004) and an outbreak of buffalopox in India (Singh et al., 2006). While usually less severe than smallpox, these other poxviruses can spread from human-to-human and are considered important emerging zoonotic pathogens (Di Giulio and Eckburg, 2004; Jezek et al., 1986; Fine et al., 1988; Frey and Belshe, 2004; Fleischauer et al., 2005; Learned

TABLE 37.5 Poxviruses that infect humans and cause disease

Genus and species (disease)	Primary reservoir	Geographic region	Mode of transmission	Protection provided by vaccinia vaccination
Orthopoxvirus				
Cowpox	Rodents	Europe, Africa, central and northern Africa	Direct contact	Yes
Monkeypox	Rodents	Central and West Africa	Direct contact, respiratory droplets	Yes
Vaccinia	Unknown[a]		Direct contact	
Variola (smallpox)[b]	Humans	US, Russia	Direct contact, respiratory droplets	Yes
Yatapoxvirus				
Tanapox	Nonhuman primates	Kenya, Zaire	Direct contact	No
Yabapox	Nonhuman primates	Central Africa	Direct contact	No
Parapoxvirus				
Pseudocowpox (milker's nodules and paravaccinia)	Ungulates	Worldwide	Direct contact	No
Bovine papular stomatitis	Ungulates	US, Canada, Africa, Australia, New Zealand, Great Britain, Europe	Direct contact	No
Orf	Ungulates	North America, Europe, New Zealand	Direct contact	No
Sealpox	Seals	North Sea, Pacific Ocean, Atlantic	Direct contact	No
Molluscipoxvirus				
Molluscipox (molluscum contagiosum)	Humans	Worldwide	Direct contact	No

[a] Genetic analysis of vaccinia reveals it to be different from cowpox; its origin is unknown, but it may be an extinct horsepox virus.
[b] Smallpox was declared eradicated in 1980.

et al., 2005). Of further concern is camelpox, the closest genetic relative to variola virus (Afonso et al., 2002b), which was a component of the Iraqi biological weapons program (Zilinskas, 1997).

HISTORY OF THE SMALLPOX VACCINE

Variolation

Well before the development of microbiology and the germ theory the idea that physical separation from the ill would protect the healthy was independently developed and utilized by most civilizations (Dixon, 1962; Fenner, 1988). Separate huts or even villages were designated for those harboring infection and ships entering port cities were frequently quarantined.

China, India, and several Middle Eastern countries had developed a procedure to protect themselves from the effects of smallpox (Dixon, 1962; Behbehani, 1983; Fenner, 1988). In Asia, people who had undergone less severe disease provided infected scab material which was ground to a fine powder and inhaled through the nose by healthy individuals. This procedure was termed insufflation and resulted in a severe, generalized rash which resembled a mild case of smallpox. In Persia, a modification of this procedure was used whereby pus from a smallpox lesion was scraped into the skin of a healthy individual, who soon developed a severe local lesion frequently accompanied by satellite pustules. The cutaneous method of variolation was thought to be somewhat less severe than the inhalation method. Both practices were later called "variolation" to distinguish them from "vaccination" with cowpox virus and were characterized by a much less severe form of smallpox with mortality rates of about 1–2% in contrast to smallpox's 30% death rate. An unfortunate side effect of variolation was that the subjects were contagious, and could and did cause further outbreaks of smallpox. Variolation was practiced in Asia and the Middle East and was slowly brought to Europe by travelers to the Middle East. The main advocate of the practice was Lady Mary Wortley Montagu, who was introduced to the technique in Turkey (Dinc and Ulman, 2007) and helped to establish the practice of variolation in England (Behbehani, 1983).

Vaccination

Contrary to popular belief, the idea that cowpox (an orthopox virus related to variola) infection brought with it immunity to smallpox did not originate with Edward Jenner. Numerous reports describing this phenomenon have been found dating back to the 1760s, over 30 years before Jenner published his work. While practicing variolation in his country, Jenner noticed that he was unable to variolate many of his patients who had previously contracted cowpox. The potential to develop a safe and effective protective measure against smallpox held great appeal for him and he began investigating this phenomenon by inoculating his 10-month-old son and two neighborhood children with cowpox taken from the hands of his son's nurse. When he tried to variolate them some time later, both his son and the nurse were unable to be infected with smallpox. Over the next 10 years he carefully performed numerous additional experiments. The most famous of his subjects was James Phipps, who, at the age of 8, was inoculated with cowpox taken from an infected nursemaid, Sarah Nelmes on May 14, 1796. Despite vocal opposition, the success of his "inoculation" was clear and within 10 years of its inception, large-scale vaccination was being practiced throughout the world. As vaccination was safer, less painful, and did not spread smallpox many European nations began to outlaw variolation and impose compulsory vaccination. It soon became apparent that inoculation with cowpox did not provide lifelong protection against smallpox and regular revaccination was instituted. Widespread vaccination began to control the number, frequency, and mortality of smallpox epidemics throughout the 19th century and had even eliminated smallpox in many of the more developed countries by the 1940s and 1950s.

SMALLPOX VACCINE

In the early years of vaccination, a wide variety of poxviruses were utilized including: cowpox, sheeppox, goatpox, horsepox, swinepox, and buffalopox. Over time physicians began to use vaccinia virus for immunization against smallpox. The source of vaccinia virus is, to this day, unknown. While various explanations for its origins have been postulated, the most common are: (1) a derivative smallpox virus, altered by years of passage in laboratories and domesticated animals, (2) a derivative cowpox virus, similarly altered by laboratory passage, and (3) a remnant strain of now extinct horsepox virus. As shown in Fig. 37.8 numerous poxviruses have been sequenced

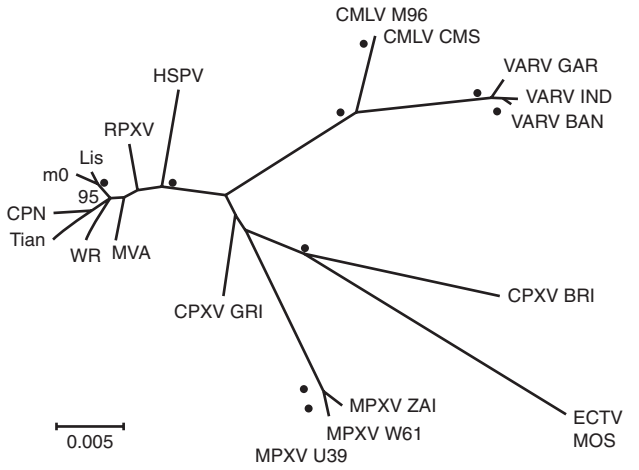

FIGURE 37.8 Sequence diversity in poxviruses. Conserved OPV central genomic nucleotide sequences were aligned using DIALIGN, and gapped regions were realigned with CLUSTAL W and trimmed with Gblocks. The scale indicates estimated distance. For additional details on the generation of the tree see the reference. Reproduced with permission from Tulman et al. (2007).

(Yau and Rouhandeh, 1973; Bhat et al., 1991; Afonso et al., 2000, 2002a, 2002b, 2005, 2006; Tulman et al., 2001, 2004) and genetic analysis shows that although closely related to rabbitpox, horsepox, and cowpox, vaccinia is a distinct viral species (Shchelkunov et al., 2000; Esposito et al., 2006; Tulman et al., 2006). Regardless of its origin, vaccinia virus proved to be a relatively safe and effective vaccine, and was the basis for all of the smallpox vaccines in widespread use during the eradication efforts.

Throughout the 1800s several key improvements were made in vaccine production and usage. Italian physicians began using calves as a source of the vaccine in 1805 and commenced large-scale vaccine production in calves in 1840 (Dixon, 1962). Another key development was the use of glycerol as a stabilizer and phenol as a bactericidal agent which occurred during the same time period (Fenner, 1988). Numerous different virus strains and species were used, grown using varied methodologies, had different titers, take rates, side effects, and efficacy (Table 37.6).

The advent of the Intensified Eradication Program brought with it standardized production methods, reporting of vaccine take rates, and quality control measures including: seed lots for virus production, maximal acceptable bacterial counts, minimum acceptable viral titers, and defined heat stability (Fenner, 1988). The vast majority of the vaccine strains were produced using large healthy animals (mainly calves but also sheep, and water buffaloes) as *vaccinifers*. The belly or the flanks of these animals were shaved, disinfected, and rinsed with sterile water.

Two perpendicular series of parallel scratches 1 mm apart were made on the prepared area. High titer seed virus was rubbed into the scarified skin and incubated for several days. The vaccine *pulp*, a mixture of epidermal cells, leukocytes, plasma, hair, bacteria, and the virus, was then scraped from the animal's skin and further processed. The vaccine lymph was prepared by grinding and homogenizing the pulp and adding glycerol (50% final concentration) and phenol (0.4% final concentration). The resulting liquid vaccine required constant refrigeration and, despite being satisfactory for countries with cold chain transportation, it was not acceptable in tropical and developing countries. Freeze-dried vaccines were more stable and could survive higher temperatures than the liquid counterparts and from the 1950s onward freeze-dried vaccines were used almost exclusively.

Vaccination techniques varied widely, but by the 1950s all of the methods had the same basic principle: to introduce the virus into the epidermis. Vaccination sites included the external side of the upper arm over the deltoid muscle, the flexor surface of the forearm, a small portion of the back, and various locations on the legs. A number of different instruments were used to introduce the virus including: needles, lancets, small knives to scratch the virus into the skin, the rotary lancet to abrade the epidermis, jet injectors which used compressed air to force the virus into the subcutaneous tissue, and the bifurcated needle, developed by Benjamin Rubin at Wyeth Laboratories in 1965. The rotary lancet was frequently associated with more severe local reactions and was phased out for safer methods. The jet injectors were quite effective but were rapidly replaced by the cheap and simple-to-use bifurcated needle (Fenner, 1988).

One major advance was the replacement of higher pathogenicity strains with safer ones which caused fewer and less severe side effects (Kretzschmar et al., 2006). By the end of the eradication effort the two most utilized commonly strains were the New York City Board of Health (NYCBOH) and Lister strains (Fenner, 1988).

In order to further reduce vaccine complications a number of laboratories developed attenuated vaccinia strains. These included CVI-78 and CVII strains, which were less reactogenic than the NYCBOH strain (Kempe et al., 1968), the modified vaccinia Ankara (MVA) strain developed through 572 serial passages in chick embryo fibroblasts (Mayr et al., 1978; Blanchard et al., 1998), and LC16m8, a Japanese strain attenuated through passage in rabbit kidney cells at 30°C (Sugimoto and Yamanouchi, 1994; Kenner et al., 2006). MVA and LC16m8 were used on tens of thousands of subjects with fewer adverse reactions than the nonattenuated strains, however as these attenuated strains were produced at the very end of the eradication effort efficacy data is lacking (Mayr, 2003; Slifka, 2005). Modern studies of these attenuated strains have refocused primarily on MVA, LC16m8, and NYVAC (McCurdy et al., 2004; Tartaglia et al., 1992). They have been safely tested in immunocompromised animal models (Earl et al., 2004; Wyatt et al., 2004), but unfortunately appear to be less immunogenic than their nonattenuated cousins and it is not clear whether or not they would provide protection against smallpox (Coulibaly et al., 2005; Puissant and Combadiere, 2006; Staib et al., 2006; Parrino et al., 2007).

In the 1960s many researchers tried to develop inactivated smallpox vaccine in an effort to reduce

complication rates. A variety of inactivation methods were tested including: heat killing, formaldehyde, UV or gamma irradiation, photodynamic inactivation, and others. For reasons that are still not understood, none of these vaccines produced satisfactory results (Fenner, 1988). One possibility is that they consist almost entirely of nonenveloped viral particles and hence may not have primed for immune recognition and clearance of the enveloped virions, a necessary requirement for protective immunity.

Currently, the only licensed vaccine is Dryvax, made by Wyeth Laboratories. The existing available doses were manufactured in the 1970s and early 1980s and stored frozen at −20°C. The smallpox vaccine is the most reactogenic of all FDA approved vaccines and has a large number of contraindications (Table 37.7), limiting its usefulness in the general population (Lane and Fulginiti, 2003). These include anyone with a compromised immune system (HIV, cancer, radiation therapy, organ transplant recipients), with skin disease such as eczema or atopic dermatitis, with a variety of heart conditions, pregnancy, and others. Many of these conditions are so widespread that it is estimated that as much as 50% of the US population today could not receive the vaccine (Kemper et al., 2002). This situation adds further urgency to the need to develop safer vaccine candidates.

The current vaccination technique is essentially unchanged from what was done during the global smallpox eradication effort (Wyeth, 2002). The typical site for vaccination is the deltoid area of the upper arm. The use of alcohol to prep the area is contraindicated as this can inactivate the vaccine virus. The multiuse vaccine vial is reconstituted with water and a sterile bifurcated needle is dipped into the vaccine. The needle will hold ~2.5 μl of vaccine containing 250,000 pock forming units of virus. The needle is then used to make several insertions in a small area of the arm (5 mm in diameter). Percutaneous immunization has been shown to promote more robust immune responses than other vaccination routes (Fenner, 1988; Fulginiti et al., 2003a). For primary vaccination three insertions are made, and if no blood is visible another three insertions are made. For revaccination 15 insertions are made. The needle is then discarded into an appropriately labeled biohazard container. Excess vaccine is then absorbed with sterile gauze and the vaccine site is covered to prevent spread of the virus. The bandage should be changed every 1–3 days and the site should be kept dry. Care should be taken to wash hands after direct contact with the site or potentially contaminated objects, and to wash clothing, towels, and bedding separately with detergent and/or bleach and to dispose of the scab properly once it falls off.

TABLE 37.7 Contraindications for smallpox vaccination

Cancer
Organ/bone marrow transplant
Steroid therapy
Disease affecting immune system (HIV, lymphoma, leukemia)
Primary immune deficiency disorder
Lupus or other severe autoimmune disease
Darier's disease
Active skin disease/condition (burns, impetigo, psoriasis, acne, poison ivy, chickenpox, herpes, severe rashes)
Current or past atopic dermatitis (eczema)
Current history of heart problems (congestive heart failure, heart attack, cardiomyopathy, stroke, chest pain)
Three or more of the following • High blood pressure • High cholesterol • Diabetes or high blood sugar • Current smoker • First degree relative with heart condition before the age of 50 Pregnancy or breastfeeding
Allergies to polymyxin B, streptomycin, chlortetracycline, neomycin, or latex

After vaccination a pock will form at the site after 3–4 days (Fig. 37.9). Over the first week, this vesicle typically grows to 5–15 mm in diameter, fills with pus, and begins to drain. After 2–3 weeks the blister will dry up and a scab will form. The scab will fall off a short time later leaving a small scar. For individuals receiving a repeat vaccination the vesicle will be smaller and resolve more quickly. Individuals receiving the vaccine should be in good general health and not have any symptoms of illness when they receive the vaccine.

Like all immunizations, the smallpox vaccine can induce a number of side effects and adverse events. These are listed in Table 37.8 and can range from common annoyances to life-threatening conditions (Lane et al., 1969, 1970b, 1970a; Goldstein et al., 1975; Fenner, 1988; Fulginiti et al., 2003b; Lane and Goldstein, 2003; Casey et al., 2005; Kretzschmar et al., 2006). Most individuals receiving the vaccine can expect to experience one or more of the following reactions: fever, headache, muscle and joint aches, chills, nausea, swelling, soreness and itching at the vaccine site, and regional lymphadenopathy. Satellite lesions may form near the vaccine site. These are typically mild and last for several days. Studies of the large-scale vaccination programs started after September 11 showed a lower number of most adverse events than expected based on historical data (Casey et al., 2005). However, multiple cases of myo- and pericarditis, inflammation of the heart tissue or the pericardium respectively,

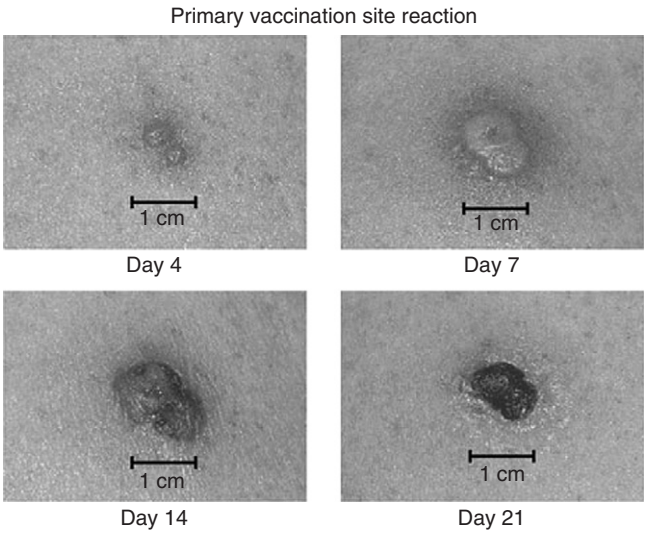

FIGURE 37.9 Characteristic smallpox vaccine "Take." Courtesy of the CDC. http://www.bt.cdc.gov/agent/smallpox/vaccination/index.asp.

TABLE 37.8 Frequencies of adverse events following smallpox vaccination (numbers represent events per million vaccinations)

	1963 National Survey[a]	1968 National Survey[a]	2003 Vaccination Programs[b]
Postvaccinial encephalitis	1.9	2.9	2.6
Progressive vaccinia	1.1	0.9	0
Eczema vaccinatum	8.7	10.4	0
Generalized vaccinia	20.8	23.4	59.7
Accidental inoculation	13.6	25.4	221.8
Myopericarditis	ND[c]	ND[c]	133.6
Death	1.1	1.3	3[d]

[a] Data from 1963 and 1968 are taken from nationwide surveys conducted by the CDC (Neff et al., 1967; Lane et al., 1969). The first number represents the incidence rate among primary vaccinees.
[b] Data from reports on the two US Smallpox Vaccination Programs that began in 2002 among civilian (n = 40,422) and military (n = 730,580) personnel (Grabenstein and Winkenwerder, 2003; Casey et al., 2005; Poland et al., 2005).
[c] ND, no data.
[d] The three deaths listed, occurred among the civilian personnel and were a result of myocardial infarctions. It is not known if they are directly related to the vaccine. No deaths have been reported among the 730,000+ military personnel receiving the vaccine.

were identified at a much higher rate than historically recorded (Halsell et al., 2003; Poland and Neff, 2003; Poland et al., 2005). Although a causal link between smallpox vaccination and myopericarditis has not been conclusively proven it remains a concern. Although the majority of these subjects recovered promptly it remains to be seen whether or not they suffer any long-term sequelae and consequently the CDC included a variety of heart conditions on the list of contraindications (Arness et al., 2004; Cassimatis et al., 2004; Gami et al., 2005).

The most common side effects of vaccination are: (1) inadvertent autoinoculation which occurs when vaccinia virus from the vaccination site is transferred to other sites on the body or to other individuals (Sepkowitz, 2003) and (2) erythematous or urticarial skin rashes, collectively termed generalized vaccinia. These rashes are fairly frequent and typically resolve spontaneously requiring no special care (Fulginiti et al., 2003b; Wollenberg and Engler, 2004). Ocular vaccinia can result in keratitis and the scarring may result in impaired vision or blindness. Topical antiviral agents can be used to treat the symptoms and in some cases VIG may be recommended. Bacterial superinfection of the vaccination site can also occur, typically by staphylococci or β-hemolytic streptococci (Fulginiti et al., 2003b). These types of infections are readily treated by appropriate antibiotic therapy and their incidence is greatly reduced by proper care of the vaccination site (Vellozzi et al., 2004).

Other more serious complications occur in patients with some degree of immunologic deficit and include: eczema vaccinatum, progressive vaccinia (vaccinia necrosum), and postvaccinal encephalitis (Fenner, 1988; Fulginiti et al., 2003b; Rock et al., 2004; Vellozzi et al., 2005).

Eczema vaccinatum can be either a localized or systemic spread of the infection. The rash progression mimics that of the normal vaccination site, however, the lesions are typically confluent and cover the areas of the skin with current or past eczema. If left untreated, patients can develop septic shock and die, therefore prompt treatment with VIG is recommended as soon as possible after diagnosis. Given the predisposition of this complication for eczematous patients it is important to refrain from vaccinating these individuals unless absolutely necessary (Engler et al., 2002).

Progressive vaccinia (also called vaccinia necrosum), is a severe illness with local progressive necrosis at the vaccination site. Inflammatory responses are absent and the lesion fails to resolve. This is soon followed by secondary lesions elsewhere on the body. Nearly all cases involved individuals with defects in cell-mediated immunity (O'Connell et al., 1964; Redfield et al., 1987). Lymphocyte transfer through

blood transfusion allows for viral clearance but also results in lethal graft-versus-host disease. Before the use of VIG and antiviral agents the disease was uniformly fatal and even the current treatment regimen (prompt hospitalization and supportive care, massive doses of VIG, and/or cidofovir) is not effective unless the T cell defect is minor or reversible.

Postvaccinial encephalitis is another rare complication with high mortality and morbidity rates. Historically the death rate was 15–25% and 1/3 of the survivors were left with permanent neurological damage. Hospitalization and supportive care are required but there is no specific therapy and VIG is ineffective and not recommended.

While rare, smallpox vaccine can cause fetal complications, hence the contraindication for pregnant women (Hassett, 2003). There have been approximately 50 reported cases of fetal vaccinia, which results in stillbirth or death of the infant shortly after delivery (Fulginiti et al., 2003b).

Historically, for every million primary vaccine recipients several hundred people would experience complications severe enough to require hospitalization and one to two people would die, typically the result of either postvaccinial encephalitis or progressive vaccinia. After the eradication of smallpox, even this small risk was deemed unacceptable and routine vaccination stopped. The complication rate in individuals receiving revaccination is far lower (about 1/10) for all adverse events.

SMALLPOX VACCINES IN DEVELOPMENT

Two obstacles hinder the testing of new smallpox vaccines. The first is that there are very few historical studies that quantitate protective immunity and there are no defined immune correlates of protection. The second point is that testing the clinical efficacy of new vaccines is not possible in the absence of endemic smallpox. Consequently, next generation vaccines are being compared side-by-side with the already licensed vaccines in order to demonstrate equivalent immunogenicity in humans and protective efficacy in animal models.

One of the first priorities has been to reexamine the licensed vaccines using modern immunological techniques and involves several large-scale vaccination programs (Stienlauf et al., 1999; Grabenstein and Winkenwerder, 2003; Poland and Neff, 2003; Combadiere et al., 2004; Kennedy et al., 2004; Orr et al., 2004; Poland et al., 2005; Amanna et al., 2006; Treanor et al., 2006; Simpson et al., 2007). Another priority was to determine if the existing Dryvax vaccine could be diluted without a loss of immunogenicity. The ability to dilute a vaccine with proven efficacy would substantially increase the utility and number of persons who could be protected given the limited vaccine stock available. These studies found that "take rates" and immune markers (antibody levels and cellular immune responses) did not differ between groups receiving undiluted, a 1:5 dilution or a 1:10 dilution of Dryvax (Frey et al., 2002; Talbot et al., 2004; Couch et al., 2007), and in fact, reducing the vaccine dose also reduced vaccine-associated side effects (Couch et al., 2007). Studies have also been conducted with the Aventis Pastuer and Lister-based vaccines with similar results (Kim et al., 2005; Hsieh et al., 2006).

New smallpox vaccines are also being developed and tested. In September 2000, Acambis Inc. received a contract to create a stockpile of 40 million doses of a new vaccine. The next year they received a second contract to create an additional 155 million doses. Acambis created two tissue culture-based vaccines using the NYCBOH strain of vaccinia ACAM1000 and ACAM2000, grown in MRC-5 or Vero cells respectively (Weltzin et al., 2003; Monath et al., 2004; Artenstein et al., 2005). Aventis Pastuer produced a vaccine similar to Dryvax which was approved for use until 1997. This vaccine is undergoing additional testing as an Investigational New Drug (IND) (Rock et al., 2006). Additionally, NIH is supporting research into MVA-based vaccines including ACAM3000 (Acambis) and IMVAMUNE-BN (Bavarian Nordic) (Vollmar et al., 2006). These vaccines are currently undergoing clinical trials and are destined to join the US strategic national stockpile which in 2004 contained over 400 million doses of smallpox vaccines. Other groups are developing vaccines based on other attenuated strains such as the Japanese LC16m8 strain of vaccinia or on the NYVAC (Kidokoro et al., 2005; Empig et al., 2006; Najera et al., 2006). An updated list of smallpox vaccine clinical trials can be found at http://www.clinicaltrials.gov.

A number of groups are working on developing DNA, protein, and peptide-based subunit vaccines for smallpox (Otero et al., 2005; Thornburg et al., 2007). Several promising candidates have demonstrated protective efficacy in multiple animal models (Hooper et al., 2000, 2003, 2004, 2007; Fogg et al., 2004, 2007; Meseda et al., 2005; Heraud et al., 2006; Sakhatskyy et al., 2006; Xiao et al., 2007). Another subunit vaccine produced in plants protects mice from lethal poxvirus infection and may provide a stable, easily administered vaccine (Golovkin et al., 2007). Theoretically these vaccines will be safer to administer as they would contain no live virus. While such vaccines

work well in animal models they do not induce robust immune responses in humans. This lack of immunogenicity is currently the focus of intense research and in the future we may see these types of vaccines not only for smallpox but also other pathogens as well (Bonilla-Guerrero and Poland, 2003; Poland, 2005).

Mice, rabbits, and nonhuman primates are typically used as animal models for studying poxvirus pathogenesis and immunity (Turner, 1967; Wallace and Buller, 1985; Williamson et al., 1990; Martinez et al., 2000; Smith and Kotwal, 2002; Esteban and Buller, 2005). Just as important as the choice of animal host is the selection of the virus strain to be used in the studies. As mentioned earlier, studies using an animal and its natural pathogen (i.e., mice and mousepox, or nonhuman primates, and monkeypox) provide different results from studies using vaccinia virus. It should be noted that these are, at best, close approximations of the human disease. For example, researchers have been able to mimic certain symptoms (characteristic rash, high mortality) of the human disease by the IV inoculation of extremely high titers (10^9 pfu) of variola (Rubins et al., 2004) into nonhuman primates which are typically resistant to variola infection.

As mentioned before, vaccinia virus is highly amenable to the insertion of exogenous DNA sequences and has shown promise as a vector for the development of vaccines for other pathogens including HIV, HBV, rabies, RSV, malaria, TB, leishmania, and numerous cancer antigens as well (Xing et al., 2005; Lindsey et al., 2006; Bejon et al., 2006; Perez-Jimenez et al., 2006; Puissant and Combadiere, 2006; Weyer et al., 2007; Wang et al., 2007; Hutchings et al., 2005).

PROSPECTS FOR THE FUTURE

In the aftermath of September 11 the United States took stock of preparedness in the event of an intentional release of smallpox (or any other biological agent). A smallpox scenarios is of concern because (1) there was no effective treatment for the disease, (2) the US population under 35 years of age was not immunized and those over 35 had not received a vaccine for decades and were likely to have waning immunity, (3) the United States had a stockpile of only 7–15 million doses of vaccine and the WHO only had 500,000 doses, (4) VIG was an unproven product and was in short supply, (5) vaccine production facilities were nonexistent and the production methods would not meet FDA requirements, (6) there was only one antiviral drug approved for human use that might be effective against smallpox—Cidofovir, (7) most physicians had never seen a case of smallpox, making early detection unlikely, and (8) public health infrastructure was inadequate and unprepared for the mass casualty situations likely to occur with a biological attack. The United States allocated hundreds of millions of dollars into biodefense spending in an effort to address these issues. In 2004, President Bush authorized Project Bioshield which appropriated $5.2 billion over 10 years to address these issues (Schuler, 2004, 2005; Lam et al., 2006; Franco and Deitch, 2007). Several years later in 2007, considerable progress had been made (LeDuc and Jahrling, 2001; Breman et al., 2003; Janoff and Lynfield, 2003; Mahalingam et al., 2004; Arita, 2005; Bossi et al., 2006; Ruef, 2006). The strategic national stockpile now holds over 400 million doses of live smallpox vaccine, with additional doses of attenuated strains currently being tested and produced (Rosenthal et al., 2001; Wiser et al., 2007). An important question now before us is what type of vaccination policy, if any, to promote (Bicknell and James, 2003; Mortimer, 2003b). Universally safe subunit vaccines are under development. Numerous promising drug candidates have been discovered with activity against poxviruses (Baker et al., 2003; Bray and Roy, 2004). A wide range of new methods for detection, identification, and analysis of poxviruses and immune responses to them have been developed (Espy et al., 2002; Earl et al., 2003; Leparc-Goffart et al., 2003; Newman et al., 2003; Cosma et al., 2004; Li et al., 2004b; Rotz and Hughes, 2004; Leparc-Goffart et al., 2005). First responders and public health infrastructure at the state and local levels has been bolstered in order to cope with mass casualty events (Meltzer et al., 2001; Hull et al., 2003; Kaplan et al., 2003). Emergency management plans have been formulated and tested using advanced computer algorithms to predict both smallpox transmission and preventive measures (Gani and Leach, 2001; O'Toole et al., 2002; Eichner, 2003; Eichner and Dietz, 2003; Grais et al., 2003; Kiang and Krathwohl, 2003). Details regarding the US emergency response plans and vaccination policy in the event of smallpox release can be found at the CDC website (http://www.bt.cdc.gov/agent/smallpox/index.asp).

This remarkable progress has come with a large price-tag; nevertheless we are far better prepared for an outbreak of smallpox now than we were a few years ago. We have a greater understanding of viral biology, infection and immunology, useful knowledge for the creation of vaccines not just for smallpox but also for SARS, avian influenza or any of the other emerging viral infectious diseases and threats we may encounter. We have developed antiviral drugs with activity against poxviruses as well as other virus families. We have sequenced poxvirus genomes and have begun to harness viral proteins as therapeutic agents for other

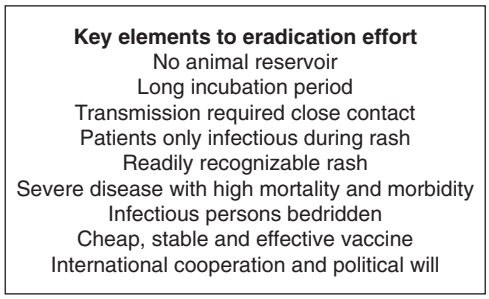

FIGURE 37.10 Key elements of the successful smallpox eradication effort.

diseases and conditions (De Clercq, 2001). We are closer to developing peptide and protein-based vaccines with far better safety profiles than live viral vaccines. There has been research into immunologic adjuvants with the potential to be used in numerous vaccines. Public health infrastructure is now better able to cope with not only biological attacks, but also natural disasters such as hurricanes, earthquakes, tsunamis, and natural outbreaks. Continuing progress in all of these areas will be necessary in order for us to be prepared for biological threats of either man-made or natural origin.

CONCLUSIONS

The eradication of smallpox is one of the greatest triumphs of modern medicine and illustrates the full potential an effective vaccination program can realize. The eradication effort cost hundreds of millions of dollars, widespread international cooperation, countless hours of effort by thousands of health care workers worldwide, and required the wide availability of an effective vaccine (Fig. 37.10). While large, these costs are dwarfed by the savings in human life, not to mention the elimination of health care, quarantine, surveillance, and prevention measure costs associated with smallpox. Several other diseases are now being considered for eradication including measles and polio. The eradication of these diseases will no doubt require efforts of a similar magnitude as those needed to eliminate smallpox yet the end results will be equally impressive.

KEY ISSUES

- Smallpox has probably killed more people than any other disease in history.
- Edward Jenner proved that cowpox can protect against smallpox infection.
- The use of vaccinia virus as a smallpox vaccine led to the eradication of smallpox in 1980.
- Smallpox has been used as a biological weapon for centuries.
- The Soviet Union had a massive bioweapons program beginning in the 1980s.
- The threat of smallpox being used as a biological weapon today is small but would have a devastating impact on society.
- The currently licensed vaccine can cause severe complications.
- New vaccines are needed but cannot be tested for efficacy against smallpox.
- There is still no effective treatment for smallpox.

OUTLINE

ABSTRACT

Tick-borne encephalitis (TBE) is a disease caused by a group of closely related tick-borne flaviviruses with an endemic range across Asia from Japan into Western Europe. TBE can range from a subclinical or mild disease to a severe disease with a high incidence of encephalitis and long-term sequelae. Related viruses have been found in North America, India, Saudi Arabia, and Malaysia, and several are associated with viral hemorrhagic fever rather than encephalitis.

There are currently four inactivated virus vaccines available for the prevention of TBE—two produced in Russia and two licensed for use in Europe. Although effective, there are some limitations with the use of inactivated virus, primarily the need for multiple doses for development of a protective immune response. There are also limitations on the availability of the vaccines and questions about the efficacy of these vaccines in protecting against tick-borne flaviviruses that cause hemorrhagic fever. Although the current vaccines have made a significant impact in parts of Western Europe, the overall incidence of disease is still increasing in many countries. A number of modern approaches are currently being examined for development of a new generation of TBE vaccines. These include the use of live-attenuated viruses, chimeric viruses, DNA vaccines, and protein subunit vaccines. Each technology has shown some promise in animal models, but clinical trials have not been reported for any of the novel vaccine candidates. With current licensure requirements, the active use of any new vaccine is still several years away; however, with disease incidence increasing, the need for improved vaccines will continue.

INTRODUCTION

Tick-borne encephalitis (TBE) is a disease that is endemic from Western Europe, across Asia, and into parts of Japan. TBE accounts for 7000–10,000 cases of illness annually with nearly 4000 cases reported in Europe alone in 2006 [Tick-Borne Encephalitis International Scientific Working Group (TBE-ISW) http://www.tbe-info.com]. The causative agent for TBE is TBE virus (TBEV), a member of the TBE serocomplex of flaviviruses that are related serologically and genetically. TBEV causes two clinically distinct diseases, depending on the subtype of virus. The disease found in Europe is typically biphasic with a relatively low mortality rate and few sequelae in survivors. The disease in eastern Asia is much more severe with a higher mortality rate, significant sequelae in survivors, and the potential to develop chronic or persistent disease. To date there are no effective therapeutics for the treatment of TBE.

There are currently four known vaccines available for prevention of TBEV and one that is in use in India for Kyasanur Forest disease virus (KFDV). Two of the TBEV vaccines are licensed for use in Europe while the remaining two are manufactured for use in Russia. All four TBEV vaccines are inactivated virus vaccines that are manufactured following similar processes. The principal variation between the four vaccines is the choice of virus strain used. Two of the manufacturers use a Western subtype TBEV as the basis for their vaccine while both of the Russian vaccines have been developed using a Far Eastern subtype virus.

There is currently a significant effort to develop TBEV vaccines that are not based on the use of an inactivated virus. The concerns about inactivated virus vaccines center around the potential for incomplete inactivation, the need for multiple vaccinations and boosters, and relatively poor immunogenicity in some people. Modern vaccine development focuses on the use of subunit vaccines, live-attenuated vaccines, or DNA-based vaccines. The benefit of subunit vaccines is that there is no virus present in the vaccine; hence, the likelihood of virus reactivation or reversion is nil. The limitations of subunit vaccines include the need for multiple vaccinations and boosters, and their efficacy may be determined by the quality of the adjuvant used in the vaccine formulation. Live-attenuated vaccines include naturally attenuated viruses, artificially attenuated viruses, and recombinant virus vaccines. There have been a wide variety of candidates developed for vaccine trials and all have the advantage of requiring a single vaccination with periodic boosters. The limitations of these vaccines are the significant concern about vaccine reversion and the use of genetically modified viruses in humans. DNA-based vaccines have shown some promise as most are a combination of live-attenuated and subunit vaccines that are capable of replicating, but only contain a portion of the TBEV genome and cannot generate infectious TBEV. Most DNA vaccines use alternative virus vectors, such as adenoviruses, to express TBEV proteins and induce a protective immune response. However, the use of DNA vaccines has met with some resistance, as there is concern about the production of replication-competent highly pathogenic viruses, an unlikely event given the construction of the vaccines.

As with vaccine development for many viruses, the development of vaccines for TBEV has entered the modern age where the demands for safety and efficacy sometimes collide.

HISTORY OF TBE

A neurologic disease with high mortality was first recognized around 1932 in Far Eastern regions of the former Union of Soviet and Socialist Republics (USSR) (Silber and Soloviev, 1946). Initially, this disease was thought to be Japanese summer encephalitis. The virus was thought to be transmitted through interpersonal contact and movement of the disease between endemic regions was believed to be due to movement

of forest workers (Silber and Soloviev, 1946). The first published description of TBE was in 1936 by Silber et al. and described the disease in far-eastern Russia (then the USSR) (Silber and Soloviev, 1946). Laborers in forested regions frequently became ill from a severe neurologic disease that often resulted in death. In 1937, L.A. Silber led a special expedition with a mandate to study TBE in the eastern USSR. Silber et al. determined that ticks were the primary vector for the contagion and that *Ixodes persulcatus* ticks were the most likely vector (Silber and Soloviev, 1946). Subsequently, Chumakov et al. demonstrated experimentally that *I. persulcatus* could transmit the disease (Chumakov and Gladkikh, 1939). In 1937, two groups were able to isolate the virus and clearly demonstrate that the isolated virus was responsible for the disease (Silber and Soloviev, 1946). Subsequently, the virus was named Far Eastern encephalitis virus (Silber and Soloviev, 1946). The isolation of the virus also led to the first effort to generate a vaccine, as Smorodintsev developed a formalin-inactivated vaccine that was used in forest workers in endemic regions (Smorodintsev et al., 1941). A number of subsequent studies characterized the clinical aspects of Far Eastern encephalitis including the first descriptions of chronic and progressive forms of the disease (Silber and Soloviev, 1946). In the early 1940s Far Eastern encephalitis was described in Siberia and the European part of the USSR (Chumakov et al., 1944). It was noted at that time that the virus in Siberia and European USSR caused a different clinical disease than Far Eastern encephalitis, and it was proposed by Chumakov et al. (1944) that the diseases be termed Far Eastern and Western encephalitis to reflect their clinical differences.

Outside of the USSR, TBE was first recognized in epidemics in Czechoslovakia in 1948 and 1949 and the virus was isolated in 1949 from both humans and ticks (Gallia et al., 1949; Hloucal, 1960). This virus was found to be serologically related to the Far Eastern and Western encephalitis viruses, and the milder clinical disease in the Czechoslovakian epidemics suggested that these viruses were of the Western subtype. In 1951–1952, a large epidemic of Western encephalitis was reported in the Roznava district of Czechoslovakia. In this outbreak, it was determined that transmission of the virus in goat milk played a major role in the epidemic in which more than 600 people were affected (Blaskovic, 1958). Smorodintsev had previously shown that Far Eastern encephalitis virus could be transmitted by drinking raw goat's milk (Silber and Soloviev, 1946; Smorodintsev, 1958).

Since its discovery, TBE has now been recognized in many countries in Europe, including most of Eastern Europe and parts of Western Europe (Fig. 38.1). The endemic range for Western subtype TBE reaches east to the Ural mountains while the endemic range for the Far Eastern subtype ranges from Eastern Europe to far-eastern Russia and Hokkaido island in Japan with some reports of TBEV in far-eastern China. The endemic areas of the viruses are essentially coincident with the endemic range of their primary tick vectors. *Ixodes ricinus*, the principle vector for Western subtype TBEV, is found primarily in Europe, parts of Asia, and North Africa. *I. persulcatus*, the vector for Far Eastern subtype TBEV, is found across northern Asia (Brown et al., 2005).

Since the discovery and identification of TBEV, a number of related viruses have been identified (Table 38.1). All of these viruses are transmitted by ticks and there is a certain degree of serological cross-reactivity among the viruses. These viruses include Omsk hemorrhagic fever virus (OHFV) that was first isolated in 1947 in Siberia from human blood (Chumakov, 1948); Langat virus (LGTV) isolated in Malaysia in 1956 from tick pools (Gordon Smith, 1956); Kyasanur Forest disease virus (KFDV) that was isolated in India in 1957 from humans, monkeys, and ticks (Work, 1958); Powassan virus (POWV) isolated in Canada in 1958 from human brain (McLean and Donohue, 1958); and Alkhurma virus (ALKV) isolated in Saudi Arabia in 1996 from human blood (Zaki, 1997). OHFV, KFDV, and ALKV are all associated with viral hemorrhagic fever, and KFDV and ALKV have also been shown to produce encephalitis in humans (Zaki, 1997). POWV appears to cause primarily subclinical disease but can result in extremely severe and lethal encephalitis. LGTV does not typically cause disease in humans and in the 1970s, the E5 strain of LGTV was developed and tested as a potential live-attenuated vaccine for TBEV (Mayer, 1975; Mayer et al., 1976; Price and Thind, 1973; Price et al., 1970).

Since the discovery of these viruses, the tick-borne flaviviruses in the TBE serocomplex have been shown to be closely related serologically. Genetic analysis of these viruses has subsequently confirmed serological data. The TBEV have since been divided into three subtypes (Far Eastern, Siberian, and Western) and genetic variation between the viruses correlates well with differences in clinical presentation described when Far Eastern and Western encephalitis were first recognized.

ETIOLOGIC AGENTS

Classification

The genus *Flavivirus* in the family *Flaviviridae* consists of approximately 70 related viruses that are typically transmitted by mosquitoes or ticks, yet there are several flaviviruses that are classified as "no known

FIGURE 38.1 Worldwide distribution of tick-borne flaviviruses with significant human health issue.

vector" as there does not appear to be an arthropod host associated with virus transmission (Calisher and Gould, 2003). The mosquito-borne flaviviruses consist of viruses such as dengue virus (DENV), yellow fever virus (YFV), and viruses in the Japanese encephalitis virus serocomplex including Japanese encephalitis (JEV) and West Nile viruses (WNV). The mosquito-borne viruses can also be delineated by their arthropod vectors, as DENV and YFV are typically transmitted by *Aedes spp.* mosquitoes while JEV serocomplex viruses are transmitted by *Culex spp.* mosquitoes. There is also a significant amount of serological and genetic diversity among the mosquito-borne flaviviruses (Gould et al., 2001, 2004; Zanotto et al., 1995).

There are two subsets of tick-borne flaviviruses: those that are associated with seabirds and those with mammals (Gould et al., 2001, 2004). Mammal-associated tick-borne flaviviruses subset contains the only viruses known to cause disease in humans and is commonly referred to as the TBE serocomplex of viruses. The TBE serocomplex is genetically divided into four major clades representing Far Eastern subtype TBEV, Siberian subtype TBEV, Western subtype TBEV, and Louping Ill virus (LIV) (Gould et al., 2001, 2004; Zanotto et al., 1995). Other viruses in the serocomplex have very few species and form their own clades.

The progenitor virus for the TBE serocomplex is thought to be POWV (Gould et al., 2001, 2004; Zanotto et al., 1995). The evaluation of evolutionary trends of the TBE serocomplex is that the virus migrated from eastern Asia across Asia and into Europe with Western subtype TBE and louping ill viruses (LIV) representing the most recently evolved virus subtypes (Gould et al., 2001, 2004; Zanotto et al., 1995) (Fig. 38.2).

The level of serologic and genetic diversity among the tick-borne flaviviruses is much less than among the mosquito-borne viruses. There is approximately 30% nucleotide variation between POWV and LIV, and Western subtype TBEV, the most distant relatives. There is 16% nucleotide variation between Far Eastern subtype and Western subtype TBEV. The diversity at the amino acid level is about 23% between POWV and LIV, the least related viruses (Lin et al., 2003). There is less than 4% amino acid diversity between Far Eastern and Western subtypes of TBEV (Lin et al., 2003). This high level of similarity at the nucleotide and amino acid

level is further borne out in structural similarities of the viral envelope (E) protein, the primary immunogen on the surface of the virion, as these viruses are difficult to distinguish serologically. The high level of similarity further suggests that vaccines raised against one member of the TBEV serocomplex will show a high level of cross-reactivity against other members of the complex.

Flavivirus Genome Organization

The flaviviruses are small enveloped viruses with a diameter of approximately 50 nm. The virus particle is composed of 90 envelope (E) protein dimers arranged in a herringbone type array (Kuhn et al., 2002) (Fig. 38.3). Interspersed among the E protein lattice is the viral membrane (M) protein, though the precise location of the M protein is not clear. The viral particle contains the single-stranded positive-sense RNA viral genome that is approximately 11 kb in size. The viral genome is translated as a single polyprotein and is co- and post-translationally cleaved to generate 10 individual proteins, three structural and seven nonstructural proteins (Fig. 38.4). The structural proteins consist of the capsid (C), pre-membrane (prM), and E proteins while the nonstructural proteins include NS1, NS2A, NS2B, NS3, NS4A, NS4B, and NS5. NS2B and NS3 associate to produce a viral protease and NS5 functions as a helicase

and the viral RNA polymerase. The flavivirus nonstructural proteins serve a number of functions, but are primarily associated with viral replication (e.g., NS1, NS3, and NS5) and polyprotein processing (e.g., NS2B and NS3), although the function of some of the nonstructural proteins is poorly understood. Several nonstructural proteins have been associated with stimulating or moderating the host response to viral infection by interferon induction or inhibition (e.g., NS5) and induction of apoptosis (e.g., M protein).

The structural proteins make up the total protein component of the flavivirus virions as none of the nonstructural proteins are included in the virion. The C protein is associated with the viral RNA although the role of the C protein in RNA organization in the virion is still unclear. The prM protein functions as a chaperone and facilitates folding of the E protein. This is an important role that cannot be overlooked, as a number of vaccine development strategies have included DNA vectors that encode the prM and E proteins to generate subviral particles. The lack of the prM protein results in poor protein expression and poor immunogenicity. During virion organization the prM protein is assembled along with the E protein, but the protein is cleaved during virus maturation by a furin-like protein leaving only the M protein in the mature virion with the E protein. The flavivirus E protein is the major virus protein on the surface of the virion. The E protein is the primary immunogen for the flaviviruses and serves as a receptor-binding protein and fusion protein (Chen et al., 1997; Chu et al., 2005; Hung et al., 2004; Lee and Lobigs, 2000; Mandl et al., 2000). The structures of the E protein from several flaviviruses have been solved and it has been shown to have three distinct domains—I, II, and III (Modis et al., 2003; Rey et al., 1995). Domain I is the central domain and serves as a hinge between domains II and III. Domain II is the dimerization domain and also contains the viral fusion peptide. Domain III is the receptor-binding domain (Chu et al., 2005; Hung et al., 2004; Lee et al., 2006) and is also a principal target for neutralizing antibodies (Beasley and Barrett, 2002; Crill and Roehrig, 2001; Lin and Wu, 2003; Sanchez et al., 2005; Thullier et al., 2001). During viral attachment and entry, the virus binds to an as-yet-unidentified cell surface receptor, is internalized in clathrin-coated pits, and undergoes fusion with endosomal membranes during a low pH-induced conformational rearrangement (Bressanelli et al., 2004; Heinz and Allison, 2000, 2001; Kuhn et al., 2002; Modis et al., 2004; Stiasny et al., 2002, 2005; Zhang et al., 2004). Following fusion, the viral RNA is released into the cell cytoplasm where replication occurs.

The flavivirus entry provides potential intervention points for neutralizing antibodies in a protective response to viral infection. The first is at the point of viral attachment. A neutralizing antibody could bind to the E protein domain III and prevent the virus from binding to cell surface receptors. A number of neutralizing monoclonal antibodies are known to interact with domain III to prevent infection by different flaviviruses (Beasley and Barrett, 2002; Crill and Roehrig, 2001; Kaufmann et al., 2006; Lin and Wu, 2003; Sanchez et al., 2005; Volk et al., 2004; Wu et al., 2003; Wu and Lin, 2001). A second point of inhibition is prevention of membrane fusion. Antibodies can bind to the viral E protein and inhibit the pH-induced rearrangement of the E protein that occurs in cellular endosomes to allow fusion of the viral envelope protein with the endosomal membrane. Several monoclonal antibodies are thought to neutralize flavivirus infection in this manner. Epitopes for these antibodies have been mapped to several regions of the viral E protein including domains I and II (Beasley and Aaskov, 2001; Oliphant et al., 2006).

EPIDEMIOLOGY

Significance as Public Health Problem

TBE is a widespread arboviral encephalitis that is of significant human heath importance. As discussed earlier, TBEV was first isolated in far-eastern Russia and has since been found across Asia with related viruses found throughout Europe, the British Isles, and also in North America (Fig. 38.1). TBE is a significant human health issue in Europe where 2000–4000 cases are reported annually with the total number of cases increasing (TBE-ISW http://www.tbe-info.com) (Table 38.2). The current case numbers are reflective of a significant vaccination effort in some countries in Europe, particularly Austria, where total case numbers have been reduced by 90% of their pre-vaccine totals. Prior to the development and effective use of TBE vaccines there were more than 600 cases annually in Austria. Although TBE is a notifiable disease in many countries, most countries in Europe were not reporting consistently prior to the mid-1970s.

However, despite a reduction in the number of annual TBE cases due to improved vaccination coverage and changes in personal behavior in some countries, the range of TBE endemicity appears to be increasing and therefore the total case number is also on the rise. Recent reports of virus isolation or amplification of TBE RNA from tick pools has provided evidence of TBEV circulation in locations where this virus has not been previously found (Haglund, 2002; Skarpaas et al., 2004). The increase in the endemic range of TBE is thought to be associated with the increased range of *I. ricinus*, the principal vector for TBEV in Europe and *I. persulcatus*, the vector for Far Eastern subtype TBEV

(Haglund, 2002; Johan et al., 2006; Lindgren and Gustafson, 2001; Skarpaas et al., 2004, 2006; Skarphedinsson et al., 2005). However, studies of climate change and its correlation with incidence of TBE suggest that climate change specifically may not be associated with the northern migration of TBE (Randolph, 2004; Rogers and Randolph, 2006). However, the increasing range of TBEV is important as new endemic foci have naïve populations and do not yet have extensive vaccination programs in place.

TBEV is transmitted to humans via the bite of infected ticks. The tick life cycle consists of three distinct phases: larvae, nymph, and adult. Ticks in all three phases have been shown to have the capacity to transmit TBEV although only the larvae and nymphs are likely to play a significant role in the TBEV life cycle (Nuttall and Labuda, 2005). TBEV has also been shown to be transmitted transstadially (Nuttall and Labuda, 2005) and transovarially (Rehacek, 1962). TBEV transmission cycles between infected ticks and small mammals or birds, which are the principal hosts for immature ticks. Adult ticks typically feed on goats, deer, or other ungulates that are not typically susceptible to TBEV and, subsequently, do not play a significant role in virus transmission (Nuttall and Labuda, 2005).

Potential as Biothreat Agent

TBEV is considered a potential biothreat agent largely due to its pathogenicity, ability to be transmitted via aerosol, lack of therapeutic treatment, and limited vaccine coverage. While these parameters make TBEV a highly dangerous virus, the inability of TBEV to be transmitted by human-to-human contact, the instability of the virus in UV light, and the lack of a suitable arthropod vector in many parts of the world would make extensive outbreaks of this virus difficult to engineer. TBEV is relatively stable when kept in cool conditions and it appears to also remain active in

liquids for extended periods of time (Kharitonova and Leonov, 1985). There has also been evidence, based on accidental laboratory exposures, of aerosol transmission of TBEV (Scherer et al., 1980); however, conclusive studies have not been published. TBEV can also clearly survive the stomach and gut since the ingestion of contaminated milk has long been recognized as a means of transmission (Gritsun et al., 2003b; Moritsch and Kovac, 1960; Pogodina, 1958, 1960).

CLINICAL DISEASE

As discussed earlier, TBEV infection can result in diseases with varying severity depending on the subtype of TBEV involved. Western subtype TBEV generally causes a milder biphasic disease while Far Eastern subtype typically causes a much more severe disease with paresis and neurological sequelae more common and a higher mortality rate. The typical course of TBE can last up to 8 weeks from the time of infection with more severe cases lasting considerably longer. There has also been evidence of latent or persistent infections due to Far Eastern or Siberian subtype TBEV in both humans and nonhuman primates (Frolova and Pogodina, 1984; Gritsun et al., 2003a, 2003b; Pogodina et al., 1981a).

Western subtype TBEV and Far Eastern subtype TBEV cause clinically distinct diseases. Western subtype TBEV is typically characterized as a biphasic disease. However, in approximately 65% of persons infected with Western subtype TBEV, the infection remains inactive or ends after the first phase of disease. Of the remaining 35% of patients, the majority have a disease that follows the typical biphasic disease profile and progresses to the much more severe second stage characterized by neurological symptoms. In some cases, the first phase of disease is very mild, or asymptomatic, with the onset of clinical illness corresponding to the second, severe, phase of disease (Gritsun et al., 2003b; Reisner, 1981). Following infection, Western subtype TBEV typically has an incubation period that lasts from 2 to 18 days (Gritsun et al., 2003b). There is no indication of disease during the incubation period. Following the incubation period, disease onset can be rapid with nonspecific systemic signs of disease predominating. These signs include headache, fatigue, myalgia, nausea, general malaise, and fever with body temperatures rising to more than 38°C. This first stage of disease generally lasts for 1–8 days and corresponds to the viremic phase. The first phase of disease is followed by an afebrile period that can last from 1 to 20 days. Symptoms of disease generally subside during this period. The second phase of disease begins with a rapid onset of symptoms following the afebrile phase. Manifestations are generally similar to the first phase of disease, but are more severe with extremely high fevers and significant evidence of neurological involvement. Patients typically develop meningitis, meningoencephalitis, meningoencephalomyelitis, or meningoencephaloradiculitis (Gritsun et al., 2003b). The meningitis usually resolves and the case fatality rate is 1–2%. Some patients who have more severe disease can develop long-term sequelae; however, long-term health effects of the infection are generally minor. There is also evidence of age-dependence in disease severity whereby children have less severe disease and sequelae than adults, especially the elderly (Krausler, 1981; Kunz, 1974; Logar et al., 2000; Messner, 1981).

In persons infected with a Far Eastern strain of TBEV, the incubation period is similar and onset is sudden. Symptoms can include headache, high fever, vomiting, myalgia, photophobia, and sensorial and visual changes. Prodromal symptoms are rare. Patients also develop signs of neurological involvement such as paresis, paralysis, seizures, and coma over the course of disease (Burke and Monath, 2001; Clarke and Casals, 1965). Paralysis normally begins in the upper extremities including the shoulders and neck and is accompanied by hyperesthesia. Disease can be complicated by flaccid lower motor neuron paralysis where evidence of ascending paralysis or hemiparesis is a development that results in a poor prognosis (Clarke and Casals, 1965). A poliomyelitis-like illness has also been described (Silber and Soloviev, 1946). The case fatality rate is estimated at 20–30%. Unlike infection with Western subtype TBEV, neurological sequelae are much more common in individuals infected with the Far Eastern subtype virus. These include atrophy and paresis of the brachial plexus and neck muscles, paresis of the lower extremities, and other sequelae resembling poliomyelitis. As mentioned above, TBEV has also been shown to cause persistent or chronic disease, although only the intermediately pathogenic Siberian subtype has clearly been associated with this phenomenon (Gritsun et al., 2003a, 2003b; Pogany et al., 2003; Pogodina et al., 1981a, 1981b, 1981c).

TREATMENT

There are currently no approved therapeutic interventions for TBE. The onset of encephalitis or meningitis requires supportive care in an intensive care ward where treatment protocols are general and depend on the severity of disease. Corticosteroids may be used in certain circumstances to reduce inflammation while

specific treatments to reduce or prevent seizures may also be provided if symptoms arise. General pain medications and sedatives may be used. Intubation and ventilation support may also be required.

A few experimental therapies for TBE have been attempted in animal model systems. These include the use of phosprenyl, an immunomodulatory compound (Danilov et al., 1996), the interferon inducers Poly I:C and tilorone hydrochloride (Hofmann and Kunz, 1972) and amiphenosine (Libikova, 1968). None of these therapies have been included in clinical trials.

PATHOGENESIS

Description of Disease Process

The exact mechanism of the disease process during TBEV infection has not yet been determined, but general hypotheses can be drawn based on clinical data, and data from other neurotropic flaviviruses and arboviruses.

Virus is introduced via tick bite and thought to replicate locally where it may either infect or be phagocytosed by resident macrophages or Langerhans cells. These cells are then believed to migrate to draining lymph nodes where further replication occurs. Replication in the lymph nodes leads to release of the virus into the lymphatic system and subsequent release into venous blood flow where the virus is distributed systemically. It is also possible that virus could penetrate endothelial cells lining lymph vessels to allow infection of surrounding tissues.

TBEV clearly targets neural tissues, but it is not clear how the virus penetrates the blood-brain barrier (BBB). Several hypotheses have been proposed for penetration of the BBB by neurotropic flaviviruses, but none have been conclusively proven. These include migration across or through endothelial cells (Dropulic and Masters, 1990; Liou and Hsu, 1998), the use of toll-like receptors (Wang et al., 2004), and migration across the olfactory epithelium (McMinn et al., 1996; Monath et al., 1983). There have also been suggestions for the point of viral penetration of the BBB through damaged endothelial cells (Lustig et al., 1992). Given the presence of encephalitis or meningitis in afflicted individuals, it seems reasonable to assume that damage to vascular endothelial cells and migration of inflammatory cells may at least contribute to viral introduction into the brain; however, it is not clear whether inflammation is a response to virus that is already in the CNS.

As discussed above, Far Eastern subtype TBEV frequently causes neurological damage to peripheral neurons, particularly in the brachial plexus. These data suggest the possibility of peripheral penetration of the CNS and subsequent migration of virus to the brain in cerebral spinal fluid. The use of magnetic resonance imaging (MRI) has recently proven useful in the detection of damage to the spinal cord and brain during some acute TBEV infections. MRI has identified damage to a range of tissues including anterior horns of cervical and thoracic vertebrae, lumbar nerve roots, basal ganglia, and thalamus in more severe cases (Alkadhi and Kollias, 2000; Bender et al., 2005; Pfefferkorn et al., 2007; Stich et al., 2007), but has also shown that the majority of afflicted persons have normal MRI results (Alkadhi and Kollias, 2000).

Studies examining the localization of Western subtype TBEV viral antigen in historical postmortem samples have identified a fairly specific distribution of viral antigen in the brain. TBEV appears to target large neurons of the anterior pons, medulla oblongata, dentate nucleus, Purkinje cells, and striatum (Gelpi et al., 2005). This study also found that infiltration of cytotoxic T cells was a common result of infection. These data and other evidence suggested that the CD8 positive T cells may contribute to the loss of nerve cells (Gelpi et al., 2005).

PROTECTIVE IMMUNE RESPONSE

The immune response to TBEV infection includes all aspects of host immunity from a strong innate inflammatory response to activation of cell-mediated immunity (CMI) and humoral immunity (HI). Evidence suggests that a cell-mediated response is required for effective clearance of virus, but CMI is also thought to be at least partially responsible for neural damage during severe cases of disease (Gelpi et al., 2005, 2006). HI also plays a protective role during TBEV infection as anti-TBEV IgM and IgG levels in both serum and the CNS are elevated during infection (Gunther et al., 1997; Kaiser and Holzmann, 2000). The vast majority of studies examining the immune response to TBEV have been performed in vaccinated individuals. In these studies, both CMI and HI play a significant role during vaccination. The majority of TBEV vaccines tested to date are nonreplicating vaccines consisting of inactivated virus, subviral particles, or viral subunits. In all cases, it is evident that the stimulation of neutralizing antibodies is correlated with protective immunity. As with other virus diseases, the stimulation of CMI is more closely associated with viral replication; hence, a significant cell-mediated response is not usually seen following vaccination with inactivated virus.

Humoral Immunity

The role of humoral immunity in the protection against infection by flaviviruses, including TBEV, is well established. All currently licensed vaccines have been evaluated for their efficacy by determination of the neutralizing antibody titer induced by the vaccine. The development of neutralizing antibodies is the clinical correlate of protection of a successful vaccine. What is less well understood is the role of humoral immunity in the protection of naïve individuals during a natural infection with TBEV. Very few studies have examined this aspect of disease carefully in humans with studies on convalescent patients making up the majority of these studies. It is clear that the production of virus-specific IgM and IgG occurs during manifest infections and that both are found in serum and the central nervous system (CNS). IgM levels are presumably high during the prodromal stage of disease (8–14 days following infection). IgM levels wane over the course of disease, but are still detectable in some patients at 4–10 months post-infection (Hofmann et al., 1983). It is not clear why some patients would maintain elevated IgM levels.

A majority of patients with TBE have been shown to have elevated IgM and IgG levels in their CSF at presentation with patients demonstrating intrathecal production of IgM and IgG at 15 days post-presentation (Kaiser and Holzmann, 2000). However, it has been shown that the presence of IgM or IgG in the CSF is not a prognostic indicator for the outcome of disease (Gunther et al., 1997; Kaiser and Holzmann, 2000). Patients with low levels of serum IgG (Kaiser and Holzmann, 2000) or CSF IgM (Gunther et al., 1997) early in disease may develop a more severe illness due to an inability to rapidly clear the virus and allow an increased viremia. Individuals with manifest TBE develop high neutralizing titers of IgG with a peak toward the end of the disease phase. IgG titers wane somewhat, but remain elevated (Klockmann et al., 1991). As there are no documented cases of secondary infections with TBEV it is assumed that protective antibody titers remain elevated for life.

The demonstration of virus-specific IgM or IgG is the principal diagnostic tool used for demonstrating a positive TBEV infection. ELISAs represent the primary assays used for the determination of TBEV infection while hemagglutination inhibition assays have also been used as a diagnostic tool. However, neutralization assays are considered the best method for demonstrating the induction of a protective antibody response against TBEV as previous exposure to flaviviruses (e.g., yellow fever vaccine) can confound results from ELISA and hemagglutination inhibition assays (Holzmann et al., 1996). The limitation of neutralization assays is the necessity of working with live virus. TBEV is considered a BSL-3 or BSL-4 virus in most parts of the world; hence, it is not readily available in clinical diagnostic laboratories.

The development of protective antibodies is the basis for successful vaccine development (see below for more extensive discussion). Studies in humans have measured IgM and IgG levels in vaccinated mice and found that neutralizing antibodies are produced following the initial vaccination, but that the titer is significantly increased following secondary and tertiary vaccination. The levels of neutralizing antibodies in humans remain high for several years post-vaccination with early studies indicating that positive hemagglutination titers fell below 70% at 3–4 years after the final boost (Kunz et al., 1991). A more recent study found that some vaccinated individuals were seropositive more than 8 years following their final vaccination, suggesting that the 3-year requirement for boosters could be extended, at least in healthy adults under 50 years old (Hainz et al., 2005; Rendi-Wagner et al., 2004b). However, in elderly persons serum antibody titers wane more quickly, so that shorter booster intervals are indicated in order to maintain protection (Hainz et al., 2005).

Cell-Mediated Immunity

The role of CMI in TBE is unclear at the present time. There have been very few studies that have examined CMI in TBE patients and most point to the CMI as being more detrimental to the host, via CD8-mediated killing of neurons, than beneficial. One study examined the proliferative ability of T-cells isolated from infected individuals and found that a depression of the proliferative response of T-cells led to more severe disease (Shilov and Ryzhaenkov, 2000). Studies examining the CSF of TBE patients have found that an increased cell counts in the CSF are common and that these cells are predominantly lymphocytes (Logar et al., 2000; Ziebarth-Schroth, 1972). There is also evidence that increased CNS cell counts are correlated with more severe disease (Kaiser and Holzmann, 2000). Histopathology studies have also suggested that CD8+ cells may be associated with damage to neurons (Gelpi et al., 2005). Indirect examination of the role of CMI in the CNS suggests that a significant T cell response is likely, as the chemokines CXCL10 and CXCL11 were both elevated in infected individuals (Lepej et al., 2007). CXCL10 and CXCL11 are IFN-γ responsive chemokines that are associated with T-cell recruitment.

As discussed above, the production of a strong neutralizing antibody response to vaccination is the hallmark of successful vaccination. The cell-mediated response is typically less robust as viral replication appears to be required for a strong T-cell response and current vaccines are inactivated non-replicating viruses. In order to stimulate a more profound T-cell response, a number of replication competent vaccines have been developed. Examination of the cellular response to replication-competent vaccines found induction of Th1 type (CD8+)-mediated immunity (Aberle et al., 2005) that may be associated with viral nonstructural proteins (Gomez et al., 2003) while viral C and E proteins are associated with induction of a CD4+ response (Gomez et al., 2003). There remains a number of unknowns regarding the induction of a strong cell-mediated response to vaccination, including the development of a memory response and the potential induction of a detrimental inflammatory response.

While replication-competent vaccines appear to be the best approach for generating a more complete and long-lasting immune response to vaccination, there remains a significant concern about the potential production of infectious virus from these systems.

HISTORY OF TBE VACCINES

Tissue culture–derived TBE vaccines were first developed in 1960 in Russia (Levkovich et al., 1960), and field trials have thereafter demonstrated the efficacy (Chumakov et al., 1963). In 1971, a collaborative effort between the Institute of Virology at the University of Vienna, Austria, and the Microbiological Research Establishment at Porton Down, United Kingdom, started with the aim of developing a vaccine to protect against TBE. An Austrian isolate (strain Neudörfl) of the Western TBEV subtype, subcloned in specific pathogen-free (SPF) chicken embryo cells was used to produce the vaccine antigen. The initial vaccine contained virus grown in suspensions of primary SPF chicken embryo cells, clarified by centrifugation and purified by hydroxylapatite chromatography after formalin inactivation (Kunz, 2003). The vaccine was stabilized with human albumin and further contained aluminum hydroxide as adjuvant. Between 1973 and 1975, this candidate vaccine was administered to about 30,000 people. The Austrian company Immuno took over the vaccine from that point and started commercial marketing of the product in 1976 under the name FSME-IMMUN®. More than 400,000 people received the first generation of this vaccine in Austria and high seroconversion rates (greater than 90% by hemagglutination inhibition test) were observed after two doses (Kunz et al., 1976). Due to a relatively quick decline in antibodies after the second dose, a third immunization was indicated after 9–12 months (Barrett et al., 2003). This vaccine showed a concerning rate of local and systemic side effects, such as headache, malaise, and pyrexia. Since contaminating proteins were assumed to be their cause, continuous-flow zonal centrifugation of the inactivated virus was introduced in 1979 to purify the antigen (Heinz et al., 1980). The new product had a significantly improved purity level, showed good immunogenicity and a reduced level of side effects (Kunz et al., 1980). In the late 1990s the manufacturing process was further modified (Barrett et al., 2003) by changing the seed virus used to inoculate the primary chicken embryo cells from mouse brain–derived material to seed stocks passed twice in chicken embryo cell culture. This passage history eliminated the potential risk of carrying contaminating mouse brain protein into the final product. Further modifications at that point were the elimination of thiomersal and human serum albumin (used as stabilizer) from the formulation. This new formulation was named TicoVac®. Unexpectedly, the elimination of stabilizer led to an increase in adverse events, mostly high fever in infants and young children (Marth and Kleinhappl, 2001). Subsequently, FSME-IMMUN® containing human serum albumin as stabilizer was reintroduced in 2001 in dosages for adult and pediatric applications.

A second European product (Encepur) was developed by Behring-Werke, Marburg (Germany), in the late 1980s using the K-23 strain, a Western subtype isolate from Southern Germany, and reached the market in 1992 (Girgsdies and Rosenkranz, 1996). A pediatric formulation was developed and released in 1995 due to the high incidence of adverse reactions observed in children, especially after the first dose. The Encepur vaccines are produced using essentially the same process used for production of FSME-IMMUN®, the only differences are that virus seed of K-23 was always produced in chicken embryo cells and different stabilizers were applied.

The first vaccine tested in the early 1960s to control KFD in the area of Shimoga district, Mysore state of India, was a 5–10% suspension of formalin-inactivated RSSEV (Far Eastern subtype) (mouse brain preparation) produced by Walter Reed Army Institute of Research laboratory, Washington, D.C., United States. It was injected subcutaneously, two doses a week apart followed by a third dose five weeks after the second. About 4000 vaccinees displayed no unwanted reaction such as allergic and febrile reactions (Aniker et al., 1962). The vaccine induced weak hemagglutination inhibition antibody response but stimulated no

complement fixation antibody response. The vaccine also failed to evoke boost responses in many individuals with previous KFDV infection. The RSSEV-based vaccine was therefore found to be ineffective in reducing the attack rate of KFD or in modifying the disease course (Pavri et al., 1962; Shah et al., 1962). The first effort to produce a KFDV-based vaccine was made by growing KFDV in brains of infant mice and subsequent inactivation by formalin. The vaccine retained potency up to six months if it was stored in a refrigerator and induced neutralizing antibodies in mice (Mansharamani et al., 1965). Another experimental KFDV vaccine was also produced by growing the virus in chick embryo cells, but the product was poorly immunogenic and failed to evoke neutralizing antibody responses in mice (Dandawate et al., 1965a, 1965b). In 1966, another formalized experimental vaccine was successfully prepared by growing KFDV in chick embryo fibroblast cell cultures. The vaccine was found to be immunogenic, potent, stable, and safe (Mansharamani and Dandawate, 1967; Mansharamani et al., 1967). Field trials with this tissue culture vaccine yielded acceptable results, as they induced neutralizing antibodies in 50% of the vaccinees and stimulated protective responses in ~23% of vaccinees (Banerjee et al., 1969). Efforts were also made to develop a live-attenuated KFDV vaccine by attenuating the strain P9605 through serial tissue culture passages. Langurs (*Presbytis entellus*) vaccinated with this attenuated KFDV generated neutralizing antibodies and survived challenge (Bhatt and Anderson, 1971). In another experiment, two dosages of formalin-inactivated KFDV administered to langurs by subcutaneous route induced neutralizing antibodies. The antibodies, though transient, could be detected up to 15 months after administration of the first dose of vaccine. Although the vaccine did not completely protect the langurs from challenge, it prevented death (Bhatt and Dandawate, 1974). A surveillance study indicated that the formalized KFDV vaccine has some, but not absolute, protective effect on vaccinees in Sagar-Sorab taluks of Shimoga district (Upadhyaya et al., 1979).

LGTV is a member of the TBE serocomplex isolated in Malaysia, which is a BSL-2 virus. An attenuated LGTV vaccine based on the E5 strain was also tested and showed protection against KFDV (Thind, 1981). Kayser et al. (1985) studied the human antibody response to immunization with 17D YFV and inactivated TBEV vaccine. They reported that vaccines producing hemagglutination inhibition titers >20 against TBEV showed cross-reaction with KFD. The formalin-inactivated KFDV vaccine produced in chick embryo fibroblasts has been licensed and is currently in use in the endemic areas in Karnataka state of India. The locations for vaccination were selected on the basis of prevalence of KFDV activity in the previous years, including the villages from which mortality in monkeys was reported and those adjacent to the KFDV-affected areas. The efficacy of the vaccine was satisfactory, exerting a highly significant protective effect (Dandawate, 1994). In outbreak situations, almost all individuals, including children, are being routinely vaccinated by the local government authorities. However, the occurrence of KFD cases, despite vaccination, suggests some changes in virus antigenic determinants have occurred. The KFDV strain currently used for vaccine preparation was isolated late in the 1950s. Thereafter, KFDV strains have not been well characterized at the molecular level; hence, possible antigenic drift and diversity since its first introduction in India during the late 1950s remain poorly understood. The trend of increasing KFD cases in Karnataka state warrants development of a new vaccine preparation that includes currently circulating KFDV. Improper storage of vaccine and lack of maintenance of cold chain resulting in inactivation of the vaccine could be another reason for the vaccine failures.

CURRENT LICENSED VACCINES

At least four formalin-inactivated TBE vaccines are currently available, derived from virus grown in chick embryo fibroblasts, inactivated by formaldehyde and purified by either chromatography or continuous flow centrifugation (Table 38.3). These vaccines are administered along a two-dose schedule followed by a booster immunization at one year and recommended booster injections every 3–5 years. They are produced in Austria (Baxter Vaccine; previously Immuno AG), Germany (Novartis, previously Beringwerke), and the Russian Federation (Institute of Poliomyelitis and Viral Encephalitides and Virion Company). Active surveillance in Austria has demonstrated a dramatic decline in the incidence of TBE in vaccinated groups, with an estimated vaccine efficacy of at least 96% (Kunz, 2003). The main reported side effect with currently available vaccines is post-vaccination fever and allergic reactions in children. A series of improvements to the available vaccines were introduced to reduce their reactogenicity. In Germany, the vaccine is widely used to immunize children in high-risk areas. The Russian vaccines also induce high seroconversion rates and are believed to be highly effective, albeit safety data are not readily available (Table 38.3).

An inactivated virus vaccine for KFD was developed many years ago for use in India (see above)

TABLE 38.3 Current Licensed TBE vaccines

	FSME-IMMUN®	Encepur ™	Encevir	TBE vaccine
Manufacturer	Baxter Vaccines, Vienna, Austria	Novartis Vaccines and Diagnostics, Germany	Virion Corporation, Tomsk, Russia	Chumakov Institute for Poliomyelitis and Viral Encephalitides, Moscow, Russia
Virus strain (subtype)	Neudörfl (Western subtype)	K-23 (Western subtype)	205 (Far Eastern subtype)	Sofjin (Far Eastern subtype)
Production method	Cultured in primary chicken embryo cells, purified after formaldehyde inactivation by continuous-flow zonal centrifugation	Cultured in primary chicken embryo cells, purified after formaldehyde inactivation by continuous-flow zonal centrifugation	Cultured in primary chicken embryo cells, purified and concentrated after formaldehyde inactivation	Cultured in primary chicken embryo cells, purified and concentrated after formaldehyde inactivation
Excipients	Aluminum hydroxide, human serum albumin	Aluminum hydroxide, sucrose	?	?
Countries licensed	Austria, Germany, Switzerland, Hungary, Czech Republic, Baltic States, UK, Canada	Germany, Austria, Switzerland, Czech Republic, Baltic States, Russia	Russia	Russia
Pediatric vaccine	1–<16 years old	1–<12 years old	Same as adults	Same as adults
Vaccination schedule (conventional)	0, 1–3 months, 6–15 months Booster doses for adults as per 2005 Austrian Immunization Plan <60 years: first booster after 3 years, subsequently 5-year intervals ≥60 years: 3-year-interval booster doses for children per manufacturer: 3-year intervals	0, 1–3 months, 9–12 months Booster doses for adults as per 2005 Austrian Immunization Plan <60 years: first booster after 3 years, subsequently 5-year intervals ≥60 years: 3-year-interval booster doses for children per manufacturer: 3-year intervals	3 doses	3 doses
Vaccination schedule (accelerated)	Day 0, day 14, 6–15 months Booster doses: as above	Day 0, 7, 21 First booster at 12–18 months, subsequent booster doses as above	NA	NA
Immunogenicity (seroconversion) (conventional schedule)	Adults: 92.9–97% after second dose, 100% after third dose Children: 98.5–100% after second dose, 100% after third dose	Adults: 100% after second dose Children: clinical trials not available	NA	NA
Immunogenicity (seroconversion) (accelerated schedule)	Adults: clinical trials not available Children: 95% after second dose	Adults: 100% after primary series (3 doses) Children: 100% after primary series (3 doses)	NA	NA
Safety	Mild–moderate systemic and local reactions common Fever in very young children common Fever in older children occasional Fever in adults infrequent Severe neurologic reactions rare		NA	NA

(Dandawate et al., 1965a, 1965b, 1980; Mansharamani and Dandawate, 1967; Mansharamani et al., 1965, 1967; Upadhyaya et al., 1979). The vaccine called anti-KFD is produced by the Virus Diagnostic Laboratory (VDL) of the health department of the State government of Karnataka (Shimoga, India). This vaccine is not particularly efficacious and boosters are required annually. Annual epidemics still occur in the endemic area with several hundred cases reported every year (Pattnaik, 2006).

VACCINES IN DEVELOPMENT

Rationale for Next-Generation Vaccines

Issues with Current Vaccines

Safety Since the development of the first TBE vaccines in Europe in the early 1970s (Barrett et al., 2003), a number of safety issues have been observed and new formulations introduced aimed at addressing these issues. As stated above, in 2000, a new, albumin-free formulation of TBE vaccine (Ticovac) was released by Baxter. This formulation elicited severe vaccination side effects in the form of high fever in more than 1% of vaccinated children. As a consequence, in Germany the vaccine use was restricted to individuals 12 years and older. Recently, a lower dosage (50% of the adult dose) with human albumin as a stabilizer was approved in children under the age of 12 after studies showed that this formulation does not induce fever (Marth and Kleinhappl, 2001). A study of the other commercial TBE vaccine Encepur®, established that doses of antigen administered to children should be at least twofold lower than those administered to adults to reduce the risk of fever above 38°C (Girgsdies and Rosenkranz, 1996). Most of the side effects seem to be attributable to the ability of inactivated TBEV particles in combination with alum to stimulate a strong cytokine response (TNF-α and IL-1β) (Marth and Kleinhappl, 2001). Polygeline was used as a proteineous stabilizer in former vaccines causing a relatively high rate of allergic reactions, especially in children. A new formulation has recently proven to show a lower incidence of side effects (Zent and Hennig, 2004). In a study using current (adult) formulations, local reactions were observed in 33–45, systemic reactions in 13–38, and fever in 0.2–9% of the individuals in study groups after receiving their first dose of vaccine (Loew-Baselli et al., 2006). Thus, while the new formulations appear to be safer than their previous counterparts, safety remains a concern. Due to the risks associated with TBE vaccinations [between 2001 and 2005, approximately 1% of vaccinees experienced serious adverse reactions (source: Baxter Product monograph FSME-IMMUN)], vaccination and re-vaccination rates in some endemic areas are lower than one would expect based on virus prevalence, disease severity, and incidence rates, especially in children.

In addition to clinical safety concerns, there are also issues related to vaccine production. Large-scale growth of pathogenic viruses requiring BSL-3 containment adds significantly to the challenges and cost of manufacturing the existing inactivated vaccines.

Multiple Doses All current vaccines require at least three doses to achieve sufficient protective efficacy, followed by another booster after 1–3 years (Beran, 2005; Schondorf et al., 2007). Even when the recommended vaccination schedule is followed, not all subjects develop protective titers of neutralizing antibodies (Ehrlich et al., 2003). Cases of vaccine breakthrough are well documented in the literature, showing the importance of sufficient neutralizing antibody titers (Bender et al., 2004; Kleiter et al., 2007). Shortening of the time intervals between initial vaccinations (accelerated schedule) compromises the magnitude of maximal antibody levels and the duration of protective immunity (Zent and Broker, 2005). Thus, induction of protective efficacy with the currently available products requires several doses and an extended period of time—an abbreviated dosing schedule would therefore represent a significant improvement.

Frequent Boosters The currently available vaccines normally require boosters every 3 years. In addition, clinical data suggest that severe disease outcome in TBE patients can be correlated with lower neutralizing titers (Kaiser and Holzmann, 2000) showing the importance of maintaining sufficient neutralizing antibody titers against TBE viruses. Passive protection by serum transfer was previously used as a treatment of TBE infections in humans, but is not available anymore since there were indications that this treatment can lead to severe disease outcome (Waldvogel et al., 1996). This might be linked to the fact that success with serum transfer is only successful if it occurs before the virus enters the CNS (Nalca et al., 2003). This suggests that in order to properly protect individuals over the long term with the vaccines currently available, regular boosting is required to maintain appropriate serum titers of neutralizing antibodies. Increased durability of immune response and protective efficacy would represent a distinct improvement to the existing vaccines.

Lower Efficacy in the Elderly Population Recent data indicate that it may be acceptable for individuals up to 49 years old to extend the booster interval with the currently available vaccines to 5 years (Beran, 2005). For older persons boosters are still required every 3 years (Rendi-Wagner et al., 2004a). This is due to lower virus neutralizing titers observed in elderly persons, especially after only completing the initial vaccination course (3 doses) (Rendi-Wagner et al., 2004a). Hainz et al. (2005) described a study of vaccine efficacy, which showed that 1–2 years after the last vaccination, 16% in a group of persons over 60 years old had TBE-specific ELISA titers below the recommended levels (<100VIE units). Among individuals of the same age group who were last vaccinated 2–3 years previously, 27% tested negative. Waning antibody titers potentially compromising efficacy, seem to be particularly problematic in the immunosenescent population.

Protection Range The commercially available vaccines are only indicated for protection against a single TBE subtype (CEEV or RSSEV). While cross-neutralizing activity against Far Eastern strains has been demonstrated with current vaccines, the cross-reactive virus-neutralizing titers are lower (Hayasaka et al., 2001; Leonova et al., 2007). No current product claims protective efficacy against the even more distantly related viruses of the TBE complex such as POWV, OHFV, and KFDV. A vaccine which could protect against the spectrum of TBE complex viruses would provide a significant advantage over existing products—especially since no products of satisfactory quality are available for protection against KFDV and OHFV.

Other Approaches to Vaccine Development

Recent experimental approaches to produce novel TBEV vaccines include DNA vaccines (Schmaljohn et al., 1997) and recombinant vaccinia viruses (Dmitriev et al., 1996) (Table 38.4). Vaccinia strains expressing the segment of proteins from E to NS1 provided the best level of protection. Novel vaccines could also be based on attenuated strains of TBE viruses. Studies have shown that deletions in the 3′ noncoding region can lead to highly attenuated mutants in the mouse model (Mandl et al., 1998). Large deletions in the capsid protein seem to lead to attenuation by disturbing virus assembly (Kofler et al., 2002). An approach using chimeric viruses based on swapping the prM and E structural protein genes into a dengue-4 virus backbone with a 30 nucleotide deletion in the 3′ noncoding region (TBEV/DEN4Δ30 and LGT/DEN4) has shown good safety in monkey trials (Rumyantsev et al., 2006); vaccine efficacy was demonstrated against LGTV challenge, but suggests that further improvement might be necessary. Candidate vaccines based on purified, insect cell–expressed recombinant subunits have demonstrated broad protective potential, which included protection against OHFV in the mouse model.

CLINICAL TRIALS

At this time no clinical trials for novel vaccines are being reported. Post-marketing surveillance continues on the European formulations.

POST-EXPOSURE IMMUNOPROPHYLAXIS

In Russia, prevention of TBE with the use of specific immunoglobulins is still available (via a product from the Chumakov Institute of Poliomyelitis and Viral Encephalitides, Moscow). This treatment is effective when administered to tick-bitten persons within 3 days post-bite. This therapy is reported to be effective in 98% of cases in a curative context and 100% in a prophylactic context (i.e., administered to individuals before visiting natural foci of TBEV) (Charrel et al., 2004). In Europe, the two products based on TBE immunoglobulin [Encegam® (Behring) and FSME-bulin (Baxter)] were produced. However, they initially lost their license for administration to children aged up to 14 years because of a suspected association between post-exposure application of immunoglobulin and severe forms of the disease (Arras et al., 1996; Kluger et al., 1995; Waldvogel et al., 1996). Subsequently, both products were withdrawn completely from the market and are no longer available, even though the suspected antibody-dependent enhancement (demonstrated in vitro) could not be shown in vivo in the mouse model (Kreil and Eibl, 1997). It is likely that the remaining Russian product will have little future because of safety regulations regarding the use of human-derived products for treating humans.

Theoretically, active TBE vaccination could be considered as an alternative to post-exposure prophylaxis—but since increased reactogenicity has been associated with higher antigen doses, particularly at the beginning of the primary immunization course, it is unlikely that currently vaccines will be recommended for this use.

TABLE 38.4 TBE vaccines in development

Candidate	Description	Stage of development	Developer
DNA vaccine	DNA vectors expressing CEEV E or prM+E region of virus polyprotein	Some of the candidates were successful in achieving protective efficacy in mice. Gene gun application was more successful than injection	University of Vienna, Austria
DNA vaccine	DNA vectors expressing either CEEV or RSSEV prM+E region of virus polyprotein	Proof-of-concept in mouse and nonhuman primates successful with vaccine administered using particle bombardment technique	USAMRIID, Frederick, USA
DNA vaccine	DNA vectors expressing CEEV NS1 protein	DNA vaccine alone protected a significant portion of vaccinated mice from live virus challenge (Timofeev, 2004). A prime-boost approach applying a recombinant vaccinia vector expressing NS1 protein also showed a high level of protection against RSSEV (Aleshin, 2005)	Chumakov Institute of Poliomyelitis and Viral Encephalitides, Moscow, Russia
Recombinant TBE/vaccinia viruses	Recombinant vaccinia viruses were created incorporating various polyprotein segments from the capsid protein C to NS3	Candidates were successful in protecting mice from live virus challenge	VECTOR, Novosibirsk, Russia
Recombinant TBE/vaccinia viruses	Recombinant vaccinia vector was created expressing the prM+E section of CEEV	Good immunogenicity and efficacy was seen with sufficient doses in the mouse model (Holzer, 1999)	Baxter, Orth, Austria
Recombinant TBE/ adenovirus	Adenovirus (Ad51) expressing NS1 protein	Vaccine candidate protected mice against challenge and potentiated immune responses observed if administered together with killed virus vaccine	Chumakov Institute of Poliomyelitis and Viral Encephalitides, Moscow, Russia
Recombinant TBE/dengue 4 viruses	Attenuated dengue-4 vaccine strain expressing Langat or RSSEV prM+E	Recombinant viruses are safe in immunodeficient mice and induce neutralizing antibody titers in mice and nonhuman primates. Protective efficacy against Langat virus was demonstrated in nonhuman primates	NIH/NIAID, Bethesda, USA
Attenuated Langat virus	Attenuated version selected after serial passages of LGT E5 in embryonated chicken eggs—strain LGT E5	A previous candidate (LGT TP21) caused neurological disease in 1/18,570 vaccinees in a Russian clinical trial (Smorodincev, 1986). The new candidate vaccine strain shows markedly reduced neurovirulence in SCID mice (Rumyantsev et al., 2006)	NIH/NIAID, Bethesda, USA
Attenuated TBE virus	Attenuation is achieved by intentional amino acid deletions in the capsid protein region	Attenuated virus has shown safety and immunogenicity in mice	University of Vienna, Austria
Peptides from TBE NS1 protein	Various peptides identified in the NS1 protein of RSSEV representing linear epitopes were tested	One peptide (aa 37–55) provided partial protection in the mouse model of TBE virus infection	Chumakov Institute of Poliomyelitis and Viral Encephalitides and Institute of Bioorganic chemistry (both Moscow, Russia)
Recombinant E subunits	Envelope subunit proteins of RSSEV and CEEV expressed by insect cells	Candidates have shown efficacy against RSSEV, CEEV, and OHFV in the mouse model	Hawaii Biotech, Aiea, USA
Recombinant subviral particles and other recombinant proteins	Various forms of recombinantly expressed or virus-derived subunits from CEEV	Recombinant subviral particles and rosettes showed good immunogenicity and efficacy in the mouse model, while soluble forms were much less immunogenic (Heinz et al., 1995)	University of Vienna, Austria

PROSPECTS FOR THE FUTURE

All current novel TBE vaccine approaches are still of mainly academic interest and have not reached the industrial development stage. It is unlikely that a recombinant subunit or live-attenuated TBEV vaccine will be licensed within the next 5 years.

Post-exposure treatment using TBE Ig is no longer recommended in almost all European countries and it is expected that during the next 5 years the recommendation to use Igs for post-exposure treatment will be revoked for the remaining European Union (EU) member states. Recommendations for post-exposure prophylaxis on the basis of active TBE immunization are not expected in the near future.

KEY ISSUES

- The endemic range of TBE viruses is increasing in multiple regions across the world.
- The increase in TBE case numbers is believed to be largely associated with an increase in outdoor activity and increased contact with the tick vectors.
- Although mortality rates associated with TBEV infections are not very high, the most serious effect is the high prevalence of long-term sequelae caused especially by the Far Eastern strains.
- Due to considerable stability, members of the TBE complex are considered to be serious candidates to be used as biowarfare agents that could be disseminated via various routes of exposure.
- The quality and quantity of available vaccine in many Eastern European countries is poor. Vaccine coverage in those endemic areas is well below the desirable range.
- No commercial vaccines are available to protect against "exotic" members of the TBE complex (Kyasanur Forest Disease and Alkhurma viruses).
- The cost of well-established and effective "Western" vaccines is high and as recently as in the 2007 season there has been a shortage in available doses.
- Vaccines require routine boosts to maintain efficacy, especially in the elderly population.

West Nile

John T. Roehrig
Arboviral Diseases Branch, Division of Vector-Borne Infectious Diseases, Centers for Diseases Control and Prevention, U.S. Public Health Service, Department of Health and Human Services, Fort Collins, CO, USA

OUTLINE

ABSTRACT

West Nile virus (WNV) is an emerging flavivirus throughout the western hemisphere. Originally isolated in Africa in 1937, WNV jumped continents, first to Europe, and later to North America in 1999. Since its original discovery in the New York City area in 1999, WNV has been on an inexorable march west and south through North, Central, and South America, demonstrating a 20% human morbidity rate and a 30% equine case-fatality rate. By the end of 2007, there have been over 27,000 human cases of WNV with 1086 human case fatalities in the United States alone. The unexpected introduction of WNV into the United States continues to serve as an excellent example of the effects an emerging infectious disease can have on the public health infrastructure of a country, and the subsequent steps taken to track, prevent, and control such events.

INTRODUCTION

Although West Nile virus (WNV) can be considered an "old" virus historically, it is currently an "emerging" viral agent and serves as a model of a bioterror threat. In 1999 WNV was first discovered in the New York City area. How and when WNV made the jump from the Middle East to North America has been and probably will never be adequately explained (Lanciotti et al., 1999). It has been assumed that the virus was introduced in an infected mosquito or a legally or illegally imported bird. In the fall of that year, the U.S. Centers for Disease Control and Prevention's Division of Quarantine undertook a study to identify commerce flow between the two regions, but were never able to determine a likely source for the virus. Regardless of how WNV jumped continents, WNV has had a significant economic and public health impact on the United States. As the virus moved westward with a 20% human morbidity rate and a 30% equine case-fatality rate, considerable resources were invested in surveillance, diagnostics, prevention, and control of this disease. National guidelines for prevention and control of WNV in the United States were drafted in 1999, modified twice, and are still used today (http://www.cdc.gov/ncidod/dvbid/westnile/resources/wnv-guidelines-aug-2003.pdf).

There were a number of lessons learned or relearned from this experience. The state and local public health infrastructure needed to respond to a major vector-borne disease outbreak was in shambles from years of neglect. The last major vector-borne disease outbreak in the United States occurred in the late 1970s and was caused by St. Louis encephalitis (SLE) virus. Even though enzootic/endemic transmission of viruses like LaCrosse and eastern equine encephalitis viruses occur on a yearly basis, public health dollars were spent on vector-borne disease programs in only a handful of jurisdictions. The national collective public health expertise was maintained only at the CDC through their longitudinal programs. Because of that expertise, a national response was mounted rapidly, and programs were initiated and funded to reestablish the infrastructure and knowledge base necessary for vector-borne disease prevention and control programs. These programs are essential since it is apparent that once a mosquito-borne agent takes hold in a new region, it is virtually impossible to eradicate, and that even with relatively low human case-fatality rates, the social, human behavioral, and economic load can be significant. As always, the trick is to develop a creative vision to guide retention of the newly developed expertise as vector-borne diseases again fade from the short collective memories of the public and politicians.

SHORT HISTORY OF THE DISEASE

WNV was first isolated from the serum of a febrile woman in the West Nile district of Uganda in 1937. Since that time, WNV has circulated in endemic and occasionally epidemic transmission cycles throughout Europe, Western Asia, Africa, the Middle East, Australia (as Kunjin virus), and North and Central America (Fig. 39.1). Major outbreaks of WNV have been documented throughout the world (Table 39.1). In 1999 a WNV outbreak was recognized in the United States for the first time. This initial human and animal outbreak was identified in the New York City area. Genetic studies determined that this virus introduction likely occurred from the Middle East, most likely from Israel (Lanciotti et al., 1999). Since that time, WNV has spread westward through the entire continental U.S. and into Canada, Mexico, Central America, and some Caribbean islands (Table 39.2 and Fig. 39.2).

ETIOLOGIC AGENT

Classification

WNV is an arthropod-borne virus (arbovirus) and as such is transmitted to humans and other animals through the bite of a virus-infected mosquito, usually of the genus *Culex*. WNV is a member of the family *Flaviviridae*, genus *Flavivirus*. The WNV genome is a positive-sense, single-stranded RNA of about 11,000 nucleotides (Fig. 39.3). The RNA genome has a single open-reading frame that encodes a polycistronic precursor protein (Rice et al., 1985). Three structural proteins: capsid, (C), premembrane (prM), and envelope (E), and seven nonstructural proteins: (NS1, NS2A, NS2B, NS3, NS4A, NS4B, and NS5) are encoded by the genome (Chambers and Rice, 1987; Rice et al., 1985). The 5′-end of the genome is noncoding, capped, and not polyadenylated. The 3′-end of the genome is noncoding and assumes a stabilized, folded structure that has been well-studied. Serological classification places WNV within the Japanese encephalitis virus (JEV) complex along with other medically important flaviviruses such as SLE, Murray Valley encephalitis (MVE), and Kunjin (KUN) viruses.

Antigens Encoded by the Agent

The WN virion contains a nucleocapsid formed by C proteins that protects the viral genomic RNA. The virion is enveloped. The envelope is derived from host

cell membrane that has been modified by the insertion of the prM and E-proteins. The prM protein is cleaved in a host cell-dependent manner to pr and M protein during late viral maturation. The M protein stays incorporated in the virion envelope while the pr is released into the extracellular fluid. The virion structure has been solved by cryoelectron microscopy (Fig. 39.4). The envelope is highly ordered and is composed of 90 closely packed homodimers of the E-protein (Kuhn et al., 2002; Mukhopadhyay et al., 2003). The primary antigens for all flaviviruses are the E, C, prM, M, NS1, NS3, and NS5 proteins. The immunogenicity of the NS2A, NS2B, NS4A, and NS4B has not been well-studied.

PROTECTIVE IMMUNE RESPONSE

Antibody

The adaptive, protective immune response to WNV infection is driven by the presence or absence of antibodies that neutralize virus infectivity. Virus-neutralizing antibodies are largely elicited by the E-protein (for review, see Roehrig, 2003). There is nothing remarkable about the human antibody response to WNV infection. Upon infection WNV elicits IgM, IgG, and IgA responses. The IgM response begins early, frequently before onset of symptoms, and can persist in serum or cerebrospinal fluid (CSF) in cases of WN neuroinvasive disease (WNND) (Kapoor et al., 2004; Roehrig et al., 2003). IgM is usually always detectable in serological assays by 7–8 days post-onset of symptoms. IgA antibodies are also detectable early in infection and have half-lives similar to IgM (Prince et al., 2005b).

TABLE 39.2 WNV activity in the United States, 1999–2006

Year	States[a]	Humans/fatalities	Birds	Mosquito pools	Veterinary

IgG antibodies are detectable soon after infection and are maintained for years.

Structural Proteins

The molecular structure of the flaviviral E-protein has been solved by x-ray crystallography for WN (Nybakken et al., 2006; Kanai et al., 2006), dengue (DEN) 2, DEN 3, and tick-borne encephalitis (TBE) viruses (Modis et al., 2003, 2005; Rey, 2003; Rey et al., 1995). While the E-protein amino acid sequences vary, the overall E-protein structure appears to be conserved among all flaviviruses studied thus far. The E-protein is the most important viral antigen for eliciting a protective immune response and is a Class II viral fusion protein that undergoes an irreversible oligomeric reorganization at acidic pH (Modis et al., 2004; Rey, 2003; Zhang et al., 2004). Antibodies to the E-protein limit or neutralize viral infectivity by blocking attachment of viruses to cells and blocking virus-mediated cell-membrane fusion, both of which are critical steps in virus infection (Butrapet et al., 1998; Crill and Roehrig, 2001; Gollins and Porterfield, 1986; Roehrig, 2003).

The E-proteins of TBE and DEN viruses have been studied most completely, and flaviviral structure–function relationships that are generally applicable to all flaviviruses have been developed and are reviewed in detail elsewhere (Allison et al., 1999; Guirakhoo et al., 1989; Heinz et al., 1982, 1983, 1984, 1991; Mandl et al., 1989; Rey et al., 1995; Roehrig et al., 1998). Briefly, three structural domains, I, II, and III, have been identified in the E-protein monomer (Fig. 39.5). These structural domains appear to be identical to the functional and antigenic domains C, A, and B previously identified for TBE and DEN virus E-proteins (Rey et al., 1995). Domain II (A-domain) is the dimerization region and contains the fusion peptide. This domain contains flavivirus cross-reactive epitopes. Domain III is an immunoglobulin-like structure that is likely involved in cell attachment and can be rescued from proteolytically cleaved E-protein as a stable 9–10 kDa peptide (approximately amino acids 300–400). Domain III can also be expressed in a variety of expression systems. Domain III elicits strongly neutralizing and virus-specific antibodies. Domain I contains the molecular "hinge" about which the low pH catalyzed oligomeric reorganization occurs (Bressanelli et al., 2004; Modis et al., 2004; Stiasny et al., 2004). It is not surprising that important epitopes in Domains I and II are highly conformational. It is important to note that only DEN viruses are glycosylated at N67, and WNV does not have an N-linked glycosylation motif at this location. In addition, utilization of the N153 N-linked motif by WNV is variable. It has been shown that usage of the N153 glycosylation motif helps define viral neuroinvasion (Beasley et al., 2004, 2005).

Panel B, C-alpha trace showing the fitted E-protein heterodimers looking down the fivefold axis. Courtesy of Baerbel Kaufmann and Richard Kuhn, Purdue University (see color plate section).

The C and prM proteins can elicit antiviral antibody. It has been suggested that anti-prM and anti-E-protein antibodies can neutralize virus infectivity by interfering with viral attachment to dendritic cell-specific ICAM-3 grabbing nonintegrin (DC-SIGN) bearing dendritic cells (Barba-Spaeth et al., 2005; Kwan et al., 2005; Lozach et al., 2005; Marovich et al., 2001; Modis et al., 2005; Navarro-Sanchez et al., 2003; Palmer et al., 2005; Sakuntabhai et al., 2005; Tassaneetrithep et al., 2003; Wu et al., 2000). The significance of this observation in vivo has yet to be thoroughly explored; however, evidence with both WNV and DEN virus suggest that virus–DC-SIGN interaction may play a pivotal role in capturing virus through mannose residues in their N-linked glycosylation sites onto susceptible cells (Pokidysheva et al., 2006).

Nonstructural Proteins

The most important antibody response to flaviviral nonstructural proteins is elicited by the NS1 protein (Cane and Gould, 1988; Costa et al., 2006; Henchal et al., 1988; Konishi et al., 1991; Macdonald et al., 2005; Putnak and Schlesinger, 1990; Schlesinger et al., 1986, 1987, 1993; Zhang et al., 1988). The anti-NS1 response has been intensely studied in DEN and yellow fever (YF) virus-infected mice. Passive antibody protection studies using murine anti-NS1 monoclonal antibodies demonstrated some protective effects against DEN or YF virus infection. Since the NS1 protein is not expressed in the infectious virion, but rather it is expressed on virus-infected cell surfaces, it is believed that anti-NS1 antibodies mediate protection at the level of the virus-infected cell. Similar studies with viruses causing encephalitis—like WNV—have not been performed. Antibody responses to other NS proteins of WNV have not been well-studied; however, the antibody response to the WNV NS5 protein has served as the target to diagnose WNV infections in humans using a microsphere immunoassay.

T-Cell Epitopes

As with all viruses, both CD4 and CD8 T-cells are required to drive the immune response to flaviviruses. WNV is no exception. WNV T-cell epitopes have not been well-defined; however, results from other

Fusion loop (aa 98–110)) marked in DII. Structural coordinates from Modis et al. (2003) (see color plate section).

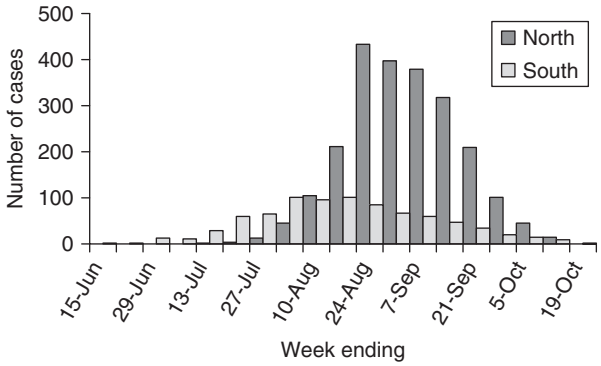

FIGURE 39.6 Distribution of human WNND in temperate (north) and more tropical (south) regions of the United States.

closely related flaviviruses (e.g., JE and MVE viruses) can likely be extrapolated to WNV. Recent studies in animal models have reaffirmed the requirement for a CD8 T-cell response for viral clearance and recovery (Klein et al., 2005; Shrestha and Diamond, 2004; Shrestha et al., 2006; Wang et al., 2003b). The NS3 protein seems to contain the most important flaviviral cytotoxic T-cell epitopes (Douglas et al., 1994; Hughes, 2001; Kesson et al., 2002; Kurane et al., 1991, 1995, 1998; Lobigs et al., 1994, 2003; Mathew et al., 1996; Okamoto et al., 1998; Rothman et al., 1996; Zivny et al., 1995). Helper T-cell epitopes have been identified on the E-protein as well (Mathews et al., 1991, 1992; Roehrig et al., 1992).

EPIDEMIOLOGY

Significance as Public Health Problem

WNV now accounts for the largest number of cases of viral encephalitis in the United States. Worldwide WNV is an arbovirus, primarily transmitted by the mosquitoes of the genus *Culex* (e.g., *Culex tarsalis*, *Culex pipiens pipiens*, *Culex pipiens quinquefasciatus*, *Culex salinarius*, and *Culex nigirpalpus* in the United States). Mosquito-borne transmission to humans in temperate climates usually peaks in the late summer and early fall (Fig. 39.6). Mosquito-borne transmission to humans in milder or more tropical climates can occur throughout the year, whenever mosquitoes are active.

In the United States alone, however, 62 species of mosquitoes have been shown to be infected with WNV. The actual vector-status of many of these mosquito species remains to be determined. WNV is a zoonotic disease with birds being the primary natural reservoir. Over 300 species of birds have been shown to be WNV-infected in the western hemisphere. Humans are primarily infected through the bite of a WNV-infected mosquito. Recently, other modes of WNV transmission have been identified such as blood transfusion, tissue transplantation, percutaneous occupational exposure, breast feeding, and intrauterine transfer (Hayes and O'Leary, 2004). The last two modes of transmission have been documented, but are very rare (O'Leary et al., 2006; Paisley et al., 2006).

Even though WNV has now been in the United States since 1999, molecular epidemiological analysis of current and past strains of the U.S. WNV has demonstrated low-level genetic drift, with remarkable overall phenotypic stability (Davis et al., 2005; Lanciotti et al., 1999, 2002). WNV can be divided into two genetic lineages (1 and 2), with lineage 1 WNVs primarily responsible for major human outbreaks (Fig. 39.7). Lineage 1 strains have been divided into four clades: A, B, Indian, and KUN (Beasley et al., 2004).

Potential as Biothreat Agent

The potential of using WNV as an agent to inflict mass human casualties via aerosol application is small. The experience of the United States following the introduction of WNV has demonstrated, however, that WNV

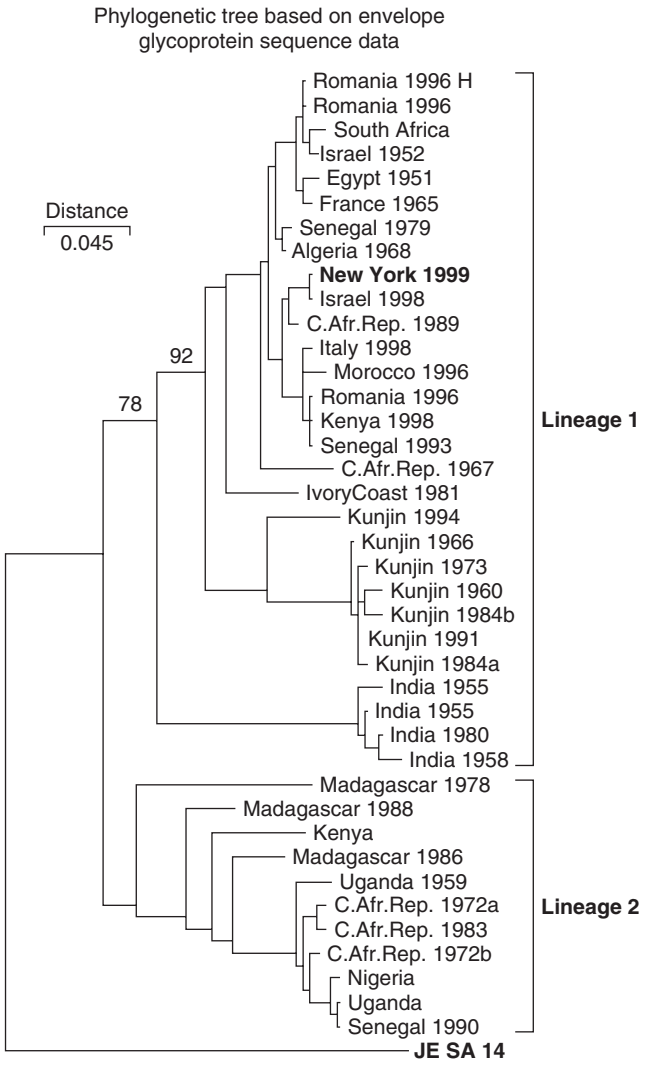

FIGURE 39.7 Phylogenetic tree of WNV based on E-protein gene sequence data. Two major lineages (1 and 2) are shown. Courtesy of R. Lanciotti, CDC. MEGA, distance tree, Kimura 2-parameter, neighbor-joining.

transmission can cause significant human, avian, and equine outbreaks, and can be quite financially costly. The determination that WNV can be transmitted from human-to-human through transfer of contaminated blood products has resulted in the screening of the entire U.S. blood supply for WNV on a continuing basis (Anon 2002; Anon 2003a; Anon 2003b; Busch et al., 2005a; Cameron et al., 2006; Custer et al., 2006; Epstein, 2005; Gallian et al., 2005; Hardinger et al., 2003; Harrington et al., 2003; Hiatt et al., 2003; Humar, 2004; Iwamoto et al., 2003; Kiberd and Forward, 2004; Kleinman et al., 2005; Lee et al., 2005; Macedo de Oliveira et al., 2004; Petersen and Epstein, 2005; Prince et al., 2005a; Rados, 2003; Stramer et al., 2005). This testing is quite costly, but has been shown to have likely averted over 4000 blood-borne WNV infections in the United States since it was initiated. A similar survey for WNV-contaminated blood in Mexico, identified only one WNV positive specimen (Sanchez-Guerrero et al., 2006).

CLINICAL DISEASE

Approximately 20% of human infections with WNV result in clinical disease. Less than 1% of human infections with WNV result in WNND (Mostashari et al., 2001). Incidence of WNND and death increase with age; however, persons of all ages appear equally susceptible to infection. West Nile fever (WNF) is characterized by an acute onset of flu-like symptoms including fever, headache, malaise, and myalgia, and frequently a transient rash. WNND may result in meningitis, encephalitis, and poliomyelitis-like flaccid paralysis resulting from infection of the anterior horn cells of the spinal motor neurons (Hayes et al., 2005; Jeha et al., 2003; Li et al., 2003; Sejvar et al., 2003). Individuals with WNND may suffer from relatively long-term sequellae that may persist for years (Klee et al., 2004). The overall case-fatality rate for WNND is approximately 9–10% (O'Leary et al., 2004).

DIAGNOSIS

The diagnosis of WNV infection in humans is primarily based upon the detection of WNV-specific IgM in serum or CSF specimens from individuals with clinically compatible symptoms of WNF or WNND (Malan et al., 2004; Martin et al., 2002, 2004). WNV-specific IgM is usually detectable by 8 days post-onset of clinical symptoms and is measured in an IgM antibody-capture enzyme-linked immunosorbent assay (MAC-ELISA). There are currently three U.S. Food and Drug Administration approved WNV-reactive MAC-ELISAs commercially available. Individuals with WNV-specific IgM in their CSF are considered confirmed WNV infections. One caveat of IgM testing is the possible long-term persistence of WNV IgM in serum (greater than 12 months with some patients) (Roehrig et al., 2003). This observation could confuse interpretation of the actual time of infection.

Newer platforms for detection of anti-WNV antibody have been developed. These microsphere immunoassays detect IgM or IgG antibody specific for either the E or NS5 proteins (Johnson et al., 2005, 2007; Wong et al., 2003, 2004). The advantages of these tests are the requirement for smaller specimen volumes, less time to perform testing, and the ability to multiplex

testing using a variety of arboviral antigens with a single specimen.

Because of the possibility of flaviviral cross-reactivity of serum IgM with other flaviviruses, a second-tier and more virus-specific assay (plaque-reduction neutralization test, PRNT) is frequently performed. The PRNT is more virus-specific that ELISAs, but is usually only performed in state public health laboratories or national reference laboratories. Because of the aforementioned serological cross-reactivities of flaviviral immune sera, it is also important to acquire a complete travel and vaccination history from a suspected WNV patient.

For infected humans, nucleic acid amplification tests (NAATs) such as reverse-transcriptase polymerase chain reaction (RT-PCR) or real-time PCR (e.g., TaqMan) and nucleic acid sequence-based assay (NASBA) are useful in only about 50% of cases maximally (Lanciotti, 2003; Lanciotti and Kerst, 2001; Lanciotti et al., 2000). This low level of sensitivity results from a low WNV viremia at the time of hospital presentation of an ill individual. The NAATs are more useful in screening blood donations for WNV contamination (Macedo de Oliveira et al., 2004; Pealer et al., 2003). WNV NAAT-positive blood donations are usually acquired prior to the onset of disease in the blood donor when viremias are higher. Currently every U.S. blood donation is tested for WNV contamination using FDA approved NAATs (Busch et al., 2005a, 2005b; Custer et al., 2006, 2004; Kleinman et al., 2005; Prince et al., 2005a; Tobler et al., 2005).

With appropriate fresh or formalin-fixed tissue specimens (e.g., brain tissue), WNV infection and can be unambiguously identified by immunohistochemistry or in situ PCR, and occasionally virus isolation (Agamanolis et al., 2003; Iwamoto et al., 2003; Shieh et al., 2000). Unfortunately these specimens are only available upon autopsy of a fatal WNV infection.

TREATMENT

Current treatment for WNF and encephalitis is purely supportive, and the degree of treatment depends on the severity of symptoms. Mild WNV infections may require only medication for pain and liquids for rehydration; however, severe WNND may require ventilator support.

Antivirals

There are no licensed antiviral agents designed for or proven to be effective against WNV infection. Two antivirals, ribavirin and interferon, have been used on a compassionate basis, with very limited success. Ribavirin can inhibit WNV multiplication in vitro in human neural cell culture at high doses (Crance et al., 2003; Day et al., 2005; Jackson, 2004; Jordan et al., 2000; Leyssen et al., 2005). There have been no controlled subhuman primate studies to determine the ability of ribavirin to limit WNV infection.

More is known about the antiviral effects of alpha-interferon; however, no controlled experimental studies of the therapeutic value of interferon during WNV infection of subhuman primates or humans have been reported (Anderson and Rahal, 2002; Guo et al., 2005; Hrnicek and Mailliard, 2004; Kalil et al., 2005; Liu et al., 2005; Morrey et al., 2004; Samuel and Diamond, 2005; Scholle and Mason, 2005; Wang et al., 2003a). In the mouse model of infection, WNV resistance has been linked to the presence or absence of functional 2′,5′-oligoadenylate synthetase and RNase L gene complexes that participate in the interferon response (Kajaste-Rudnitski et al., 2005; Lucas et al., 2003; Mashimo et al., 2002; Perelygin et al., 2002; Silvia et al., 2004; Urosevic, 2003; Yakub et al., 2005). The requirement for interferon in an innate murine response to WNV infection was confirmed by observing enhanced virulence of WNV in interferon-deficient mice. While human trials are underway, to date only anecdotal observations of the antiviral efficacy of alpha-interferon in humans have been reported.

Preexposure Antibody Prophylaxis and Postexposure Antibody Therapy

Because protection from flaviviral infection can be mediated by virus-neutralizing antibody, it seems plausible that preexposure antibody prophylaxis would be a reasonable approach to disease prevention. Studies in mice using polyclonal and monoclonal antibodies have shown that virus-neutralizing antibodies can prevent challenge with WN, SLE, JE, TBE, or MVE viruses (Engle and Diamond, 2003; Gould et al., 2005; Hsieh et al., 1963; Kreil, 2004; Kreil et al., 1997, 1998a, 1998b; Kreil and Eibl, 1997; Mathews and Roehrig, 1984; Roehrig et al., 2001; Roodyn, 1974; Simkova, 1959). The timing of the antibody application is critical for animal survival. Results from most previous investigations suggest that once the virus has entered the brain, any therapeutic effect of antibody is lost. A recent study with WNV in an inbred mouse and hamster models demonstrated that murine or human MAbs or human single-chain variable region antibody fragments human could cure also WNV-infected animals (Morrey et al., 2006, 2007; Gould

et al., 2005; Oliphant et al., 2005). Similar data does not exist for humans.

PATHOGENESIS

After being bitten by a WNV-infected mosquito, the virus replicates in local cell populations. Splenic dendritic cells have been implicated as a site of WNV replication (Kulkarni et al., 1991). Virus then spreads to the draining lymph nodes and enters the blood stream. It has been recently hypothesized that virus entry into the central nervous system (CNS) is via increased permeability of the blood-brain barrier (Wang et al., 2004). Previous studies with SLE virus suggested that this virus enters the CNS directly from the blood through exposed neurons of olfactory system (Monath et al., 1983). Other mechanisms of viral entry into the CNS, such as retrograde virus transport via non-olfactory neurons, has not been ruled out (Hunsperger and Roehrig, 2005). WNV will infect a variety of neurons in the brain, brainstem, and spinal cord (Agamanolis et al., 2003; Ceccaldi et al., 2004; Guarner et al., 2004; Hayes et al., 2005; Kleinschmidt-DeMasters et al., 2004; Shieh et al., 2000). There are no well-characterized genetic factors associated with human risk of acquiring WNND; however, deficiencies in the 2′, 5′-oligoadenylate synthetase pathways and the subsequent interferon response has been associated with murine susceptibility to WNV (Bonnevie-Nielsen et al., 1995; Kajaste-Rudnitski et al., 2005; Lucas et al., 2003; Mashimo et al., 2002; Perelygin et al., 2002; Yakub et al., 2005). A generalized skin rash has been associated with WNF; however, it is not known if the virus replicates in the skin.

Preliminary observations in mice and humans indicate that a genetic predisposition to severe WNV disease may be associated with a nonfunctional CCR5 gene product. The significance of these observations await corroborative studies (Glass et al., 2005, 2006).

VACCINES

No WNV vaccines are approved for human use. There are, however, four vaccines approved by the United States Department of Agriculture (USDA) for use in horses (Ng et al., 2003). The vaccine currently commercially available is a formalin-inactivated cell culture-based vaccine requiring two doses and is produced by Fort Dodge Animal Health. The parental virus for this vaccine is a strain of WNV isolated from a horse 1999 WNV outbreak in the New York City area. It is currently administered as a monovalent vaccine; however, there should be no problem with multivalent formulations including other killed equine encephalitis vaccines. Currently annual booster immunizations are recommended for this vaccine.

The second vaccine, developed in a partnership between Fort Dodge Animal Health and researchers at the U.S. Centers for Disease Control and Prevention is a DNA vaccine that expresses the prM and E-protein of WNV in the form of a virus-like particle (Davis et al., 2001). This vaccine has USDA approval and is currently in production for an eventual commercial release. It has also been used to protect successfully the endangered California condor population in the western United States (G.-J. Chang, personal communication). This is the first DNA vaccine ever approved for commercial applications, and is also in Phase I human clinical trials.

The other vaccines are recombinant vaccines. One vaccine is a canarypox virus-vectored WNV vaccine (Minke et al., 2004), and the other is a WNV/YF chimeric virus (Arroyo et al., 2004).

VACCINES IN DEVELOPMENT

Rationale of Second/Third/New Generation Vaccines

Besides inactivated and DNA vaccines, a variety of other WNV are currently in various stages of development (Table 39.3). Any WNV vaccine will require appropriate expression of the E and prM proteins. Three new vaccines: a WNV/YFV chimera (ChimeriVax, Acambis, Ltd.); a WNV/DEN2V chimera (U.S. CDC); and a poxvirus-vectored vaccine, express the WNV prM and E-proteins in heterologous viral backgrounds. An additional candidate is an attenuated WNV vaccine, and as such elicits an authentic adaptive immune response to all WNV proteins. The benefit of including the NS1 protein as part of a recombinant vaccine is still an open issue. From a public health perspective, the additional protection possibly afforded by anti-NS1 antibody has to be balanced by the inability to differentiate current infections with WNV from individuals vaccinated with prM/E-based WNV vaccines based on the presence or absence of anti-NS1 antibody.

Discovery/Basic Science

Flavivirus vaccine development has had a checkered past. The YF vaccine developed in the early

1900s has been one of the safest and most effective live-attenuated vaccines ever produced. Since that time, a variety of approaches have been used for other medically important flaviviruses such and TBEV and JEV, with reasonable success. The identification of approaches to produce vaccines by recombinant DNA technology has been problematic. There were many attempts to develop E-protein based vaccines in the 1980s, most of which were not successful. Problems were associated with our lack of understanding of the requirements for appropriate expression of the E-protein. It was determined that many E-protein epitopes were discontinuous (nonlinear) and, therefore, conformational in nature. It was also hypothesized (and later proven) that the E-protein is a class II fusion protein that undergoes an oligomeric reorganization resulting in cell-membrane fusion. This oligomeric reorganization results in loss of important E-protein epitopes and implies that that vaccine production protocols will require careful control of pH during production runs.

Studies with TBEV and DENV determined that E-protein synthesis required the presence of prM protein. The prM protein likely functions as a chaperone protein for the E-protein maintaining its conformation during maturation in low pH exocytic vesicles. Late in viral maturation the prM protein is cleaved by cellular serine proteases (e.g., furin) activating the E-protein fusion potential (Elshuber et al., 2003). Failure to cleave the prM protein results in altered expression of E-protein epitopes, an E-protein with reduced fusion capacity, and virus with lower infectivity. Since the prM cleavage enzymes are cell-dependent, the virion prM/E composition and virus infectivity will vary depending on the host cell used for vaccine production. For other viruses encoding Class II fusion protein (e.g., alphaviruses) ablation of the multibasic serine protease cleavage motif in the analogous chaperone proteins has actually been used as an attenuating mutation for vaccine development.

The contribution of the nonstructural proteins to protective humoral and cellular immunity needs further evaluation. For example, even though NS1 has been shown to be of some value eliciting protective antibody, a recent study with DENV confirmed that the E-protein drives the protective antibody response when analyzed using replicating WNV/DENV chimeric viruses differing E and NS proteins (Calvert et al., 2006). It is also unclear whether or not chimeric WNV vaccines that carry heterologous nonstructural proteins will be less efficient at eliciting long-term immunity and effective viral clearance mechanisms when a vaccinee is faced with a wild-type viral challenge.

Preclinical Development, Including Relevant Animal Models

Preclinical evaluation of vaccines for encephalitic flaviviruses has the advantage of the availability of a number of relevant animal models. Initial animal testing for attenuation, neuroinvasion, and neuroinvasiveness is usually performed in suckling, weanling, or adult mice. Recently a C57Bl/6J mouse model has been used for WNV studies (Diamond et al., 2003). The limitation of this mouse strain is the variable infectivity of WNV. A hamster model has also recently been developed for WNV. Similar to the C57Bl/6J mouse model, the hamster model shows variable WNV infectivity (Sbrana et al., 2005; Tesh et al., 2005; Tonry et al., 2005; Xiao et al., 2001). Persistent WNV infection has been identified in these hamsters (Tesh et al., 2005; Tonry et al., 2005). This observation should be valuable in studying persistent WNV disease. Subhuman primates and horses serve as large animal models for WNV vaccine testing, and have been used successfully.

Human Vaccine Trials

There are two vaccines in limited Phase I or Phase II human clinical trials at this time—the ChimeriVax WNV (Monath et al., 2006) and the WNV DNA vaccines (Table 39.3). There are no WNV vaccines in Phase III human clinical trials. Adequate Phase I and II human clinical trials for WNV vaccines should be achievable. Due to the inconsistent and unpredictable nature of WNV activity, Phase III human efficacy studies are likely to be problematic and may require a large number of study participants. Since the highest value target for WNV vaccination will be the elderly due to the increased severity of WNV infection in this age group, it will be important to include older individuals in all stages of vaccine evaluation.

PROSPECTS FOR THE FUTURE

The likelihood that WNV or related flaviviruses will be used as a bioterrorism agent is not high. Flaviviruses in general are not overly stable in the environment, nor is there good evidence that they are easily transmitted via aerosol. As was the case with WNV, the real threat would be establishing a stable natural mosquito–host transmission cycle. This would permit natural spread of disease. Once these natural cycles are established, and depending in the reservoir host, the outbreak could be contained if the host is relatively immobile (e.g., rodents) or be widespread if the

TABLE 39.3 WNV vaccines

host is very mobile (e.g., birds). Because reverse genetics works well with flaviviruses, genetic modifications could be made that would result in phenotypic differences that could enhance virus virulence or transmissibility. Whether or not such manipulations would be worth the effort is beyond the scope of this review.

There are no significant scientific impediments to the development of a safe and effective WNV vaccine for humans. The economics of the need for this vaccine will continue to drive its development. If WNV continues to be a public health problem in the United States—and there is no reason to believe it would not—vaccine development will continue to a successful conclusion.

KEY ISSUES

Key issues surrounding WNV that still need to be addressed:

- Continued development of a WNV vaccine.
- Developing more specific serodiagnostics for WNV and other flaviviruses.
- Understanding better the viral virulence and pathogenesis in the human.
- Developing approaches to better predict WNV activity.
- Maintaining vector-borne viral disease expertise and response infrastructure.

ACKNOWLEDGMENTS

The author would like to acknowledge the members of the Arbovirus Diseases Branch, CDC. Without the tireless efforts of these individuals, the CDC would not have been able to adequately respond to the WNV emergency in 1999 and subsequent years.

OUTLINE

ABSTRACT

Yellow fever virus (YFV) is a mosquito-borne flavivirus that is the causative agent of yellow fever (YF), which is a disease that ranges in severity from an influenza-like syndrome to severe liver and renal dysfunction, circulatory shock, and hemorrhage. The disease causes substantial morbidity and mortality; case fatality rates often exceed

20% and, despite the availability of a vaccine, it is still a major public health problem for sub-Saharan Africa and tropical South America, and travelers to endemic areas. The virus is maintained in endemic areas of Africa and South America by enzootic transmission between mosquitoes and monkeys, and the epidemiology of the disease reflects the geographical distribution of the mosquito vectors. There are seven genotypes of this virus with five circulating in different geographic areas of Africa and two in South America. Two live-attenuated YF vaccines were simultaneously developed: the French neurotropic vaccine (FNV), or Dakar vaccine, and the 17D vaccine. In the 1980s the manufacture of FNV was completely discontinued because the World Health Organization (WHO) prohibited vaccination of children under 14 years old due to the high incidence of encephalitis. The development of the highly effective, live-attenuated 17D vaccine in the late 1930s is one of the milestones in vaccine research. The vaccine is safe and highly efficacious with one dose of vaccine giving immunity for at least 10 years, and may be lifelong immunity. Neutralizing antibodies are the correlate of protection. There are three substrains of the YF 17D vaccine in production today (17D-204, 17DD, and 17D-213). The WHO has standardized the seed lot and manufacturing processes, and published guidelines for approval of vaccine production and vaccination certificates. There are a number of contraindications for YF vaccination which include age, thymus disease, pregnancy, breast-feeding, immune suppression, and hypersensitivity to eggs. In recent years, a rare but significant number of severe adverse events have been reported involving vaccine-associated viscerotropic and neurotropic disease. Current vaccine development involves utilizing the 17D vaccine virus backbone, via infectious clone technology, to develop a variety of chimeric virus vaccines, some of which have reached clinical trials for human use.

INTRODUCTION

Yellow fever virus (YFV) is a mosquito-borne flavivirus that is the causative agent of yellow fever (YF), which is a disease that ranges in severity from an influenza-like syndrome to severe liver and renal dysfunction, circulatory shock, and hemorrhage. The disease causes substantial morbidity and mortality; case fatality rates often exceed 20% (Monath, 2004) and, despite the availability of a vaccine, is still a major public health problem for sub-Saharan Africa and tropical South America, and travelers to endemic areas (WHO, 2003). The virus is maintained in endemic areas of Africa and South America by enzootic transmission between mosquitoes and monkeys, and it can be transmitted transovarially from one mosquito to another (Marchous and Simond, 1905; Beaty et al., 1980; Monath 2004; Barrett and Monath, 2003b). There is an urban transmission cycle involving *Aedes aegypti* mosquitoes and humans (WHO, 2003; Barrett and Monath, 2003b). A highly effective, live-attenuated vaccine (strain 17D) has been available since the late 1930s (Strokes et al., 1928).

SHORT HISTORY OF THE DISEASE

Although the first mention of YF is in a Mayan manuscript reporting an epidemic that occurred in Guadeloupe and the Yucatan in 1648 (Carter, 1931; Hobson 1963), Griffin Hughes was the first to use the term "yellow fever" to describe the disease in his book in 1750 (Garrison, 1929). It is thought that the virus originated in Africa and then spread to South America due to the slave trade and trading routes (Lepiniec et al., 1994; Mutebi et al., 2001; Bryant et al., 2007). Subsequently, large epidemics occurred throughout the 18th and 19th centuries in the Caribbean islands, the United States, Africa, Europe, West Indies, and South America (Garrison, 1929; Powell, 1949; Taylor, 1951; Duffy, 1966; Coleman, 1984, 1987; Waddell, 1990–1992; Patterson, 1992). The isolation of wild-type YFV in the late 1920s (Strokes et al., 1928; Mathis et al., 1928) led directly to the development of highly effective live-attenuated vaccines in the 1930s. The vaccines, together with mosquito control measures, made epidemic control possible and resulted in the eradication of the virus from Europe and the United States. Currently, YF is considered to be a reemerging disease in areas of sub-Saharan Africa and tropical South America, where it causes regular epidemics. Thirty-three countries (15°N to 10°S of the equator), with a combined population of 508 million, are at risk in Africa. In the Americas, nine South American countries and several Caribbean islands are at risk, with Bolivia, Brazil, Colombia, Ecuador, and Peru at the greatest risk. Unvaccinated ecotourism travelers to endemic areas are also at risk of contracting YF.

ETIOLOGIC AGENT(S)

There were many debates regarding the agent that caused YF and Carlos Findlay was the first to suggest that mosquitoes transmitted the disease (Findlay, 1881; Chastel, 2003). Reed et al. (1901) confirmed that

mosquitoes (*Ae. aegypti*) transmitted the agent and demonstrated that it was a virus because it was capable of passing through bacterial proof filters. Thus, YFV was the first animal virus shown to be transmitted by an arthropod host.

Classification

YFV is the prototype member of the genus *Flavivirus*, which is named after the Latin word for yellow, *Flavus*. The *Flavivirus* genus is one of three genera in the *Flaviviridae* family, the others being *Pestivirus* and *Hepacivirus*. The *Flavivirus* genus contains three major ecological subdivisions: tick-borne viruses, mosquito-borne viruses, and viruses with no known arthropod vector. The tick-borne viruses are subdivided into mammalian and seabird groups. The mosquito-borne viruses are subdivided into Aroa, dengue, Japanese encephalitis, Kokobera, Ntaya, Spondweni, and YF groups. The viruses with no known arthropod vector contain the Modoc and Rio Bravo groups. The YF group contains mosquito-borne Banzi, Bouboui, Edge Hill, Jugra, Potiskum, Saboya, Sepik, Uganda S, Wesselsbron, and YF viruses, plus the non-vector-borne Entebbe bat, Sokoluk and Yokose viruses. YFV has a spherical, enveloped nucleocapsid of 30 nm diameter and the entire virion measures approximately 50 nm in diameter. The envelope (E) protein is a dimer that sits parallel to the surface of the virus in association with the membrane (M) protein (Kuhn et al., 2002).

ANTIGENS ENCODED BY AGENT

The genome of YFV is approximately 11,000 nucleotides in length, depending on the strain, with the 17D-204 vaccine virus genome 10,862 nucleotides in length. The 3411 amino acid polyprotein is flanked by a 5′ noncoding region of 118 nucleotides and a 3′ noncoding region of 511 nucleotides (Rice et al., 1985; Dupuy et al., 1989). The 5′ terminus has a type 1 cap followed by two conserved nucleotides (AG) and the 3′ terminus lacks a poly A tract (Rice et al., 1985). The polyprotein encodes 10 proteins: the structural proteins; capsid (C), membrane (M) and envelope (E) are encoded by the N-terminal one-third of the polyprotein and the nonstructural proteins; NS1, NS2A, NS2B, NS3, NS4A, NS4B and NS5 are encoded by the C-terminal two-thirds of the polyprotein. Five YFV proteins (E, M, NS1, NS2B, and NS3) have been shown to be involved in immune responses in the host and these are illustrated in Fig. 40.1. The major immunogen is the E protein, which encodes epitopes inducing neutralizing antibodies that are primarily responsible for the protective immune response. The M protein has also been shown to contain epitopes inducing neutralizing antibodies but these have weak neutralizing activity (Schlesinger et al., 1983). NS1 is unusual, as it is a nonstructural protein that is glycosylated (N_{130} and N_{208}); it induces antibody-dependent cellular cytotoxicity and fixes complement. Human cytotoxic T cell epitopes are found on the E structural protein

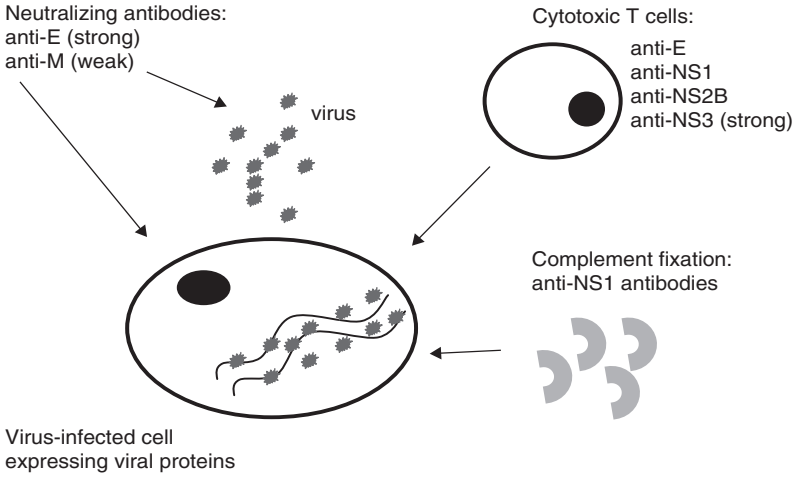

FIGURE 40.1 Yellow fever virus proteins that induce the host immune response (from Monath, 2001). The photomicrograph shows yellow fever virus particles in endoplasmic reticulum (magnification × 280,000). The E glycoprotein, which is inserted in the cell membrane–derived envelope, contains three conformational epitopes that are responsible for virus neutralization. These neutralizing antibody epitopes on the E protein are the principal mediators of protection against reinfection. The E protein and the nonstructural proteins (NS1, NS2B, and NS3) have cytotoxic T cell epitopes which generate cytotoxic T cells that clear virus-infected cells during recovery. Type-specific and cross-reactive complement fixation epitopes are also found on the NS1 protein, which generate production of cytotoxic antibodies that bind complement and help clear virus during the recovery phase.

and the NS1, NS2B, and NS3 nonstructural proteins (Co et al., 2002; Van der Most et al., 2002). Studies with mosquito-borne West Nile virus (WNV) were the first to show that the majority of flavivirus E protein epitopes were conformational (Gollins and Porterfield, 1986). Monoclonal antibodies have identified a number of overlapping epitopes on the E protein (Cammack and Gould, 1986; Schlesinger et al., 1984). Physically these epitopes are either strain-, YF type-, complex-specific or flavivirus genus common, while biologically some of these epitopes are associated with hemagglutination inhibition (HI), which may or may not be associated with neutralization (Schlesinger et al., 1983, 1984; Geske et al., 1983; Buckley and Gould, 1985; Cammack and Gould, 1986; Heinz, 1986; Gould et al., 1985, 1989; Barrett et al., 1989, 1990a, 1990b; Sil et al., 1992; Ledger et al., 1992). Overall, few epitopes are involved in neutralization and very few elicit high titer neutralization (Buckley and Gould, 1985; Cammack and Gould 1986; Ledger et al., 1992). To date, few epitopes have been mapped to specific amino acids on the E protein: two YF type-specific epitopes have been mapped to amino acids 71/72 and 153/155, a wild-type epitope to amino acid 173, and a 17D-204 substrain-specific epitope to amino acids 305 and 325 (Lobigs et al., 1987; Ryman et al., 1997, 1998). Like the E protein, NS1 has been shown to have YF type- and complex-specific, and flavivirus genus common epitopes. Some of these NS1 epitopes are involved in complement fixation but none are involved in neutralization (Putnak and Schlesinger, 1990; Schlesinger et al., 1983, 1986, 1990).

PROTECTIVE IMMUNE RESPONSE

Infection with wild-type YFV results in lifelong immunity and the YF 17D vaccine is also highly effective; immunity occurs within 10 days in 95% of vaccinees and induces protective immunity against all known wild-type strains. YFV induces rapid and specific humoral and cell-mediated immune responses, which will be discussed under the next two subheadings. The humoral response is better characterized than the cell-mediated response, while the innate immune response is an active area of research at the present time.

Antibody Response

IgM antibodies are detected by one week postvaccination, reach a peak by two weeks postvaccination, and then they decline over several months (Lhuillier et al., 1986). The neutralizing and HI antibody responses are rapid and detected by seven days postvaccination (Porterfield, 1954; Theiler and Casals, 1958). The HI antibody peaks 1–2 months post-immunization and then steadily declines, whereas the neutralizing antibody response persists and is the primary mechanism of protection against reexposure. Complement fixation antibodies are detected by two weeks post-wild-type infection and their levels increase rapidly but they are not seen postvaccination. These antibodies bind complement to help clear virus during recovery from infection and their levels drop by 4–12 months post-wild-type infection (Putnak and Schlesinger, 1990; Schlesinger et al., 1986, 1990). All studies to date indicate that neutralizing antibody is the correlate of protection with over 98% of vaccinees being fully protected for at least 10 years and neutralizing antibodies persist for at least 45 years (Sawyer, 1931; Bauer and Hudson, 1930; Groot and Ribeiro 1962; Poland et al., 1981; Lobigs et al., 1987; Brandriss et al., 1990; Niedrig et al., 1999; Monath and Heinz, 1996; Monath et al., 2000).

CMI Response

The17D vaccine strain is a potent inducer of CD4+ and CD8+ cytotoxic T cell responses against the nonstructural proteins NS1, NS2B, NS3, and the E structural protein (Reinhardt et al., 1998; Co et al., 2002; van der Most et al., 2002). A study by Santos et al. (2005) showed increases in CD3+, CD4+, and CD8+ T cells in vaccinees and re-vaccinees at 30 days postvaccination. Studies involving CD4 knockout mice have shown that CD4+ T cells are central to the immune response against YFV through antibody and cytokine production, B cell activation, and posterior plasma cell differentiation (Liu and Chambers 2001). CD8+ T cells also contribute to the protective immune response by mediating viral clearance (Doherty, 1996). The CD8 T cell response to YFV reaches its peak 1–2 weeks postvaccination and is detectable up to 19 months, which is thought to contribute to vaccine efficacy (Reinhardt et al., 1998; Co et al., 2002). There is also a significant increase in tumor necrosis factor (TNF) peaking on days 2 and 7 postvaccination (Hacker et al., 1998), which interferes with virus replication by activating or causing the differentiation of T cells and macrophages (Herbein and O'Brien, 2000). One recent study examining the activation events and modulatory pathways in T cells after vaccination found that CD4+ T cells were activated early (day 7), CD19+ T cells were activated by day 15, and CD8+ T cells were activated late (day 30). This up-regulation of modulatory features on CD4+ and CD8+ cells at day 15 caused a lower level

of CD38+ T cells by day 30 postvaccination (Martins et al., 2007).

Innate Immune Response

Recent studies have shown that the innate immune system also plays an important role in determining the strength and quality of adaptive immune responses against viruses such as YF. Toll-like receptors (TLR) are key sensors that recognize double- and single-stranded RNA (Takeda et al., 2003; Beutler, 2004). The 17D vaccine strain replicates minimally (perhaps abortively) in dendritic cells without causing substantial apoptotic cell death (Barba-Spaeth et al., 2005; Palmer et al., 2007) and stimulates TLR 2, 7, 8, and 9 (Querec et al., 2006), which results in the production of type I interferon and other inflammatory cytokines (Wheelock and Sibley, 1965) and dendritic cell activation and maturation. These activated dendritic cells most likely migrate to regional lymph nodes and stimulate both cell-mediated and humoral adaptive immune responses (Iwasaki and Medzhitov, 2004; Barba-Spaeth et al., 2005; Kawai and Akira, 2006; Palmer et al., 2007; Querec and Pulendran, 2007). Viral interaction with alternate TLRs modifies the Th1 and Th2 cytokine balance produced by the activated immune cells, and it is possible that nonviral vaccine components could also influence this balance (Querec et al., 2006; Querec and Pulendran, 2007). The interferon-induced peripheral lymphocyte response from vaccinees may be mediated in part through the action of 2′-5′ oligoadenylate synthetase. Levels of this enzyme are increased in lymphocytes by day 4 postvaccination and reach a maximum at day 7. This enzyme catalyzes the production of 2′-5′ oligoadenylates, which activates latent RNAase, which degrades viral mRNA and impairs cellular protein synthesis (Bonnevie-Nielsen et al., 1989, 1995). Natural killer cells have also been shown to play a role early in virus infection (Fagraeus et al., 1982).

EPIDEMIOLOGY

YF is endemic and intermittently epidemic in tropical South America and sub-Saharan Africa, with an estimated 200,000 cases and 30,000 deaths annually (Figs 40.2A and B; Robertson et al., 1996; Vainio and Cutts, 1998; Monath, 2001; Vasconcelos 2003; Vasconcelos et al., 2004; Tomori, 2004; Gubler 2004; Bryan et al., 2004; WHO, 1998, 2001, 2007a, 2007b, 2007c; WHO/UNICEF, 2005; Roberts, 2007; Barrett and Higgs, 2007). YFV is thought to have originated in Africa and then was subsequently introduced into South America by slave trade travelers (Bryant et al., 2007, Bryant et al., 2004). This is supported by the greater heterogeneity of African YFV genomes compared to those in South America (Lepiniec et al., 1994; Mutebi et al., 2001; Gould et al., 2001; Barrett and Monath, 2003b). Further supporting evidence comes from the phylogenetic studies that show that West African strains are closer to South American strains than the central or East African strains (Lepiniec et al., 1994; Chang et al., 1995; Wang et al., 1996) and there is more genetic diversity in central and West African strains (Barrett and Higgs, 2007). Nucleotide sequencing studies have identified seven genotypes, based on ≥9% nucleotide variation, using the prM and E sequences in a neighbor-joining tree, with 5 circulating in different geographic areas of Africa and two of South America (Lepiniec et al., 1994; Mutebi et al., 2001; Vasconcelos et al., 2004). In general, YFV strains have evolved slowly (Deubel et al., 1986; Lepiniec et al., 1994; Chang et al., 1995). There are two genotypes in West Africa: the West Africa genotype I (occurs in Eastern Ivory Coast, Burkina Faso, and Nigeria to Cameroon) and the West Africa genotype II (occurs in Western Ivory Coast and Mali to Senegal) (Lepiniec et al., 1994; Mutebi et al., 2001). The three other genotypes were identified in Central and Eastern Africa: the East and Central African genotype (occurs in Central African Republic, central Sudan, Ethiopia, and the Democratic Republic of Congo), the East African genotype (occurs in Kenya, Southern Sudan, and Angola), and the Angola genotype (based on a single isolate from Angola) (Mutebi et al., 2001; Onyango et al., 2004b). There are two genotypes in South America: the South American genotype I (occurs in Brazil, Panama, Columbia, Ecuador, Venezuela, and Trinidad) and the South American genotype II (occurs mainly in Peru and Bolivia, with some isolates from Brazil and Trinidad) (Bryant and Barrett, 2003).

The virus has three transmission cycles: the sylvatic (or jungle), the intermediate, and the urban cycle. The transmission cycle involves horizontal and vertical transmission of the virus in the mosquito vectors (Diallo et al., 2000; Vasconcelos et al., 2001b; Mondet et al., 2002). The importance of transovarial transmission (Marchous and Simond, 1905; Beaty et al., 1980) in maintaining the transmission cycle is not known. It is thought that the infected mosquito eggs allow for "over wintering" of the virus because they survive desiccation and hatch the next rainy season (Barrett and Monath, 2003b). In the jungle cycle, which occurs in tropical rainforests, the virus is transmitted only between lower primates by canopy-dwelling wild mosquitoes, usually *Haemagogus* spp. in South

(A)

FIGURE 40.2 Yellow Fever endemic zones in Africa (A) and South America (B) as of 2007 (from CDC Web site http://wwwn.cdc.gov/travel/yellowBookCh4-YellowFever.aspx#667). Yellow fever occurs in sub-Saharan Africa and tropical South America, where it is endemic and intermittently epidemic. These endemic areas have evidence of yellow fever transmission to humans and/or its potential, because there are competent mosquito vectors and the virus is present in nonhuman primates.

America (Vasconcelos et al., 2003) and mostly *Aedes africanus* in Africa. The virus is enzootic in the rainforests of Africa and South America. The disease in non-human primates varies with South American primates often succumbing to the disease, whereas African primates often show no signs of infection. Human infections in the jungle cycle are usually occurring in young men who work in the rainforest areas (Barrett and Monath, 2003b). The intermediate, or savannah, cycle only occurs in the jungles of Africa, where there is some human activity on the moist savannah ground, usually farming. A variety of *Aedes* sp. of semidomestic mosquitoes that feed on nonhuman primates are the vectors in this cycle (Germain et al., 1980; Mutebi and Barrett, 2002) and they will often also feed on humans if they come into the savannah areas. It is this cycle in Africa that is regarded as the zone of emergence because this is thought to be where the virus evolved to become an important human pathogen (Barrett and Higgs, 2007). In the urban transmission cycle, the virus is transmitted between humans by domestic *Ae. aegypti* mosquitoes in Africa (Johnson et al., 2002; Barrett and Higgs, 2007). Urban YF has not been seen in South America since 1928 except for small outbreaks in Brazil in 1928, Trinidad in 1954, and Bolivia in 1999 (Monath, 1999; Van der Stuyft et al., 1999; Barrett et al., 2007; WHO, 2006a, 2006b).

Thus, YF epidemiology reflects the geographical distribution of the mosquito vectors: *Haemagogus* spp. in South America and *Aedes* spp. in Africa (Monath, 2004). The vast majority of cases (>80%) are in Africa due to a combination of more people in Africa and more effective vaccination programs in South America.

(B)

FIGURE 40.2 (Continued)

The greatest risk of a large epidemic occurs when infected humans return to urban areas and are fed on by the domestic vector mosquito *Ae. aegypti*, which then transmits the virus to other humans. The world distribution of *Ae. aegypti* extends from 40° North to 40° South latitude (most tropical to subtropical regions) and this distribution is expected to increase with global warming (Fig. 40.3, Gubler, 2002; http://www.searo.who.int/LinkFiles/Dengue_chap-7.pdf).

Significance as Public Health Problem

In the 18th and 19th centuries, YF was a huge public health problem until mosquito control measures and production of an effective vaccine brought the epidemics under control in the 20th century. Yet as we enter the 21st century this virus is once again a significant public health problem (Robertson et al., 1996; WHO, 1998; Barrett and Higgs, 2007) and is classified as a reemerging disease.

Urban YF was eliminated from South America in 1928 (see above), whereas sylvatic YF continues to be transmitted from monkeys to humans via mosquitoes in the rainforest ecosystem. Thus, most South American cases are in residents and those who work in forested or transitional areas of Bolivia, Brazil, Colombia, Ecuador, Venezuela, Guyana, French Guiana, and Peru (http://wwwn.cdc.gov/travel/yellowBookCh4-YellowFever.aspx#667). The disease is only partly controlled due to incomplete vaccination of residents and workers, and provides a potential source of infection to population centers that have been reinfested with *Ae. aegypti*. Sylvatic YF is

(A)

(B)

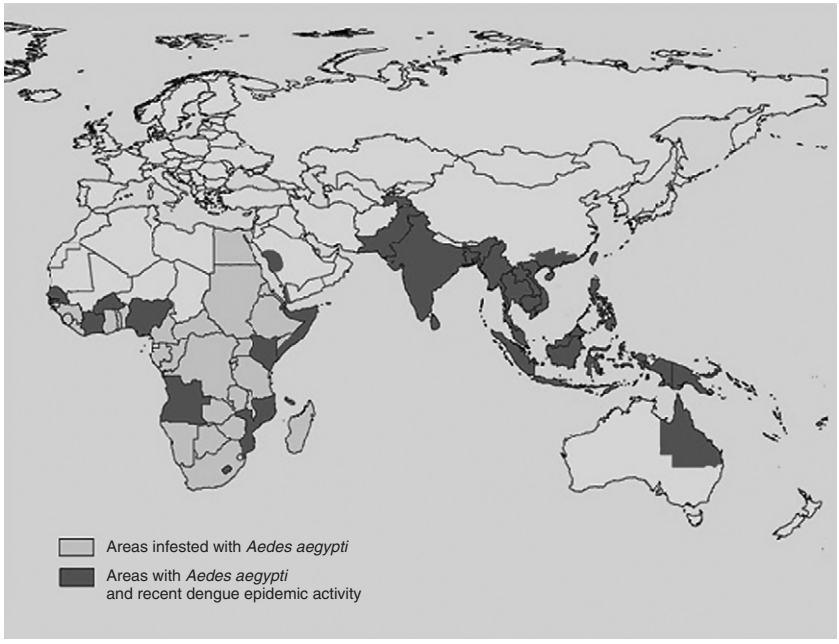

FIGURE 40.3 Distribution of *Aedes aegypti* in the Americas (A) and Eastern Hemisphere (B) (http://www.searo.who.int/LinkFiles/Dengue_chap-7.pdf). *Ae. aegypti* is found in or near human habitations and has two peak periods of biting activity: several hours in the morning after daybreak and several hours before it gets dark. However, this mosquito may feed at any time during the day, especially indoors, in shady areas, or when it is overcast.

endemic in the north and west of Brazil (Mondet et al., 1996; Vasconcelos et al., 1997, 2001c; Codeço et al., 2004) and there is a risk of emergence in the large coastal population centers, such as Sao Paulo and Rio de Janeiro (Filippis et al., 2001). In addition, reinfestation of the country with the *Ae. aegypti* vector in the 1970s greatly increased the risk of YF urbanization in Brazil (Fig. 40.3; Gubler 2002; Lourenco-de-Oliveira et al., 2004). It is hard to quantitate the risk, but it could be as high as 29% during epizootic periods (Codeço et al., 2004; WHO, 2007c). The expanding infestation in South America by *Ae. aegypti* has resulted in large epidemics of dengue, another mosquito-borne flavivirus disease also transmitted by this mosquito, yet there has not been a corresponding increase in YF disease. Many authors believe it is only a matter of time before urban YF returns to South America. Nonetheless, there continues to be periodic epidemics and epizootics of

YF activity in the border area of eastern Colombia and western Venezuela (Rifakis et al., 2006), and the foothills of the eastern Andes mountains.

In Africa, the risk of urban YF epidemics has increased greatly because of the increased risk of YFV transmission due to high mosquito vector densities in areas where there are large nonimmune populations. It is significant that most YF cases are in infants and children, who have the greatest risk of severe disease with case fatality rates as high as 20% (Arguin et al., 2007). The United Nations reported that African urban population growth rates are the most rapid in the world (United Nations, Population Division, 2001), with the proportion of urban to rural populations predicted to reach 63% by the year 2020, including 70 cities that will have more than a million people by 2015 (United Nations, World Urbanization Prospects, the 1999 revision; Meeting the Urban Challenge, Population Reports Series M, number 16 United Nations, World Urbanization prospects, the 1999 revision). Urban cities have large numbers of "shantytowns" with inadequate water supplies and lack of proper public sanitation services; people store drinking water in containers that serve as breeding sites for *Ae. aegypti*. Since 2000, 18 countries in Africa have reported cases of YF (Roberts, 2007). The situation is complicated as high levels of resources, both from national and international support, are needed to effectively control urban outbreaks, which deprive these countries of scarce resources to control other diseases and to improve health services. Today, the World Health Organization (WHO) estimates that 12 countries (Benin, Nigeria, Burkino Faso, Ghana, Liberia, Senegal, Cote d'Ivoire, Cameroon, Gabon, Toga, Guinea, and Sierra Leone) have large nonimmune populations that are at high risk and 100 million people need immunization now (http://www.who.int/csr/don/archive/disease/yellow_fever/en/index.html) and a large catch-up immunization campaign, cosponsored by WHO and Global Alliance for Vaccines and Immunization, is being planned to fill the need. A further problem is that traditionally the countries most severely afflicted by YF have followed a policy of emergency control vaccination, rather than the more effective inclusion of the 17D vaccine in their Expanded Program of Immunization (EPI) (Monath and Nasidi, 1993).There was an epidemic in Cameroon in 1990 (Vicens et al., 1993) and outbreaks in Senegal in 1995 and 1996 (Thonnon et al., 1998), Sudan in 2003 (Onyango et al., 2004a, 2004b), Cote d'Ivoire in 2006 (World Health Organization, 2006b), and Togo in 2007 (World Health Organization, 2007a). For the continent of Africa to effectively bring YF under control it is estimated that it will require 80% vaccination coverage of children under age one, who are at most risk (Tomori, 2002) and that YF should be added to the EPI of all countries where the virus is endemic (Moreau et al., 1999).

In addition to the public health problems for residents of endemic areas in Africa and South America, it is a significant hazard to national and international unvaccinated travelers who visit endemic areas. During 1970–2002, there were 10 cases reported in unimmunized travelers from the United States and Europe with a mortality rate of 89% (Digoutte et al., 1981; World Health Organization, 1986, 1998, 2000; Nolla-Salas and Sadalls-Radresa, 1989; Monath and Cetron, 2002; Barnett, 2007). The number of travelers from the United States to South America and Africa has more than doubled since 1988 (International Trade Administration. U.S. resident travel to Canada, Mexico and overseas countries historical visitation outbound 1988–1999. http://www.tinet.ita.doc.gov/research/reports/basic/national). Currently, 9 million tourists from North America, Europe, and Asia travel each year to countries where YF is endemic (WHO, 1996), and potentially increase the risk of introducing YFV into North and Central America, Caribbean, Middle East, Asia, Australia, and Oceania (Tomori, 2004; Barrett and Higgs, 2007).

POTENTIAL AS BIOTHREAT AGENT

During the 1930s the Japanese experimented with YFV as a biological weapon in China. After World War II, during the 1950s, the American military researched YFV as a biological weapon, including its spread by aerosol. Most countries classify YFV at biosafety level three, or equivalent, due to the availability of a vaccine. YFV was originally on the list of CDC select agents but it has since been removed (http://www.cdc.gov/od/sap/docs/salist.pdf) due to the availability of an effective and safe vaccine. Thus, this virus is not considered a biothreat agent, although there is no effective treatment and probably insufficient worldwide vaccine production (Pugachev et al., 2005; Roberts, 2007) if the virus was used as an agent of bioterrorism. Finally, there is no doubt that YFV would be classified as a biosafety level 4 pathogen if there was no vaccine available.

CLINICAL DISEASE

There is a wide spectrum of the clinical disease from nonspecific abortive illness to a rapid and fatal hemorrhagic fever (Kerr, 1951). The incubation period is 3–6

days and there is an abrupt disease onset with fever, chills, malaise, lower back pain, myalgia, nausea, and dizziness. The patient presents with bradycardia relative to their height of fever, an acute febrile illness, and congestion of face and conjunctivae. On average, the fever lasts 3 days and younger children may show febrile convulsions. During this time the patient is viremic, with infectious virus particles 10^4/ml of blood or greater. Between two and three days after disease onset the "period of infection" begins where the patient shows the first signs of jaundice typical of YF and their serum transaminase levels begin to rise. The "period of infection" is normally followed by a 2–24 h "period of remission" where the symptoms disappear and the virus is cleared from the blood by the immune response. At this stage the majority of patients recover without any side effects, although the "convalescent phase" lasts several weeks and is characterized by fatigue and prolonged weakness with abnormal liver function tests that can last more than two months. Approximately 15–25% go on to develop "the period of intoxication" where they develop a more severe illness with vomiting, epigastric pain, renal failure, fever, jaundice, and hemorrhagic diathesis. It is at this stage that the jaundice becomes worse and the serum transaminase levels rise, reflecting the severity of the disease (Oudart and Rey, 1970). Patients exhibit a multifactorial bleeding disorder with hemorrhagic manifestations, such as bleeding from gums and needle puncture sites, epistaxis, ecchymoses, petechiae and, in many cases, there is also melena or metrorrhagia, major bleeding, and coffee grounds hematemesis. Approximately 20–50% of patients with this hepatorenal disease die 7–10 days after onset. These patients become delirious and fall into a stupor followed by coma and death, with symptoms of hypotension, hypothermia, hyperkalaemia, Cheyne-Stokes respirations, hypoglycemia, and metabolic acidosis. At this late disease stage there is also edema and perivascular hemorrhages in the brain (Monath, 2001).

TREATMENT

There is no specific treatment available for patients suffering from wild-type YF, YF vaccine-associated viscerotropic (YEL-AVD), and YF vaccine-associated neurotropic disease (YEL-AND) (CDC, 2008). Ribavirin postexposure treatment showed some benefit when used to treat the hamster model of viscerotrophic disease (Sbrana et al., 2004). A recent study confirmed that treatment with IFN alfacon-1 or ribavirin (starting 2 days postinfection) significantly improved survival of hamsters challenged with YFV. Pre-virus exposure treatment with IFN alfacon-1 also improved YF disease in infected hamsters (Julander et al., 2007b). In another study by the same group, the T-1106 (substituted pyrazine) compound was used to significantly improve survival, again in the hamster model, using two treatment regimes—one starting 4 h prior to virus inoculation and continuing twice daily until 7 days post-virus inoculation and the other one beginning 4 days after virus challenge with twice-daily treatment for 8 days (Julander et al., 2007a). Another recent study suggested that corticosteroid therapy could also influence survival of patients suffering from YEL-AVD (Vellozzi et al., 2006), although this needs further investigation to see if it is of proven benefit.

Palliative treatment of disease symptoms has changed little and includes maintenance of patient nutrition; prevention of hypoglycemia; nasogastric suction to prevent gastric distension and aspiration; intravenous cimetidine to prevent gastric bleeding; treatment of hypotension by fluid replacement and vasoactive drugs; administration of oxygen; correction of metabolic acidosis; treatment of bleeding with fresh-frozen plasma; and dialysis if needed due to renal failure (Monath, 1987). Intensive care may improve the outcome for seriously ill patients, although this is not available in poorer developing countries where most cases occur and oral rehydration salts and paracetamol are used to treat the dehydration and fever, and antibiotics are used to treat any superimposed bacterial infection (WHO, 2001).

PATHOGENESIS

Studies of YFV pathogenesis utilize experimental infection of nonhuman primates because this is the only model that shows the viscerotropic disease typical of YF infection in humans and the LD_{50} can be less than 1 plaque-forming unit for some strains in experimentally infected monkeys (Theiler, 1951; Tigertt et al., 1960). European hedgehogs show viscerotropic disease, with lesions very similar to those in nonhuman primates, and neurotropic disease after experimental infection (Findlay and Clarke, 1934a, 1934b) and a hamster model of viscerotropic disease has recently been developed by serial passage of the virus in hamsters (Tesh et al., 2001; Xiao et al., 2001; McArthur et al., 2003, 2005; Sbrana et al., 2006). This hamster model is useful, as it shows many similarities to the disease seen in humans; however, the model requires most wild-type strains to be adapted by passage

in hamsters. Wild-type and vaccine viruses cause encephalitis only in various rodent models (Monath, 2001). Animals succumb to infection when virus is inoculated directly into the brain while neurotropic disease is age-related when virus is administered by a peripheral route. For example, 17D vaccines are lethal in mice up to 5 days old, wild-type strains up to approximately 10–12 days old, and the FNV strain up to 3 weeks of age (Fitzgeorge and Bradish, 1980). The intraperitoneal inoculation of 8-day-old mice is often used to study the mouse neuroinvasive phenotype.

Description of Disease Process

Kupffer cells in the liver become infected on day 1 and the virus spreads to the kidney, bone marrow, spleen, and lymph nodes (Theiler, 1951; Tigertt et al., 1960). Fig. 40.4 illustrates the main pathogenic processes of YFV. Spleen germinal centers, tonsils, lymph nodes, and Peyer's patches all show necrosis in both monkeys and human beings, but it is uncertain whether or not it is a direct virus effect (Monath et al., 1981). There are two main areas of disease pathology: renal and hepatic damage. Renal pathology shows eosinophilic degeneration and fatty change of tubular epithelium without inflammation. Renal tubular cells of fatal human cases contain antigen, which suggests direct viral injury plays an important role, although this is not observed in experimentally infected monkeys (Monath, 2001; Theiler, 1951; Tigertt et al., 1960). Histological changes are observed in the basement membrane and cells lining the Bowman's capsule. Antigen is present in glomerulae 2–3 days after infection of monkeys; hence, the marked albuminuria is thought to be due to alteration of glomerular function (Monath et al., 1981). Severe hepatic pathology is a late event characterized by infection and degeneration of hepatocytes in both monkeys and humans (Theiler, 1951; Tigertt et al., 1960; Monath, 2001). Hepatic injury shows a mid-zonal distribution, with sparing of cells around the central vein and portal tracts. Antigen and virus RNA have been demonstrated in these midzonal hepatocytes (Monath et al., 1989; Monath, 2001), which undergo eosinophilic degeneration and have condensed nuclear chromatin that is typical of apoptotic cell death (Marianneau et al., 1998). Hepatic injury

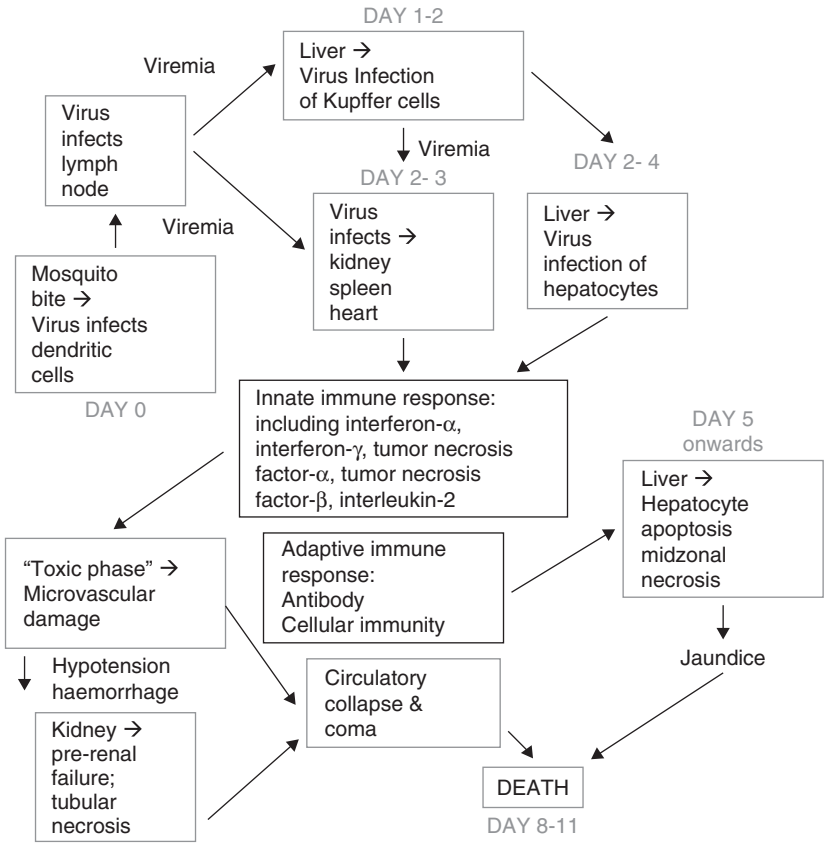

FIGURE 40.4 Pathogenesis of yellow fever virus. This is based on studies in experimentally infected monkeys and human case reports (**bold**). Speculative mechanisms (*italics*) are drawn from in vitro data or reports on other flavivirus infections. CTL: cytotoxic T lymphocyte; DIC: disseminated intravascular coagulation; IL: interleukin (from Monath, 2001).

from apoptosis explains the virtual absence of inflammatory cells, preservation of the reticulin framework, and healing without fibrosis (Monath 2001).

Hypotension and shock, which are thought to be mediated by cytokine dysregulation, followed by death, are the last stages of the disease. Kupffer cells and splenic macrophages that are infected with YFV, or are activated in response to virus injury, produce these cytokines, such as TNFα. Cytotoxic T cells could also be responsible for cell injury, oxygen free radical formation, endothelial damage and microthrombosis, disseminated intravascular coagulation, tissue anoxia, oliguria, and shock. Direct viral injury to the heart may contribute to shock because myocardial fibers have been shown to contain viral antigen and undergo apoptosis (Monath, 2001). Further studies of patients or experimentally infected monkeys are necessary to better understand the disease process, especially the late-stage shock syndrome.

Immune Response to Infection

Infection with YFV results in a rapid and specific immune response against the virus, which is highly effective and induces lifelong protective immunity. The specifics of this response are discussed further in "Protective Immune Response" above. Previous infection with heterologous flaviviruses is also known to affect immune responses to YFV, and consequently disease severity, because prior flavivirus infection can induce a cross-protective immune response. As early as the 1930s, infection with dengue virus (DEN) was thought to partially protect against YF infection and later experiments demonstrated that this was correct (Snijders et al., 1934; Sabin, 1952; Frederiksen, 1955; Ashcroft, 1979; Kurane et al., 1991). To achieve this cross-protective immune response it was necessary to actively immunize monkeys with DEN (Snijders et al., 1934; Theiler and Anderson, 1975). In addition, another study showed that African flaviviruses gave similar partial cross-protection against subsequent challenge with YFV (Henderson et al., 1970), which suggests that cross-protection between flaviviruses (termed group B arboviruses when the studies were undertaken) has an influence on the epidemiology of YF in Africa. Furthermore, epidemiological studies during a YF epidemic in the Gambia showed that humans with prior flavivirus immunity had a lower risk of developing severe YF disease (Monath et al., 1980) and studies using the hamster model of severe YF provide supportive evidence that prior exposure to heterologous flaviviruses reduces subsequent risk of fatal YFV infection (Xiao et al., 2003).

VACCINES

History

There had always been research on developing a YF vaccine but for many years it was not known what caused the disease YF. However, once the virus was isolated by two groups in 1927–1928 (Asibi and French Viscerotropic viruses) (Mathis et al., 1928; Strokes et al., 1928), there were many attempts to develop a vaccine. Several failed attempts were made to produce an inactivated single-dose vaccine by groups in France (Pettit, 1931), Brazil (Aragao, 1929), and the United Kingdom (Hindle, 1928, 1928–1929). Formaldehyde or phenol was used to inactivate virus-infected monkey liver or spleen. Testing of Hindle's vaccine in monkeys gave nonreproducible results (Hindle, 1928–1929; Okell, 1930; Davis 1931), a clinical trial in Brazil gave inconclusive results (Pettit, 1931), and at least one person who received the vaccine became infected with YFV (Burke and Davis, 1930). Subsequent attempts were made to improve the inactivated vaccines with "better" antigens using heat- or ultraviolet light–inactivated tissue cultures or mouse brain cultures. These vaccines were tested in monkeys and the fully inactivated preparations caused no illness, but also gave no protection, whereas vaccines with residual live virus caused illness and stimulated protective immunity (Gordon and Hughes, 1936). The only inactivated vaccine that gave protection against challenge was tested in mice and rabbits, but no further testing was undertaken in primates. This vaccine used multiple doses of phenol-inactivated YFV-infected mouse brain (Sellards and Bennett, 1937).

Once the virus had been isolated, there was research to develop a live-attenuated vaccine by adaptation of virus to nonhuman tissue. Two live-attenuated YF vaccines were simultaneously developed—the French neurotropic vaccine (FNV), or Dakar vaccine, in Senegal, which was attenuated by passaging in mouse brain, and the 17D vaccine, which was attenuated by passaging in mouse tissue and embryonated chicken eggs (Strokes et al., 1928; Mathis et al., 1928). In 1927, the wild-type French viscerotropic virus (FVV), or French virus strain, of YFV was isolated from Francoise Mayali, who was a patient in Dakar, Senegal (Mathis et al., 1928). The work was carried at the Institute Pasteur at Dakar and the virus was attenuated by intracerebral passage in mice. After 128 passages, the FNV was isolated and this virus underwent a further 109 passages to generate the first vaccine at passage 237. This virus was tested in monkeys for virulence and although it showed attenuation of visceral YF when inoculated extraneurally, it also showed

increased neurotropic virulence for monkeys and mice (Durieux, 1956a). This led to the first clinical trial in 1931, where a suspension of FNV and a quantity of human immune serum were simultaneously injected into volunteers because the virus was considered too dangerous to administer alone and the immune serum was used to limit the spread of the virus. A year later, FNV was inoculated subcutaneously without the immune serum. The success of this trial led to a compulsory vaccination by scarification order in 1941 for the whole military and civilian population of French West Africa using virus at passage 237–260. A year later, a program of compulsory immunization was initiated for all of colonial French West and Equatorial Africa. The success of this compulsory immunization policy was highlighted by deaths during major YFV epidemics in Nigeria and the Gold Coast, where immunization was not compulsory. Over the course of the next 10 years, the FNV strain was widely used as a vaccine until in 1951–1952, during epidemics in Central America and Nigeria, cases of postvaccine encephalitis came to light. The rate in Nigeria was 3–4/1000 vaccinations and most cases were children (38% case fatality rate). Over 38 million doses of FNV were administered mainly by scarification, sometimes alongside the smallpox vaccine, in the Francophone countries of West Africa from 1939 and 1952 (Durieux, 1956b). A further 10 years passed until in 1961 the FNV was contraindicated for children under 10 years, because of this high incidence of encephalitis in children. In 1966, production of the 17D vaccine was initiated in Dakar, Senegal, but it wasn't until 1980 that the manufacture of the FNV was completely discontinued because the WHO prohibited the vaccination of children under 14 years old (Robertson, 1993).

The 17D vaccine was derived from the Asibi strain, which was isolated from the blood of a patient (Asibi) in Ghana and passaged in monkeys (Strokes et al., 1928). Subsequently, Theiler and Smith (1937a) undertook serial intracerebral passages in mice and, like the French workers, observed that the resulting virus was attenuated in its ability to cause viscerotropic disease but showed increased neurovirulence in monkeys (Sellards, 1931). This Asibi strain of YFV was established in embryonic mouse tissue and passaged 18 times, followed by 58 passages in minced whole chick embryonic tissue. After these 58 passages, the brain and spinal cord were removed from the whole chick embryonic tissue and the virus was passaged a further 100 times and named as 17D at passage 176 (Penna, 1965). Interestingly, Theiler and Smith were working on a number of variants concurrently (17A, 17B, 17C, 17D, 17E, etc.); 17E was partially attenuated and only 17D was fully attenuated. Furthermore, Theiler was unable to repeat the attenuation process to re-derive 17D independently (Theiler and Smith, 1937a). By 1937, the 17D vaccine was being tested in humans, first in YF immune individuals and then in nonimmune individuals (Theiler and Smith, 1937b) and by 1938 initial immunization against YF had started in Brazil. Vaccination of 59,000 people indicated that the vaccine was attenuated in children and women at any stage of pregnancy. Mild reactions occurred in 10–15% of vaccinees and more intense reactions occurred in 1–2% of vaccinees at 5–8 days after vaccination, with 95% of them acquiring immunity as measured by specific antibodies (Penna, 1965). Vaccine batches began to be produced in various laboratories from available subcultures after multiple passaging of the original 17D vaccine. This led to failure of immunization due to over-attenuation of 17D vaccine batches that had been passaged 300–350 times from the initial Asibi virus because they were no longer infectious for humans (Theiler, 1951). In 1942, there were cases of hepatitis in England, Brazil, and the United States due to the practice of adding 10% human serum to the vaccine, which was contaminated with a hepatitis-causing virus, as this was necessary for stability of the vaccine virus (Smith, 1951). In Brazil, there were a few cases of encephalitis in children, depending on which substrain was utilized to vaccinate them; 0.36% of vaccinees showed CNS involvement and one person died (Georges et al., 1985). By 1945 the Standing Technical Committee on Health of the United Nations Relief and Rehabilitation Administration established manufacturing standards to control vaccine production (WHO, 1945; United Nations Relief and Rehabilitation Administration 1946). In addition, the WHO established a seed lot system to resolve these problems and those of over-attenuation or under-attenuation of 17D vaccine by passaging in tissue culture (WHO, 1959). In the early 1950s, 12 million people were successfully vaccinated with 17D in southern Brazil in response to outbreaks of YF (de Sousa Manso, 1956). Following the large epidemic of YF in West Africa in 1965, 1966 saw the decline in use of the FNV and the beginning of the sole use of 17D-derived vaccines, which are still in use today.

Current Licensed Vaccines

There are three substrains of the 17D vaccine that are used in vaccine production today. The 17D-204 vaccine substrain is utilized in all countries, except Brazil, where the 17DD vaccine substrain is used. The 17D-204 vaccine was developed from the original attenuated 17D by continued chick embryo passage

(without neuronal tissue) from passage 176 to passage 204. Subsequently, the virus was passaged in embryonated chicken eggs and all currently manufactured vaccines are manufactured at passage levels between 235 and 240. The 17DD vaccine was derived by passage in whole chick embryonic tissue with the neuronal tissue removed from p176-195; however, subsequent passages were undertaken independently in Brazil such that its development differed from 17D-204. This vaccine was passaged in embryonated chicken eggs and all currently manufactured vaccines are at passage levels 286 (Barrett, 1987, 1997). During the 1970s and 1980s it became apparent that some vaccines had been prepared in eggs contaminated with Avian leucosis virus (ALV) and so a number of manufacturers prepared ALV-free seeds of 17D virus in order to remove the endogenous retrovirus. The Robert Koch Institute in Germany, on behalf of WHO, established a new seed lot of 17D-204, termed 213/77 or 17D-213, which was certified free of ALV contamination, and is used at passage 239–240 of 17D-204 virus in embryonated chicken eggs (Post et al., 1992).

Over the years there have been many manufacturers. The 17D-204 substrain has been manufactured in France, Senegal, United States, the Netherlands, United Kingdom, Germany, and India, and 17DD vaccine in Brazil and Colombia. The 17D-213 vaccine has been manufactured in Nigeria and Russia, plus Berna Biotech in Switzerland (Pfister et al., 2006) but never marketed by the latter. At the present time there are only four recognized producers: Sanofi Pasteur in France and United States, Institut Pasteur, Dakar, Senegal, and Bio-Manguinhos, FioCruz, Rio de Janiero, Brazil. All manufacturers are prequalified by the WHO to provide vaccine for use in developing countries. The Chinese also produce a 17D vaccine for internal use, but the substrain is not known.

The genomes of 17DD (Duarte dos Santos et al., 1995; Galler et al., 1998), 17D-204 (Rice et al., 1985, Dupuy et al., 1989), and 17D-213 (Duarte dos Santos et al., 1995; Galler et al., 1998) vaccine viruses and parent wild-type Asibi virus have been sequenced (Hahn et al., 1987). Unfortunately, the original 17D virus is not available. The three substrains differ slightly in sequence, thus justifying their classification as substrains (Galler et al., 1998), but they share 20 amino acid substitutions and four nucleotide changes in the 3′ noncoding region. The capsid gene and 5′ noncoding region of wild-type Asibi and 17D vaccine viruses were identical in sequence (Table 40.1; Monath and Barrett, 2003).

The genomes of FVV and FNV have also been sequenced and found to differ by 35 amino acids and 4 nucleotide changes in the 3′ noncoding region (Table 40.2; Wang et al., 1995). Again the 5′ noncoding regions were identical in sequence. Interestingly, the two attenuation processes (17D substrains and FNV) shared two common amino acid substitutions at M-36 (L → F) and NS4B-95 (I → M; Tables 40.1 and 40.2; Monath and Barrett, 2003; Wang et al., 1995). However, there is no evidence to date that these encode common attenuating mutations. In addition, monoclonal antibodies have been generated against wild-type and vaccine strains. Wild-type (Schlesinger et al., 1983; Sil et al., 1992; Gould et al.,1985, 1989; Cammack and Gould, 1986; Barrett et al., 1990a, 1990b; Sil et al., 1992) and vaccine-specific epitopes (i.e., recognize 17D and FNV viruses only) (Gould et al., 1985, 1989; Schlesinger et al., 1983, 1984; Barrett et al., 1990a, 1990b; Sil et al., 1992), and 17D-204- and 17DD substrain–specific epitopes (Schlesinger et al., 1983; Geske et al., 1983; Gould et al., 1985; Barrett et al., 1989) have all been identified on the E protein.

Agent/Strain Used in Vaccine, How Produced, Number of Doses Administered to Give Protective Immunity

In 1957, the WHO published "Requirements for YF Vaccine" which standardized the seed lot and manufacturing processes for the 17D substrain viruses. Subsequently, in 1959, they published guidelines for WHO approval of vaccine production and vaccination certificates, which were updated in 1971, 1976, and 1981 (World Health Organization 1959, 1971, 1976, 1981). Seed viruses are assessed for the potential to be viscerotropic by measuring liver enzyme levels in nonhuman primates. All new primary and secondary seed pools for vaccine production have to be tested for immunogenicity and neurovirulence in groups of 10 or more Cynomologus or Rhesus monkeys (Levenbrook et al., 1987). The criterion is that not more than 10% of monkeys develop severe clinical signs of encephalitis and 90% of monkeys must have viremia that should not exceed 1.65×10^4 pfu/ml (or mouse LD_{50}/ml) and must develop neutralizing antibodies (WHO, 1976). These neutralizing antibodies are measured by either protection of groups of six or more weanling mice against intracerebral mice challenge with the FNV substrain or by plaque reduction assay. In addition, any inflammatory and histological changes associated with pathogenesis are scored in the brains of the monkeys. The WHO also sets guidelines for the manufacture of vaccine, and it should be noted that techniques do vary between the manufacturers; hence, complete standardization is difficult (Barrett, 1987, 1997). The vaccine virus is cultured in embryonated chicken eggs, with the requirement that all embryos must be harvested by 12 days postinoculation (World Heath Organization, 1976), and then the embryoes are minced, aliquoted, and lyophilized using aseptic technique. After the suspension is freeze-dried, it is placed in nitrogen-filled flame-sealed ampoules and stored at 0–5°C temperature. Some producers include stabilizers, such as gelatin, peptone, lactose, sorbitol, histidine, or alanine, with the vaccine to maintain the viability of the vaccine at high temperatures such as that found in tropical countries (De Souza Lopes et al., 1988a; Barmr and Bronnert, 1984; Georges et al., 1985). Once produced, the WHO has designated control tests that must be carried out to determine vaccine potency. This lyophilized vaccine must not lose more than 90% infectivity after incubation at 37°C for 2 weeks and it must be tested for any contaminating agents (WHO, 1945). The virus content of the vaccine must be at least 1000 mouse LD_{50}, or 1000 pfu, and this is quantified by mouse LD_{50} or a cell culture assay (plaque reduction or infectious $dose_{50}$) in porcine or monkey kidney Vero cells (Barrett, 1987, 1997). Since there can be variability in the calculation of virus titers by different manufacturers using one of these two methods (Seagroatt and Magrath, 1983) an international reference standard was established for vaccine potency. Despite this some more recent studies have shown that there are inconsistencies between the amount of virus needed to infect tissue culture cells and to kill a mouse (De Souza Lopes et al., 1988b; Sood et al., 1995). In addition, there is variability in infectivity levels. One study showed that 178 pfu (30 mouse LD_{50}) (Freestone et al., 1977) immunized 85% of volunteers while another showed that 200 pfu (600 mouse LD_{50}) (De Souza Lopes et al., 1988b) immunized all volunteers. In practice, most vaccines are found to contain between 5000 and 200,000 pfu/dose (De Souza Lopes et al., 1987). Control tests have to be performed in three different laboratories in the WHO list of approved laboratories. If the batch passes these tests it is approved by the WHO. The vaccine is reconstituted with 0.5 ml water and one dose injected subcutaneously. Vaccinees receive WHO-approved vaccination certificates for 10 years protective immunity (Barrett, 1987, 1997; CDC, 2008) with booster immunizations given as required.

Vaccine Recommendations, Including Potential to Administer with Other Vaccines

The WHO recommends that this vaccine is not administered to children less than 6 months of age, and 9 months in some countries. In the United States, the CDC recommends that adults and children over 9 months old (Cetron et al., 2002) who are at risk of contracting YFV infection are vaccinated. Tourists traveling to Africa and South America plus adults working there are the main groups receiving vaccination. The recommended interval to the booster dose is 10 years (http://wwwn.cdc.gov/travel/yellowBookCh1-GenRecVaccination.aspx). It should be pointed out that it is likely that a single dose gives at least 20–30 years immunity, maybe lifelong immunity. However, data are only available on long-term immunity for a relatively small group of vaccinees such that a 10-year booster regimen is used to maintain immunity. There are a number of contraindications of vaccination: age, pregnancy, breast-feeding, thymus disease, immune suppression, and hypersensitivity, and these are discussed in the section "Contraindications of Vaccination, Including Special Risk Groups."

In general, commonly administered vaccines can safely and effectively be given on the same day without impairing antibody responses or increasing the rates of adverse reactions. Inactivated vaccines do

not interfere with the immune response to other inactivated or live-virus vaccines; hence, they may be administered at the same time, but at separate sites. The immune response to a live-virus vaccine could be impaired if administered within 28 days of another live-virus vaccine. Whenever possible, injected live-virus vaccines should be given at least 28 days apart. If two injected live-virus vaccines are not administered on the same day but less than 28 days apart, the second vaccine should be re-administered at least 4 weeks later (Kroger et al., 2006). Simultaneous administration of all necessary vaccines is encouraged for people who are at the recommended age to receive vaccination and for whom no contraindications exist (http://wwwn.cdc.gov/travel/yellowBookCh1-GenRecVaccination.aspx). Table 40.3 shows vaccines that have been successfully coadministered with the 17D vaccine. Although chloroquine (antimalarial prophylaxis) is known to inhibit the replication of YFV in vitro, it does not seem to adversely affect antibody responses to the 17D vaccine (Tsai et al., 1986). There are no data on coadministration with the inactivated Japanese encephalitis (JE) vaccine, although interference is unlikely because prior infection or immunization with JE does not interfere with YF vaccination (Wisseman et al., 1962; Sweet et al., 1962).

Countries Where Vaccine Is Licensed, Including Manufacturers

There are four countries where the vaccine is licensed for manufacture: Brazil (Bio-Manguinhos, Fio-Cruz, Oswaldo Cruz Foundation, Rio de Janeiro); United States (Sanofi Pasteur Inc., Swiftwater, Philadelpia); France (Sanofi Pasteur, Marcy L'Etoile), and Senegal [Institut Pasteur, Dakar (an updated situation from the WHO technical report series no 872, 1988)].

Indications for Vaccination/Target Populations

As early as 1988, the Joint WHO/UNICEF Technical Group on Immunization in Africa recommended incorporation of YF vaccine in routine child immunization programs of countries at risk for YF in Africa and South America. Currently the WHO recommends that the vaccine be administered in countries at risk for outbreaks: 31 African countries, 2 countries in WHO Eastern Mediterranean Region, and 11 South American countries. The following is a summary of the differing vaccination policies of at-risk countries. Angola, Benin, Burkina Faso, Cameroon, Central African Republic, Chad, Congo, Côte d'Ivoire, Democratic Republic of Congo, Gabon, Ghana, Gambia, Guinea Bissau, Liberia, Mali, Niger, Sao Tome & Principe, Senegal, Sierra Leone, Togo, and Kenya (part of country) immunize infants at 9 months old. Namibia vaccinates only regions at risk. Nigeria, Bahamas, and Belize vaccinate infants at 9 months and recommend the vaccine for travelers to endemic countries. Argentina, Panama, Paraguay, and Venezuela immunize infants at 1 year old who reside in tropical areas of the country, at-risk groups, and recommend the vaccine for travelers. Bolivia immunizes all infants at 12–23 months old. Colombia, Equador (part of country), Guyana, Peru, and Suriname (part of the country) immunize infants at 1 year old. Honduras immunizes children at 1 year old and recommends the vaccine for travelers. Brazil immunizes infants at 9 months old, adults every 10 years, and recommends the vaccine for travelers. Jamaica immunizes infants at 1 year old, adults every 10 years, and recommends the vaccine for travelers. Trinidad & Tobago immunize infants at 1 year old and children at 11 years old. The Maldives immunizes people from 18–45 years old in part of the country. France immunizes infants at 6 months old and 11 years old (part of the country) and has mandatory vaccination for French Guyana. In general, other countries outside of sub-Saharan Africa and tropical South America recommend vaccination for travelers and others who are at risk of contracting YF (WHO vaccine-preventable diseases: monitoring system 2006).

Since 2000, the Global Alliance for Vaccines and Immunization (GAVI) has provided support to poorer countries for improvement of these routine immunization policies, to help provide safe injections, and increase YF vaccination coverage. The Yellow Fever Initiative, led by WHO and UNICEF, with the support of GAVI, was also launched to help increase vaccination coverage and reduce the risk of YF outbreaks in Africa (WHO, 2007c).

In May 2007, at the World Health Assembly, the WHO and partners announced the goal is to immunize more than 48 million people in 12 West African countries over the next 5 years as a catch-up campaign to reestablish an immune barrier against YF (Roberts, 2007).

Duration of Immunity

Immunization has long been known to induce a protective antibody response that provides excellent protection against infection with the virus (Sawyer, 1931; Bauer and Hudson, 1930; Groot and Ribeiro, 1962; Rosenzweig et al., 1963; Monath and Heinz, 1996; Monath et al., 2000). Ninety percent of vaccine recipients develop neutralizing antibodies within 10 days after immunization, and 99% within 30 days. Studies have shown that protective immunity lasts as long as 35 years (Poland et al., 1981, Niedrig et al., 1999). Protection may very well be lifelong, as there are no known cases of YF infection in patients who have been vaccinated and had an appropriate initial immune response (Monath et al., 2002a). Although immunity after a single vaccination may be lifelong, international health regulations recommend revaccination at 10-year intervals. The WHO guidelines say a single dose of vaccine provides protection for 10 years and recommend booster vaccinations every 10 years, but this recommendation is not supported by specific clinical evidence (WHO, 2001). Little is known about the effect of one or more booster vaccinations on the duration of immunity. A recent study indicated that revaccination produced more pronounced neutralizing antibody increases (anamnastic response) in people with low antibody titers after the first dose of vaccine (Hepburn et al., 2006). Most vaccinees did not maintain a high neutralizing antibody titer for more than 3–5 years. If a persistent high titer is needed for protection, booster vaccinations with a frequency less than every 10 years would be needed, except in patients who have a high titer already. However, it is unknown whether a high titer is necessary for protection. All available data suggest that the detection of any level of neutralizing antibodies is sufficient for protective immunity. These findings raise new questions as to whether 10-year boosting is the best strategy and demonstrate the need for additional research on optimal dosing schedules (Hepburn et al., 2006).

Contraindications of Vaccination, Including Special Risk Groups

There are a number of contraindications for YF vaccination—the first is age (CDC, 2008). Infants younger than 6 months should not be vaccinated because they are more susceptible to YEL-AND (also known as postvaccinal encephalitis; Cetron et al., 2002). People older than 60 years have an increased risk for adverse events following vaccination (Martin et al., 2001a; Lawrence et al., 2004; Monath et al., 2005; Massad et al., 2005). There is also growing evidence to suggest that YEL-AVD and YEL-AND also appear more frequently in older people (Hayes, 2007; Barwick et al., 2004). Thus, the risk for death due to natural YF infection needs to be balanced against the risk of YEL-AVD and YEL-AND as a result of vaccination in elderly travelers (Khromava et al., 2005).

The second contraindication for YF vaccination is thymus disease. Individuals who have thymus disease or have had a thymectomy should not be vaccinated because this is a risk factor for YEL-AVD (Troillet and Laurencet, 2001; Barwick-Eidex, 2004; Vellozzi et al., 2006; Hayes, 2007; CDC, 2008). Four out of the 40 vaccine recipients with YEL-AVD reported worldwide have had thymus disease. One fatal case in the United States occurred in a 67-year-old woman, who had a thymectomy (Martin et al., 2001b) and a non fatal case occurred in a 70-year-old man who had hyperthyroidism, myasthenia gravis, and had received a thymectomy (Vellozzi et al., 2006). A third nonfatal case in Switzerland occurred in a 50-year-old man (Troillet and Laurencet, 2001) and a fourth fatal case in Colombia occurred in a 44-year-old man, who had both had a thymectomy (Hayes, 2007; Barwick-Eidex, 2004).

The third contraindication for YF vaccination is pregnancy. Currently there are insufficient data to determine whether the vaccine is safe to administer during pregnancy. Therefore, vaccination should only occur if travel to an area with risk of YF is unavoidable. Since pregnancy may affect immunologic function, serologic testing is necessary, and infants born to these women should be monitored for evidence of congenital infection and other possible adverse effects (CDC, 2008). Nonetheless, limited follow-up studies of women and newborn children indicate no abnormal effects suggesting that vaccination of pregnant women may not need to be contraindicated (Nasidi et al., 1993; Tsai et al., 1993; Robert et al., 1999; Suzano et al., 2006; Cavalcanti et al., 2007).

The fourth contraindication for YF vaccination is breast-feeding; vaccination of nursing mothers should be avoided, because of the risk of virus transmission to the baby. It is not known whether YFV is excreted in breast milk, but there have been no reports of adverse events or transmission of the virus to the baby. Nursing mothers should only be vaccinated if travel to an area with risk of YF is unavoidable (CDC, 2008).

The fifth contraindication for YF vaccination is immune suppression; any immunosuppressed person (HIV infection, leukemia, lymphoma, other malignancy, thymus disease, thymectomy, corticosteroid treatment, alkylating drug treatment, antimetabolite treatment, or radiation therapy) who is unable to effectively resist viral infections should not be vaccinated. Low-dose (prednisone or equivalent 20 mg/day), short-term (less than 2 weeks) systemic corticosteroid therapy or intra-articular, bursal, or tendon injections with corticosteroids; and intranasal corticosteroids are not thought to constitute an increased hazard (CDC, 1990, 2008). HIV-infected people who have laboratory verification of T lymphocyte counts and adequate immune system function (e.g., CD4 $> 200/mm^3$) can be vaccinated and monitored if travel to an area with risk of YF is unavoidable (Tattevin et al., 2004). Limited data indicate that the seroconversion rate is reduced; hence, serologic testing is necessary (Cetron et al., 2002; Sibailly et al., 1997). Family members of an immunosuppressed person, who themselves have no contraindications, should be vaccinated. HIV-infected individuals who have inadequate immune system function should not be vaccinated because fatal YEL-AND occurred in a 53-year-old patient with undiagnosed HIV infection who had a low CD4 count (108 cells/mm^3) (Kengsakul et al., 2002).

The sixth contraindication for YF vaccination is hypersensitivity to eggs; the vaccine is contraindicated because it is produced in chicken embryos. People who are able to eat eggs or egg products may receive the vaccine; however, some egg-sensitive persons are not allergic to cooked eggs. Gelatin, which is used as a stabilizer in some vaccines, might also cause allergic reactions. If vaccination of a person with gelatin hypersensitivity or with a questionable history of egg or chicken hypersensitivity is necessary because travel to an area with risk of YF is unavoidable, an intradermal test dose of vaccine should be administered (Aventis Pasteur, 1996; Arguin et al., 2007).

Adverse Events

The 17D vaccine is considered one of the safest vaccines and normally it is well tolerated with recipients reporting injection site pain, inflammation, mild headaches, myalgia, low-grade fevers, backache, or other minor symptoms that occur 5–11 days after vaccination. In non-placebo-controlled clinical trials, where the events reported could be unrelated to vaccination, the incidence of these minor symptoms varies from 4 to 25% and somewhere between 1 and 7% of vaccinees have to curtail regular activities (Theiler and Smith, 1937b; Smith et al., 1938; Freestone et al., 1977; Moss-Blundell et al., 1981; Digoutte et al., 1995; Lang et al., 1999; Monath et al., 2002a; Dumas et al., 1997; Kelso et al., 1999). First-time vaccinees have mild viremia (not exceeding 10^2 pfu/ml for $\geq$1 day between the third and seventh day after vaccination) which is associated with elevations of IFN-α, TNF-α which probably cause the minor symptoms reported by the vacinees, and markers of T cell activation (Wheelock and Sibley, 1965; Hacker et al., 1998; Reinhardt et al., 1998; Monath, 1999; Monath et al., 2002b). Revaccination after 10 years results in no viremia and an even lower incidence of adverse reactions because the 17D virus is neutralized by preformed antibody (Monath et al., 2002a, 2002b; Reinhardt et al., 1998).

Immediate severe hypersensitivity reactions to vaccination, which are characterized by rash, anaphylaxis, urticaria, or asthma or a combination of these, are rare with an incidence of $<$0.8/100,000 vaccinees. The vaccine is contraindicated for persons with a history of oral intolerance to eggs because it is a chicken egg extract. There can also be allergic reactions to other vaccine components in people without egg allergies (Kelso et al., 1999).

Serious adverse reactions to the vaccine are very unusual and there are two types: (1) vaccine-associated neurotropic disease (YEL-AND), encephalitis caused by neuroinvasion of the virus, and (2) vaccine-associated viscerotrophic disease (YEL-AVD), pansystemic infection with hepatitis, which is very similar to wild-type YF infection. The CDC/FDA Working Group on YF vaccines provided diagnostic definitions for YEL-AND and YEL-AVD. To diagnose YEL-AND a patients must show encephalopathy or inflammation on EEG, or CSF, testing and imaging or else they must have clinical disease with symptoms of headache, fever, and focal or general neurological dysfunction. These must occur within one month of vaccination and must be in the absence of other possible etiology. Supportive evidence comes from YFV histopathology and isolation of the vaccine virus from the patient's blood. To diagnose YEL-AVD a patient must have disease symptoms of nausea, vomiting, malaise, fever, diarrhea, myalgia, dyspnea, and they must have evidence of YFV-mediated tissue damage (jaundice, liver dysfunction, renal impairment, tachycardia, rhabdomyolysis, thrombocytopenia, hypotension, myocarditis,

disseminated intravascular coagulation, and hemorrhage) in the absence of other etiology within 10 days of vaccination (Cetron et al., 2002).

Yellow Fever Vaccine–Associated Neurotropic Disease (YEL-AND) YEL-AND (previously named postvaccine encephalitis) has been divided into three categories based on recommendations of the Advisory Committee on Immunization Practices: (1) cases with neurotropic involvement, (2) cases with an autoimmune involvement of the central nervous system, and (3) cases with an autoimmune involvement of the peripheral nervous system. All cases have similar profiles, irrespective of the manufacturing source of the vaccine, and they occur in first-time vaccinees with an onset of illness 4–27 days postvaccination and a case fatality rate <5% (Cetron et al., 2002). Historically, YEL-AND was seen as encephalitis in infants, the first cases were in children who received the FNV by scarification in the 1950s during epidemics in Central America and Nigeria only, with the highest incidence in Nigeria (3–4/1000 vaccinations; 38% case fatality rate) (Durieux, 1956b; Stones and Mac Namara, 1955). It has also occasionally been seen in young babies receiving the 17D vaccine (Anonymous, 1966). After vaccine administration was limited to children ≥6 months in 1969 there have been few reports of YEL-AND in the United States (CDC, 1969). Since 1992, six cases of encephalitis among adult vaccinees have been reported to the U.S. Vaccine Adverse Event Reporting System (VAERS) (CDC, 2002; Marfin et al., 2006) and 10 cases of autoimmune neurological disease have been reported (CDC, 2008). A total of 21 cases worldwide had been reported by June 2001 (Monath, 1999b) showing an increase in the rate of YEL-AND, but this could simply be due to the increased surveillance.

It is difficult to estimate an accurate incidence rate for YEL-AND: the earliest ones varied from 50 to 400 cases per 100,000 infants under 6 months (Monath, 2004). During a 1993 Kenyan vaccination campaign, active hospital-based surveillance estimated a rate of 5.8 cases per 100,000 vaccinees (Monath, 2004). By 2005, the reporting rate was estimated to be 0.4 reported cases per 100,000 doses distributed in the United States (Marfin et al., 2005; Khromava et al., 2005) and the rate in the United Kingdom, where another 17D-204-based vaccine was used, was similar (Kitchener, 2004). The reporting rate was highest among older vaccinees, with 1.4 reported cases per 100,000 doses in persons 60 years and older (Khromava et al., 2005). Crude recent estimates of the reported rate in the United States are lower at 0.3–0.5 cases per 100,000 doses of vaccine distributed, although the rate is higher for people over 60 years at 1.8 cases per 100,000 doses (CDC, 2008). In the most recent study, McMahon et al. (2007) give a rate of 0.23 cases per 100,000 distributed vaccine doses in the United States.

Yellow Fever Vaccine–Associated Viscerotropic Disease (YEL-AVD) Yellow fever vaccine–associated viscerotrophic disease (YEL-AVD, previously named febrile multiple organ system failure or postvaccination multiple organ system failure) has been described among recipients of vaccines produced by all 17D-204 and 17DD manufacturers and, like YEL-AND, all cases have occurred in first-time vaccinees (Cetron et al., 2002). The vaccine virus has been cultured from blood, serum, heart, liver, spleen, skin, brain, spinal cord, kidney, lungs, and skeletal muscle. Liver biopsy of a fatal case before death showed minimal periportal inflammation, mild microvesicular fatty change, and focal degeneration of parenchymal tissue without hepatocellular necrosis. YF antigen can be detected in the liver and spleen. Microscopic examination of liver tissue showed mid-zonal necrosis, steatosis, eosinophilic degeneration of hepatocytes, apoptosis with Councilman bodies, microvesicular fatty changes, and minimal inflammation. Myocarditis and tubular necrosis have also been observed and the neutralizing antibody titers against the virus were higher than expected in some patients (Vasconcelos et al., 2001a; Chan et al., 2001; Martin et al., 2001b; Doblas et al., 2006; Hayes, 2007).

YEL-AVD was first reported in the literature in 2001 (Chan et al., 2001; Martin et al., 2001b; Vasconcelos et al., 2001a; Adhiyaman et al., 2001; Troillet and Laurencet, 2001; Werfel and Popp, 2001) and was initially considered to be a recent phenomenon until Engel et al. (2006) reported that a case had occurred in a Brazilian vaccine recipient in 1975 (Vasconcelos et al., 2004). The reports investigated seven cases, and six of them were fatal following administration of three different vaccines, giving a case fatality rate of 85% (Chan et al., 2001; Vasconcelos et al., 2001a; Martin et al., 2001b). Chan et al. (2001) reported the death of a 56-year-old man taking aspirin and atorvastatin who was vaccinated against YF and meningococcus. Vasconcelos et al. (2001a) reported the deaths of a healthy 22-year-old woman and a 5-year-old girl with a history of prematurity and recurrent bouts of bronchitis and diarrhea who was vaccinated against YF, measles, mumps, and rubella. Martin et al. (2001b) reported the deaths of a 79-year-old woman with a history of hypothyroidism, polymyalgia rheumatica, and hypertension; a 67-year-old woman, who had a colectomy, ileostomy, and thymectomy; and a 63-year-old man with history of hypertension who was

vaccinated against YF, quadrivalent A/C/Y/W-135 meningococcus, oral polio, and hepatitis A. Martin et al. (2001b) reported the only survivor, a 76-year-old man with a history of Crohns disease, following YF and oral typhoid vaccination. Subsequently, further reports described individuals who survived YEL-AVD, giving a revised case fatality rate of 60% (Adhiyaman et al., 2001; Troillet and Laurencet, 2001; Werfel and Popp, 2001). Adhiyaman et al. (2001) reported a 45-year-old man who was immunized against YF, poliovirus, hepatitis A, and tetanus; Troillet and Laurencet (2001) described a 50-year-old man, who had surgery for thyoma; and Werfel and Popp (2001) reported a 71-year-old man with a history of sigmoid diverticulosis and borreliosis who all survived. The next year, a 25-year-old-man who received YF, influenza, and poliovirus vaccinations and a 70-year-old man who received YF vaccination were identified as having survived YEL-AVD (Levy et al., 2002).

Following these initial 12 reports, an additional 28 cases have been identified worldwide and reported to the CDC as of October 2007, which gives a total of 40 cases thus far (Hayes, 2007). Some of the cases have been detailed in the literature: Doblas et al. (2006) reported the death of a 26-year-old woman who was vaccinated for YF, diphtheria, and tetanus; Zhou et al. (2005) reported a 60-year-old man who had chemotherapy for rectal cancer and was vaccinated against YF and meningococcus, and survived; Gerasimon and Lowry (2005) reported the death of a 22-year-old woman who was vaccinated against YF and influenza; and Kitchener (2004) retrospectively found four cases of YEL-AVD where all of the people had received concurrent tetanus toxoid (either combined or singular formulation) vaccination. The most recent cases are a cluster of four fatal cases in Peru from a total of 42,000 given the same lot of vaccine. At the time of writing this chapter, the cause of this cluster is currently under investigation. Two potential risk factors for the development of YEL-AVD have been identified: advanced age (60 years or older) (Khromava et al., 2005; Lawrence et al., 2004) and a history of thymus disease with a thymectomy (Barwick-Eidex, 2004).

The incidence of YEL-AVD is estimated by dividing the number of reported cases by the number of YF vaccine doses distributed. The estimated frequency of YEL-AVD in the United States is 3–5 cases per 1,000,000 doses distributed, while rates are higher among people 60–69 years old (1.1 cases per 100,000 doses), and higher again among those who are over 70 years (3.2 per 100,000 doses). The estimated incidence in the United Kingdom is similar at 0.25 cases per 100,000 doses (Kitchener et al., 2004). An Australian review of adverse events following YF immunization revealed a similar increasing frequency of serious adverse events with increasing age (Lawrence et al., 2004) and a Brazilian study revealed a similar estimated risk of fatal YEL-AVD ranging from 0.004 to 0.21 fatalities per 100,000 doses (Struchiner et al., 2004).

Vaccines in Development

YF vaccine is used principally in tropical climates and the initial lyophilized vaccines without stabilizers deteriorated rapidly when exposed to temperatures above −20°C. So the development of more heat-stable vaccines became necessary. In 1987, the WHO recommended that each vaccine lot meet the following stability test: maintenance of potency (>1000 mouse intracerebral LD_{50}/human dose) with mean loss of titer ≤10-fold after being held at 37°C for 14 days. At that time only half of the YF vaccines produced worldwide met those stability standards. A number of additives were systematically investigated and the most successful formulation, used by a number of manufacturers, employs sugars, amino acids, and divalent cations [lactose (4%), sorbitol (2%), histidine (0.01 M), alanine (0.01 M), in phosphate buffered saline with Ca^{2+} and Mg^{2+}]. This stabilized vaccine loses only 0.3–0.5 $\log_{10}$ of infectivity after being held at 37°C for 14 days and it is stable for two years at 4–22°C. Despite its stability when freeze-dried, the 17D vaccine has very limited stability after reconstitution and must be discarded after an hour, and as such use of the normal multi-dose vials in tropical climates reduces the vaccine effectiveness. Improvement in vaccine stability after reconstitution is an area for future research (Monath, 1996).

The 17D vaccine is highly effective with 95% of people vaccinated showing immunity after a week and safe because >500 million doses have been administered worldwide with very rare serious side effects. Developments in molecular genetic techniques have utilized what is termed "reverse genetics" where the YFV RNA genome can be recovered from the cDNA infectious clone (Rice et al., 1989). Bray and Lai (1991) used two serotypes of DEN to create the first chimeric flavivirus and show that the structural genes of one serotype could be replaced by that of another. Chambers et al. (1999) created chimeric 17D/JE viruses that were attenuated for mice by swapping the prM and E protein genes from JE virus into the 17D 204 backbone; interestingly swapping the complete structural genes resulted in nonviable virus. This led to the ChimeriVax™ platform developed by Acambis Inc., where the YF 17D-204 vaccine virus backbone is used to create a new generation of chimeric vaccines, against DEN, WNV, and JE by swapping of the prM

and E protein genes of the heterologous flaviviruses into the 17D infectious clone backbone (Pugachev et al., 2005). This approach has proved to be very promising with the ChimeriVax-WN in phase I clinical trials (Arroyo et al., 2004; Monath et al., 2006), tetravalent ChimeriVax-DEN (Guirakhoo et al., 2002, 2004; Guirkahoo et al., 2001) in phase 2 clinical trials, and ChimeriVax-JE in phase III clinical trials (Monath et al., 2002b, 2003). Table 40.4 gives a summary of the progress of these vaccines in clinical trials. The sequencing of the 17DD genome (Duarte dos Santos et al., 1995; Galler et al., 1998) allowed the production of an infectious clone from this substrain and chimeric flavivirus vaccines were also constructed by swapping the prM and E protein genes (Bonaldo et al., 2000). A chimeric 17DD/DEN1 vaccine, using the VeMir95 Venezuelan isolate, was not avirulent for mice and was more attenuated for monkeys than the commercial 17DD vaccine (Mateu et al., 2007). A chimeric 17DD/DEN2 vaccine, using the 44-2 wild-type Southeast Asian isolate, was similarly attenuated in monkey tests (Galler et al., 2005). A chimeric 17DD/Den 2 New Guinea C (NGC) vaccine, with the carboxy terminus of an E gene from a Brazilian isolate, was attenuated in mice and gave partial protection against a lethal challenge with DEN2 NGC virus (Caufour et al., 2001). While these 17DD-based vaccines have shown promise in monkey trials, none have progressed to human clinical trials.

There has been recent interest in using the 17D backbone to develop chimeric YF viruses as a diagnostic tool for flaviviruses that need to be handled at BSL3. For example, Chimerivax-St Louis encephalitis (SLE) virus is being used at BSL2 as a surrogate for SLE virus in neutralization tests (Pugachev et al., 2004).

The 17D backbone has been used to develop a recombinant vaccine against Lassa fever virus; where the 17D 204 infectious clone expressing Lassa fever virus GP1 and GP2 in frame between the E and NS1 genes protected guinea pigs against fatal Lassa fever (Bredenbeek et al., 2006). Both the 17D-204 and the 17DD backbones are being used as prototype malaria vaccines (Tao et al., 2005; Bonaldo et al., 2002, 2005, 2006) and the 17D-204 backbone as a prototype cancer vaccine (McAllister et al., 2000) to express foreign epitopes, rather than complete antigens. The 17D-204 backbone expressing malaria epitopes at the viral serine protease cleavage site between NS2B and NS3 diminished murine liver parasite burden by 70% and provided protection for 4–8 weeks. Boosting with irradiated sporozoites (mimics immune response of vaccine-primed individuals in endemic areas) after vaccination conferred sterile immunity to 90% of mice indicating that vaccination could be sustained and magnified by the bite of infected mosquitoes (Tao et al., 2005). A second chimeric 17DD backbone expressing malaria epitopes, this time in the E protein fg loop, was attenuated for mice and monkey neurovirulence, and mouse tests showed production of antibodies that recognized the parasite protein (Bonaldo et al., 2002, 2005, 2006). To facilitate cancer vaccine studies, ovalbumin epitopes have been inserted, as model systems at different sites in the 17D-204 genome (N terminus of the polypeptide or between proteins C and prM, NS2A and NS2B, NS2B and NS3, NS3 and NS4A, or NS4A and NS4B). Immunization of mice elicited protective immunity against challenge with lethal doses of malignant melanoma cells expressing ovalbumin, and virus immunotherapy induced regression of established solid tumors and pulmonary metastases (McAllister et al., 2000). HIV vaccines are currently being developed using this same strategy (Van Epps, 2005).

Studies are also underway to develop replication-deficient 17D vaccine vectors (replicons) expressing foreign antigens in place of the envelope protein genes, e.g., Hepatitis C virus (Molenkamp et al., 2003). These so-called replicons undergo one round

TABLE 40.4 17D vaccine candidates that are under development for clinical use

Vaccine (strain)	Company	Clinical trial	References
ARILVAX™ (17D)	Acambis	Phase III	Monath et al. (2002a) Belmusto-Worn et al. (2005)

of replication and stimulate strong immune responses without the risk of complications associated with live vaccines, especially in immunosuppressed people (Jones et al., 2005; Mason et al., 2006).

Rationale of Second/Third/New-Generation Vaccines

A recent study evaluated the incremental health and programmatic cost impact of using single-dose lyophilized 17D vaccines as compared to the standard multi-dose vials in Cambodia, Ghana, and Bangladesh. A cost-effectiveness model found that single-dose presentations of the thermostable YF vaccine is a potentially cost-effective way of reducing childhood deaths and disability in low-resource countries in Asia and Africa (Levin et al., 2007).

Clinical Trials

There have been three recent phase III clinical trials involving two new YF vaccines that have been produced by companies who have bought the vaccine production technology rights. The first of these, the ARILVAX™ vaccine (Acambis, United States), was compared with a current commercial vaccine, YF-VAX® (Sanofi Pasteur Inc., USA), in a phase III double blind clinical trial in U.S. adults. There was 99.3% seroconversion of individuals given YF-VAX and 98.6% seroconversion of individuals given ARILVAX. Both vaccines were well tolerated by the recipients and the mean antibody responses elicited were well above minimal levels needed for protection. No serious adverse events were reported, although the YF-VAX recipients had more pain, edema, and inflammation at the site of the injection (Monath et al., 2002a; Barrett, 2004). The first randomized, double-blind, phase III vaccine trial in children (age 9 months–10 years) was carried out in Peru and compared the efficiency of this ARILVAX vaccine with the YF-VAX vaccine. Both vaccines were well tolerated and highly immunogenic, although the seroconversion rates were significantly higher for the ARILVAX vaccine. Any adverse reactions reported were mild and resolved without medical intervention (Belmusto-Worn et al., 2005; Barrett, 2004).

The immunogenicity and safety of another new YF vaccine, the BERNA-YF vaccine (Flavimun®, Berna Biotech Ltd., Switzerland), manufactured after the transfer of the vaccine technology from the Robert Koch Institute in Germany, was compared with the original German vaccine and a current, commercial vaccine, Stamaril® (Sanofi Pasteur, France), in a phase III bridging clinical trial. An effective immune response, with seroprotection in 100% of the individuals in all vaccine groups was elicited by all three vaccines and no adverse events were reported. There were no differences in the immune responses generated between three consecutive production batches of the BERNA-YF vaccine (Pfister et al., 2005).

POSTEXPOSURE IMMUNOPROPHYLAXIS

Early studies showed that passive antibody, the interferon inducer poly(I-poly(C), or interferon treatments are effective only before or within hours of infection, and as such these can be utilized in postexposure prophylaxis after a known exposure event, e.g., a laboratory-acquired infection (Monath,1987).

PROSPECTS FOR THE FUTURE

The new ChimeriVax platform vaccines have reached phase III clinical trials and are manufactured in Vero monkey kidney cell culture, which facilitates rapid vaccine manufacture at short notice to combat outbreaks of disease. One of the great problems with YF vaccine is supply and demand. Large numbers of embryonated chicken eggs are not available at short notice and it takes considerable labor to manufacture the vaccine. This opens up the possibility of changing the manufacture of the current 17D vaccine from embryonated chicken eggs to cell culture (Freire et al., 2005). This approach has not moved forward very far, in part due to the need of obtaining extensive safety and efficacy data on a "new" product compared to the current egg-based vaccine, which has a well-known safety and efficacy profile. Nonetheless, if a chimeric 17D-based vaccine is licensed and used it may provide the impetus to undertake additional research for a 17D Vero cell–derived vaccine. It has also been proposed that a reverse genetics Vero cell vaccine would have the advantage of a vaccine virus of defined sequence and would eliminate the quasi species found in the current vaccine. This, of course, assumes that the heterogeneity in the current vaccine does not contribute to the efficacy of the vaccine.

The reemergence of YFV in North America is a serious threat as evidenced by the West Nile epidemic brought to New York in 1999 (Lanciotti et al., 1999). Unvaccinated tourists who visit YFV endemic areas are at high risk of being infected and air travel would allow these viremic tourists to travel home quickly and be the source of an epidemic. Primary care physicians, in general, are ill prepared to diagnose

or treat YF cases due to lack of experience and the *Ae. aegypti* domestic vector is present in large numbers in the Southern states. YF is a zoonosis and therefore vector control is central to the control of the disease. The development of molecular genetic techniques allows for the possibility of control using transgenic mosquitoes, although there are a huge number of ethical issues about the release of transgenic vectors. Mosquitoes have already been experimentally engineered with resistance to YFV (Higgs et al., 1998) and this would allow for competition studies in the field to see if naturally occurring populations could be replaced with genetically engineered resistant populations. This research would open up the whole area of flavivirus control using transgenic resistant mosquito vectors.

KEY ISSUES

- YFV was the first virus demonstrated to be transmitted by mosquitoes.
- Development of live-attenuated YF vaccines is one of the milestones in vaccine research and it is one of the safest and most efficacious vaccines developed to date.
- YF is a reemerging enzootic disease that is still a major public health problem despite the availability of the vaccine.
- More research is necessary to better understand the disease pathology and host immune response.
- In recent years, a rare but significant number of severe adverse events have been reported involving vaccine-associated viscerotropic disease and vaccine-associated neurotropic disease.
- The 17D vaccine virus infectious clone backbone is being successfully used to develop a variety of chimeric virus vaccines, some of which have reached clinical trials for human use.

Anthrax

Jason E. Comer and Johnny W. Peterson
Department of Microbiology and Immunology, Sealy Center for Vaccine Development, University of Texas Medical Branch, Galveston, TX, USA

OUTLINE

ABSTRACT

The causative agent of anthrax is the spore-forming bacterium, *Bacillus anthracis*, which is considered a major bioterrorism threat because its spores are very stable, easily disseminated, and infectious by aerosol. The clinical form of the disease is dependent on the route of exposure and can manifest as cutaneous, gastrointestinal, or inhalational anthrax. Irrespective of the route acquired, septic anthrax is a devastating infection with high mortality. The virulence of *B. anthracis* is dependent on the production of an antiphagocytic capsule and two bipartite, proteinaceous toxins: lethal toxin and edema toxin. The toxins comprised three proteins, lethal factor (LF), edema factor (EF), and protective antigen (PA). PA, the binding moiety of each toxin, facilitates toxin entry into host cells. LF, the enzymatic portion of lethal toxin, is a zinc metalloprotease that cleaves the N-terminal region of mitogen-activated kinase kinases. This toxin interferes with the function of host immune cells and disrupts the endothelial barrier. EF, the enzymatic moiety of edema toxin, is a calmodulin-dependent adenylyl cyclase that converts ATP to cAMP, resulting in immune cell dysfunction and tissue edema. The pathology associated with

an anthrax infection (i.e., hemorrhage, necrosis, and edema) is the result of the action of the toxins. The current FDA-licensed anthrax vaccine comprised filter-sterilized culture media, in which an attenuated (capsule-deficient) strain of *B. anthracis* has grown, combined with aluminum hydroxide adjuvant. While all secreted or released bacterial proteins are present in the vaccine formulation, the major immunogen is PA. The levels of antibodies to PA elicited by the vaccine directly correlate with survival in infected animal models. The need for a chemically defined vaccine has led to the development of a second-generation vaccine, consisting of recombinant PA and the aluminum hydroxide adjuvant. This new vaccine has proved efficacious in the nonhuman primate and rabbit models of inhalation anthrax, and clinical trials are currently evaluating the safety and immunogenicity in human volunteers. Apart from active immunization, passive transfer of antibodies to PA is efficacious in anthrax animal models. Compounds that inhibit the action of the toxins are also being investigated. These recent advances have increased the arsenal of therapeutics that can be used in the future to improve the prognosis of anthrax-infected individuals.

INTRODUCTION

A spore-forming bacterium, *Bacillus anthracis*, is the causative agent of anthrax. Outbreaks of this zoonotic disease date back to antiquity, and today the disease is endemic among animals worldwide. Herbivores are particularly susceptible and become infected while grazing by inhaling aerosolized spores or ingesting contaminated plant material. Once inside the animal, the spores germinate and the proliferating vegetative cells quickly kill the host. Close to or at the time of death, the animal hemorrhages and bacteria-laden blood is released into the environment from the mouth, nose, and rectum. Environmental parameters signal the bacteria to sporulate, and the spores remain viable long after the animal has decomposed. The spores can be disseminated by water, wind, or scavengers carrying away pieces of the contaminated carcass. The cycle repeats when another herbivore grazes in the contaminated area. Unlike most other pathogenic bacteria or viruses, *B. anthracis* must kill its host in order to infect another.

Humans can be infected when they come in close contact with *B. anthracis*-infected animals or contaminated animal products. We are also at risk of intentional infection by biowarfare or bioterrorism. Research on *B. anthracis* as a possible biological weapon began in the 1940s, and recent events have renewed interest in finding novel vaccines and therapies to combat the agent. The current anthrax vaccine has been licensed for human use since 1970. This chapter will focus on recent advances in the development of the vaccines to prevent anthrax in humans, as well as the characteristics of *B. anthracis* that make the bacterium a bioterrorism threat.

BRIEF HISTORY OF THE DISEASE

Anthrax has been described in antiquity and may have been responsible for the fifth and sixth plagues of Egypt described in the Bible. The Roman poet Virgil described the disease in both domestic and wild animals. In the 18th century, the sheep population of Europe was decimated by an anthrax outbreak, and the human form of the disease was termed wool sorters disease because of the rate of infection in individuals working with contaminated animal fibers (Sternbach, 2003).

Robert Koch was the first person to trace the complete life cycle of the bacterium and found that *B. anthracis* formed spores that remain viable even in adverse environments. Koch also cultured the organism in vitro and inoculated healthy animalsthat ultimately developed systemic infection characteristic of anthrax. *B. anthracis* became the prototypical organism of Koch's famous postulates for identifying the causative agents of infectious diseases. Louis Pasteur later created the first live vaccine against anthrax which comprised *B. anthracis* attenuated by passage at elevated incubation temperature (Sternbach, 2003).

ETIOLOGICAL AGENT

B. anthracis is a large ($1.0 - 1.2 \times 3 - 5\mu$m), Gram-positive bacillus capable of forming stable spores in unfavorable environments such as nutrient depletion (Fig. 41.1). The bacterium contains a ~5.3 Mb chromosome and two virulence plasmids. The bacterial cells grow in long chains, and the large colonies have a ground glass-like appearance when cultured on solid agar. The organism has a biphasic life cycle; it can exist as a metabolically inactive endospore or as a rapidly proliferating vegetative cell. When bacteria are released from an animal by hemorrhage, environmental parameters such as temperature, pH, O_2 availability, sunlight, nutrient level, and certain cations signal the bacterium to sporulate. The spore comprises several layers with the internal core housing the genetic material and enzymes. The core is surrounded by an inner and outer membrane, which are constructed from the vegetative cell membrane during the sporulation process. The thick cortex is located between the two membranes

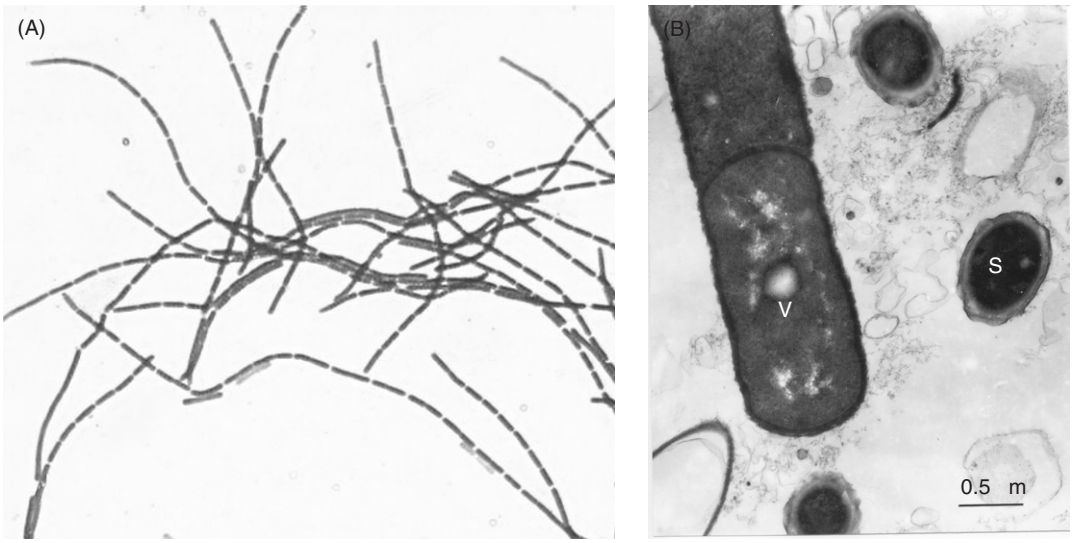

FIGURE 41.1 (A) Gram stain of *Bacillus anthracis* showing the bacilli growing in long chains. (B) Electron micrograph (EM) showing vegetative cells (v) and spores (s) at 47,000 ×. The bar denotes 0.5μm. EM courtesy of Vsevolod Popov, Ph.D., Department of Pathology, University of Texas Medical Branch, Galveston, TX.

and is structurally similar to the bacterial cell wall. The cortex is heat resistant and is responsible for protecting the spore from dehydration. The outer membrane is encompassed by the thick spore coat, which is produced by the vegetative cell and is resistant to lytic enzymes. The outermost layer of the spore is the loose-fitting exosporium. Unlike other spore integuments, the exosporium is not composed of pre-existing membranes, but is produced at the time of sporulation. Further, the exosporium does not contain vegetative cellular antigens, except for PA, which has been reported on the surface of spores (Cote et al., 2005; Guidi-Rontani and Mock, 2002). The structure of the spore makes it resistant to most disinfectants; often 10–50% bleach, 10% formalin, or formaldehyde gas is used for decontamination.

The spores are 1–5μm in diameter making them of ideal size for inhaling deep into the alveolar spaces. Once inside the host, *B. anthracis* has both intracellular and extracellular stages of growth. The spores are taken up by macrophages into an acidified endosome, where they germinate and escape the antimicrobial environment. Compounds such as L-alanine, L-tyrosine, and adenosine, which are abundant in a host, stimulate the germination process. The bacteria proliferate inside the macrophage eventually lysing the cell and continue to divide extracellularly.

ANTIGENS ENCODED BY AGENT

The virulence of *B. anthracis* is dependent on the genes encoded on two plasmids, pXO1 and pXO2. The genes for the synthesis of the poly-γ-D-glutamic acid capsule are located on pXO2. The electronegative charge of the capsule enables the bacteria to evade phagocytosis and killing and is required for dissemination to other tissues from the lungs in the mouse model of inhalation anthrax (Drysdale et al., 2005; Ezzell and Welkos, 1999).

Although pXO1 has many open-reading frames, three genes, *pag*, *lef*, and *cya*, encode protective antigen (PA), lethal factor (LF), and edema factor (EF), respectively (Mikesell et al., 1983). These three proteins comprise the two toxins, lethal toxin (LeTx) and edema toxin (EdTx) that belong to the family of bacterial binary A–B toxins. The A moieties (LF or EF) act within the cytosol of the host cell, and the B component (PA) binds the toxin complex to the target cell and facilitates the entry of the A subunit.

Transcription of toxin and capsular genes is affected by temperature (37°C) and bicarbonate/CO_2, two signals present in a mammalian host. The *atxA* gene located on pXO1 positively regulates transcription of toxin and capsule genes. Another virulence gene regulator encoded by pXO2, *acpA*, only induces expression of genes required for capsule synthesis. In addition, a chromosomal gene called *abrB* induces the toxin genes in a growth-phase-specific manner (Guidi-Rontani and Mock, 2002). This level of transcriptional control ensures that the bacterium only produces virulence factors when appropriate (i.e., when inside a host).

Two PA receptors on mammalian cells have been identified so far, namely Tumor Endothelial Marker 8 (TEM8) and Capillary Morphogenesis Gene-2 (CMG2), which are expressed by a variety of tissues

and cells (Bradley et al., 2001; Scobie et al., 2003). The 83 kDa PA protein binds to the cell surface receptor and is cleaved at the N-terminal region by a host cell furin protease (Klimpel et al., 1992). The resulting 63 kDa protein (PA63) heptamerizes forming a ring structure with competitive binding sites for three molecules of LF and/or EF (Milne et al., 1994). Once the enzymatic moiety binds to the oligomerized PA63, the complex enters the cell via receptor-mediated endocytosis. The toxins enter an acidic endosomal compartment, and the low pH causes conformational changes in PA, such that it forms a membrane-spanning channel allowing for the translocation of EF and LF into the cytosol (Ascenzi et al., 2002; Fig. 41.2).

EF is a calmodulin-dependent adenylyl cyclase that forms 3′,5′-adenosine monophosphate (cAMP) from adenosine triphosphate (ATP) in many different types of cells (Leppla, 1982). The increase in cellular cAMP causes the efflux of water and electrolytes from the cell, resulting in the characteristic interstitial edema associated with *B. anthracis* infections. The toxin has also been shown to inhibit LPS-induced TNF-α production in monocytes and inhibit phagocytosis by neutrophils (Hoover et al., 1994; O'Brien et al., 1985). The increase in intracellular cAMP also inhibits the activation of murine CD4+ T cells (Paccani et al., 2005).

LF is a zinc metalloprotease with mitogen-activated kinase kinases (MAPKKs) 1, 2, 3, 4, 6, and 7 as the only known substrates (Duesbery et al., 1998; Pellizzari et al., 1999; Vitale et al., 2000). The toxin can enter and is proteolytically active in most cells but is specifically cytotoxic for macrophages from certain strains of inbred mice (Singh et al., 1989), suggesting some other substrate or function of the toxin (Chaudry et al., 2002). The susceptibility of murine macrophages is dependent on mutations in a single kinesin-like motor gene called *kif1C* (Watters et al., 2001). Laboratory rodents are killed by injection of purified PA and LF. LeTx readily kills laboratory mice regardless of macrophage sensitivity and evidence suggests that death is the result of TNF-α-independent hypoxia (Moayeri et al., 2003), although no direct measurements of pO_2 have

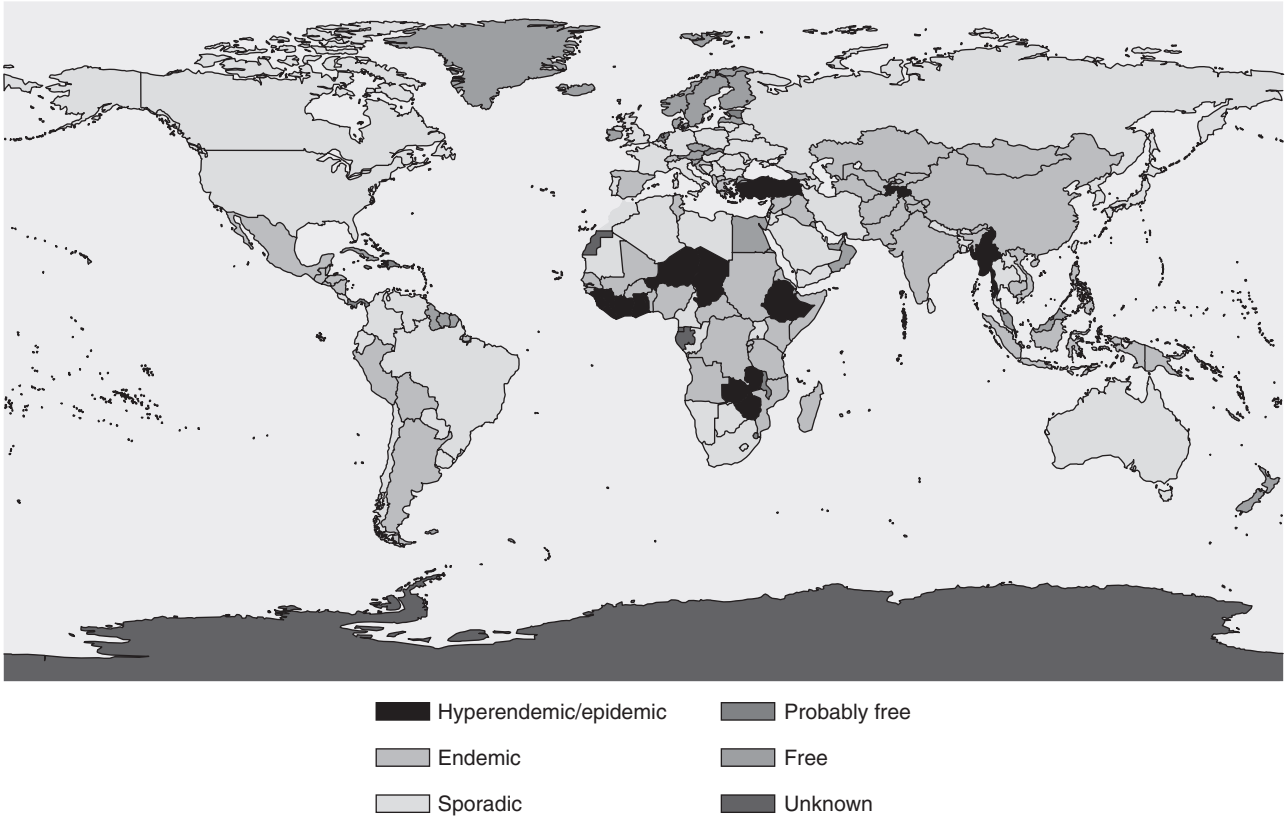

FIGURE 41.2 Mechanism of entry and action of anthrax toxins. Protective antigen (PA) binds to one of the two known anthrax toxin receptors, TEM8 or CMG2. PA is then activated by a host furin protease. The resulting 63 kDa PA molecules heptamerize, forming binding sites for three molecules of lethal factor (LF) or edema factor (EF). The holotoxin is taken into the cell by receptor-mediated endocytosis. Acidication of the endosome causes a conformational change in PA such that it forms a channel though the membrane, thus releasing LF and EF into the cytosol. LF is a zinc metalloprotease with mitogen-activated kinase kinases (MAPKKs) as its only know substrates. EF is a calmodulin-dependent adenylyl cyclase that converts ATP into cAMP (see color plate section).

confirmed this hypothesis. Infusion of the toxin into rats causes death by circulatory shock (Cui et al., 2004).

Human macrophages are not readily lysed by the toxin; however, Popov et al. (2002) showed that LeTx (1) inhibited the bactericidal activity of human monocytes, (2) suppressed production of proinflammatory cytokines, and (3) ultimately caused the cells to undergo apoptosis. The toxin also suppresses antigen presentation by murine dendritic cells, thereby inhibiting an adaptive immune response (Agrawal et al., 2003). The toxin further suppresses the adaptive immune response by inhibiting the activation of human CD4+ T cells (Fang et al., 2005) and B cells in mice (Fang et al., 2006). In addition to impairing immune cells, LeTx induces apoptosis in cultured endothelial cells (Kirby, 2004) and disrupts the endothelial barrier (Warfel et al., 2005), which may partly explain the hemorrhage observed in inhalational anthrax patients.

PROTECTIVE IMMUNE RESPONSE

There is little in the literature concerning the protective immune response to an anthrax infection in humans. Much of the data on protective immunity, namely, development of antibodies to PA, conferring protection against anthrax, are derived from studies with vaccines in animal models. In fact, as discussed later, PA is the dominant antigen in the current licensed anthrax vaccine adsorbed (AVA). Protection of rabbits vaccinated with recombinant PA (rPA) against aerosol challenge with virulent *B. anthracis* spores correlates directly with anti-PA titer (Little et al., 2004). The role in survival following infection played by anti-PA antibodies is not fully understood. Production of neutralizing antibodies, those that interfere with the anthrax toxin's ability to enter host cells, would inhibit the deleterious effects of the toxins. Further, antibodies to PA enhance phagocytosis of spores and killing of bacteria in vitro (Cote et al., 2005; Welkos et al., 2001). Although the humoral immune response is thought to be the defining factor determining immunity to anthrax, a cell-mediated response also develops. Shlyakhov et al. (1997) showed that healthy individuals vaccinated with live nonencapsulated spores respond to an anthrax-specific, tuberculin-like skin test. The relative importance of the humoral response and cell-mediated immunity in anthrax was demonstrated by passive transfer of serum and lymphocytes from PA-vaccinated mice to naïve animals. Mice receiving sera containing PA antibodies lived significantly longer than controls after challenge with a capsule-deficient strain of *B. anthracis*. In contrast, animals receiving lymphocytes died at the same rate as controls (Beedham et al., 2001).

EPIDEMIOLOGY

Anthrax is a worldwide disease affecting herbivores on most of the continents (Fig. 41.3). Anthrax is endemic in parts of South America, Asia, and Africa. North America, Europe, and Northern Asia have sporadic outbreaks of anthrax in animals and humans. Most recently, the Associated Press reported outbreaks of anthrax in cattle herds in North and South Dakota in 2005. A total of 500 unvaccinated head of cattle succumbed to the disease causing financial losses for the afflicted ranches.

Western Africa is heavily affected by anthrax, and an outbreak in Zimbabwe between October 1979 and March 1980 resulted in over 6000 cases of human anthrax, which were mostly the cutaneous form of the disease. Then between August and November 2004, a massive outbreak devastated the herds of herbivores in the Malilangwe Wildlife Reserve, Zimbabwe (Clegg et al., 2007). The slaughter and handling of raw meat from an infected cow resulted in 25 cases of cutaneous anthrax in Paraguay in 1987 (Cieslak and Eitzen, 1999). Between 1994 and 2004, 25 cases of cutaneous anthrax were reported in a clinic in the Elazig province of Turkey (Demirdag et al., 2003). Spain reported the largest number of cases in Europe, with 78–152 cases annually between 1991 and 1995, while neighboring France reported no cases between 1972 and 1994, until a fatal case of African-acquired anthrax was diagnosed. Then, in 1997 in two separate outbreaks in France, 95 cows were killed, and there were three fatal cases of anthrax in a farmer, a veterinarian, and young boy (Patra et al., 1998). Other cases of anthrax in Europe were caused by animal products imported from endemic regions (Schmid and Kaufmann, 2002).

Kazakhstan reported 73 human cases of anthrax between 1997 and 1998. A retrospective cohort analysis to determine risk factors found that all of these cases occurred following contact with infected animals, and persons butchering infected animals were at increased risk. In addition, the study reported that the risk may have been increased by the presence of abraded skin on the hands of the infected humans (Woods et al., 2004).

In recent years, the use of an attenuated veterinary vaccine in the United States and Europe has limited the number of anthrax outbreaks in livestock and thus decreased the incidence of human anthrax. In the United States, the number of human anthrax cases per

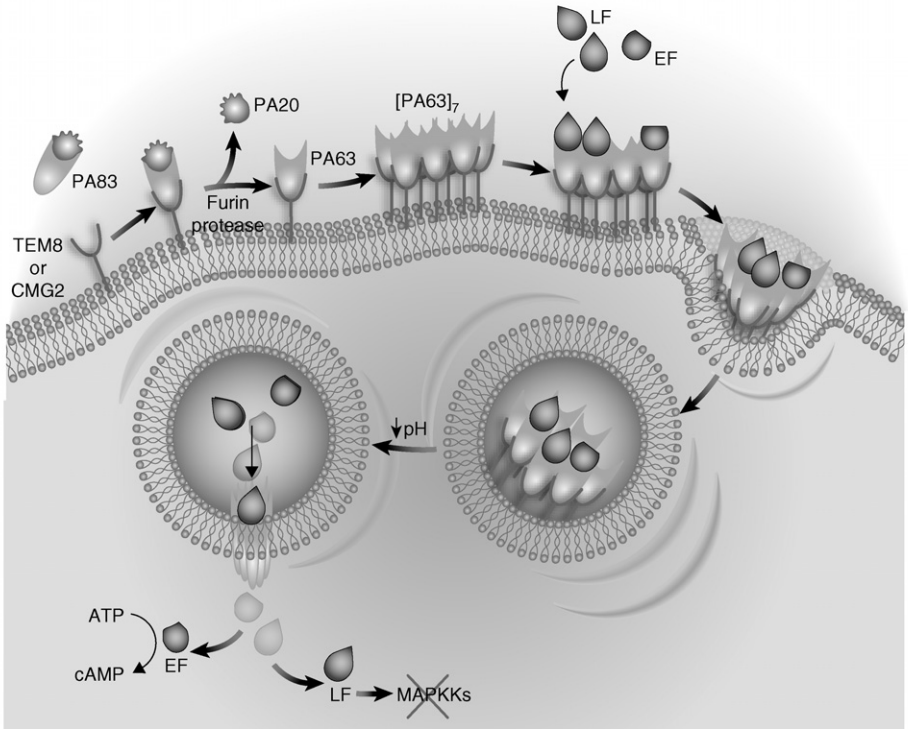

FIGURE 41.3 Worldwide occurrence of anthrax as of 2003. Map courtesy of Martin E. Hugh-Jones, Ph.D., WHO Collaborating Center for Remote Sensing and Geographic Information Systems for Public Health, Department of Epidemiology and Community Health, School of Veterinary Medicine, Louisiana State University, Baton Rouge, LA. (www.vetmed.lsu.edu/whocc/mp_world.htm (see color plate section).

year averaged about 35 in the 1950s and decreased to less than one per year since 1980. Between 1950 and 1999, 458 cases of human anthrax were reported nationally with 77% occurring before 1959. Forty-one field investigations conducted by The Centers for Disease Control (CDC) determined that the exposure sites comprised 24 agricultural settings, 11 textile mills, and 6 others. Of the 27 cases of anthrax in textile mills, 21 were cutaneous and 6 were inhalational with contaminated goat hair or sheep wool being the primary vehicles (Bales et al., 2002).

As demonstrated above, most human anthrax cases occur when individuals come in close contact with infected animals or animal products; however, some instances of human anthrax have more sinister causes. The largest outbreak of inhalation anthrax occurred in April and May of 1979 in Sverdlovsk in the former Soviet Union. Originally reported as gastrointestinal anthrax, further investigation determined that the outbreak was due to inhalation of anthrax spores. Tissue analysis of 11 victims identified four different strains of *B. anthracis* (Jackson et al., 1998). An epidemiological investigation determined that the likely source of the outbreak was the accidental release of spores from a military weapons factory, Compound 19, in southern Sverdlovsk. The incident infected 94 people and caused at least 64 deaths (Meselson et al., 1994). It was not until 1992 that Russian President Boris Yeltsin announced that the military installation was responsible for the outbreak.

Before the 2001 terrorist attack, the last reported case of inhalational anthrax in the United States occurred in California as a result of exposure to contaminated yarn imported from Pakistan (Suffin et al., 1978). In 2001, letters contaminated with anthrax spores, sent through the U.S. Postal Service, resulted in 22 cases of anthrax. In October 2001, the first case of bioterrorism-related anthrax occurred in Florida, and increased surveillance identified a total of 22 cases of anthrax between October 4 and November 20, 2001. Eleven of these cases were the cutaneous form of infection with the other 11 cases being inhalational anthrax. Five victims with inhalational anthrax died of the infection. Twenty of the 22 cases occurred in individuals who were mail handlers or exposed to work sites where the contaminated letters were processed or received (Jernigan et al., 2002). This event underscores the reason that *B. anthracis* is considered a significant threat as a biological warfare/bioterrorism agent.

Anthrax has a long history as an agent in the biological warfare arsenal. Germany investigated the possible use of anthrax against animals and humans

in World War I and II. During this time, Japan also experimented with biological weapons including anthrax and used biological weapons on Chinese civilians. The allies including Great Britain and the United States also engaged in biological weapons research. The United States formed the War Research Service at Fort Detrick, Maryland, to investigate the offensive use of anthrax. The British tested anthrax bombs on a remote island northwest of Scotland. They also prepared *B. anthracis*-laden food pellets to infect German cattle. Although they actively engaged in research, the allies did not use bioweapons in military campaigns. In 1969, President Nixon renounced the use of biological weapons and ordered all offensive stockpiles destroyed, an action that prompted the International Biological Weapons Convention, which called for the complete elimination of all offensive biological weapons worldwide (Mobley, 1995).

The use of biological weapons in conventional warfare does not appear to be a major threat, but the possibility of an anthrax attack still exists from either rogue nations or terrorist groups, and would most probably target the civilian population. The World Health Organization estimated that the aerosolization of 50 kg of dried *B. anthracis* spores over a city with a population of 500,000 would incapacitate 125,000 people and kill 95,000. Such an event would overwhelm medical resources and disrupt the infrastructure of most cities (World Heath Organization, 1970). As part of a 1999 initiative from Congress to increase public health preparedness for response to biological terrorism, the CDC categorized biological agents as A, B, or C with category A agents having the greatest effect on public health. *B. anthracis* is a level A select agent and is ranked along with *Variola major*, the causative agent of smallpox, as the two greatest bioterrorism risks to public health. While there have been no reports on person-to-person transmission of inhalational anthrax, the ease of dissemination, infective stability of the spore, and virulence of the organism make it one of the highest potential biological threats (Rotz et al., 2002).

Although a biological attack of the enormity described by the WHO has not occurred, civilian populations have been the targets of anthrax attacks. In 1993, the Aum Shinrikyo cult released an aerosol cloud of anthrax spores in Kameido, Japan, but there were no reports of clinical anthrax. Molecular analysis of spores isolated from the site established that the released spores were from an attenuated stain of *B. anthracis* used to vaccinate animals in Japan (Keim et al., 2001). In comparison, the letters used to disseminate the spores in the U.S. attack were contaminated with fully virulent, weaponized *B. anthracis* Ames strain spores. This incident proved that terrorists could effectively distribute and disseminate anthrax spores without sophisticated equipment by exploiting the society's infrastructure.

FIGURE 41.4 Case of cutaneous anthrax with characteristic eschar. A ranch hand in Edwards County Texas reportedly was infected after skinning a buffalo. The patient noticed a small pimple on his left arm 5 days after contact with the animal. The lesion progressed and the man was hospitalized for severe cellulitis, and treated with penicillin and ciprofloxacin. The lesion evolved into a single black eschar measuring 3×5 in. The individual was discharged after 9 days in the hospital. Picture courtesy of Army Major Margaret "Meg" Neidert during residency training at the Texas Department of State Health Services, Austin, Texas (www.tdh.state.tx.us./phpep/).

CLINICAL DISEASE

Anthrax occurs in three clinical forms: cutaneous, gastrointestinal, or inhalational. The type and severity of disease are dependent on the route of exposure. Ninety percent of all human cases of anthrax are cutaneous. Infection occurs when viable spores come in contact with abraded skin, and a small papule develops in 2–3 days. Within the next 24 h, a ring of vesicles forms around the papule, which starts to ulcerate and then dries resulting in the characteristic black eschar (Spencer, 2003; Fig. 41.4). The anthrax skin lesion is painless, which differentiates it from a similar painful lesion formed from the bite of the *Loxoceles reclusa* (brown recluse) spider. Even without treatment, the anthrax eschar usually resolves within 2–6 weeks. Twenty percent of untreated individuals become septic and die, but antibiotic intervention can reduce the mortality rate to $<1\%$ making this the most benign form of the disease.

Ingestion of viable spores from contaminated meat results in gastrointestinal anthrax and, depending

on the site of inoculation, can take one of two forms, either oropharyngeal or abdominal with the lesion forming at the site of entry. Oropharyngeal anthrax occurs when spores enter the oropharynx, and symptoms include sore throat, dysphagia, fever, cervical lymphadenopathy, and edema. Infection of the terminal ileum and/or cecum with hemorrhage of the mesenteric lymph nodes results in abdominal anthrax, which also presents with nondescript symptoms including abdominal pain, hematemesis, and bloody diarrhea. If untreated, the bacteria can disseminate to the bloodstream, and once septic the patient rapidly succumbs to the infection. Although rare outside of Africa and Asia, gastrointestinal anthrax has a high mortality rate. The ambiguous symptoms characteristic of early infection make diagnosis difficult, and the delay in administration of appropriate antibiotics often leads to death (Spencer, 2003).

As discussed earlier in this chapter, inhalational anthrax was usually associated with occupational exposure to contaminated animal products. Until 2001, the last case of inhalational anthrax in the United States was reported in 1978 (Suffin et al., 1978). In this chapter, we will present clinical symptoms of the first 10 cases of the 2001 U.S. bioterrorism-related inhalational anthrax as reported by Jernigan et al. (2001). The median incubation time was 4 days from the time of exposure to symptom onset. As in the case of gastrointestinal anthrax the disease starts with nonspecific symptoms including fever or chills, sweats, fatigue with malaise, and minimal or nonproductive cough, dyspnea, and nausea. All patients had abnormal chest X-rays, characteristic of inhalational anthrax including infiltrates, pleural effusion, and widening of the mediastinum (Fig. 41.5). With multiple antibiotic treatment and supportive care, the mortality rate was 45%, substantially lower than the previously published estimate of 95%.

FIGURE 41.5 Chest radiograph of an inhalational anthrax patient in 1961. The radiograph was taken 22 h before death and demonstrates the mediastinal widening characteristic of this form of the disease. Radiograph was provided by Dr. Philip S. Brachman and provided by the Centers for Disease Control and Prevention (www.cdc.gov.).

TREATMENT

Successful treatment of inhalational anthrax requires early administration of antibiotics. The initial CDC-recommended treatment for inhalational anthrax is intravenous infusion of ciprofloxacin (400 mg bid) or doxycyline (100 mg bid) coupled with other antibiotics. Following this initial treatment, patients are switched to 500 mg of ciprofloxacin or 100 mg doxycycline orally bid for 60 days. The extended treatment period is required because of asynchronous germination of anthrax spores in the lungs of exposed individuals. The CDC also recommends postexposure vaccination, but the FDA has not approved postexposure use of the vaccine. Supportive care must also be given to combat the respiratory distress associated with the acute phase of the disease (e.g., draining of the massive pleural effusions).

PATHOGENESIS

Inhalation anthrax occurs when an individual inhales viable spores. The small size (1–3 μm) of the spores allows them to travel deep into the alveolar spaces of the lungs. Once there, they are taken up by alveolar macrophages and transported to the mediastinal lymph nodes, where the spores are thought to germinate, eventually lysing the macrophages. The vegetative cells continue to proliferate and spread throughout the body via the lymphatics and circulatory system (Spencer, 2003).

The unfortunate outbreak of inhalational anthrax in Sverdlovsk provided the largest set of clinical specimens to study the pathology of human anthrax. Necropsies of victims of the outbreak consistently showed pathologic characteristics of inhalational anthrax including necrotic hemorrhage of the thoracic lymph nodes, hemorrhagic mediastinitis, and pleural effusion. Fifty percent of the cases involved

hemorrhagic meningitis, and 92% showed signs of gastrointestinal tract involvement (i.e., submucosal hemorrhagic lesions) (Abramova et al., 1993).

Quantitative microscopic findings showed that most of the severe pathologic lesions occurred in the mediastinum and mediastinal lymph nodes, the sites of initial replication of the bacterium. The investigators also observed peripheral transudate surrounding fibrin-rich edema, necrosis of veins and arteries, and apoptotic lymphocytes. The pathology (i.e., cellular death and edema) of the infection is associated with the two exotoxins produced by the bacterium (Grinberg et al., 2001). The five fatal cases of bioterrorism-related anthrax in the United States all demonstrated prominent pleural effusions and hemorrhagic mediastinitis (Guarner et al., 2003).

IMMUNE RESPONSE TO INFECTION

Anthrax survivors have been reported to develop antibodies to the bacterial capsule, PA, and, to a lesser extent, LF and EF. Anti-PA titers from the 11 cutaneous cases of the 2001 outbreak were detected as early as 12 days after symptoms developed. The six survivors of inhalational anthrax had significantly higher concentrations of anti-PA antibodies than the cutaneous anthrax patients, and concentrations remained higher more than 1 year after disease onset. Patients with detectable anti-PA titers 3–14 months after development of symptoms had detectable toxin-neutralizing antibody levels that peaked by 4–8 weeks after disease onset. Long-term immune memory from the anthrax patients was assessed by blood samples at 8–14 months after the onset of symptoms. All six inhalational anthrax survivors had PA-specific IgG memory B cells compared to only two of the seven cutaneous anthrax patients sampled (Quinn et al., 2004).

HISTORY OF ANTHRAX VACCINES

Louis Pasteur is usually credited with the discovery of the first anthrax vaccine in 1881; however, a literature review by Peter C.B. Turnbull determined that the first attenuated anthrax vaccine was developed by W.S. Greenfield at Brown Animal Sanatory Institution in London (Turnbull, 1991). The Pasteur vaccine became widely used in Europe and South America for the next 50 years. This vaccine consisted of two inoculations given2 weeks apart. The first dose comprised *B. anthracis* cells that were grown at 42–43°C for 15–20 days, while the cells for the second dose were grown at an elevated temperature for only 10–12 days. The cells grown for the first inoculation were only virulent in mice and young guinea pigs, and the second inoculum was less attenuated, because of the shorter incubation time at the higher temperature. Later analysis of the Pasteur strains determined that growth of the bacteria at 42–43°C cured the plasmid encoding the toxin genes, *pXO1*. This strain did not produce PA, an important antigen needed to induce protective immunity, and the cultures were probably made up of cured cells along with fully virulent cells capable of producing the toxin complexes (Turnbull, 1991).

The next notable advance in anthrax vaccine development occurred in 1937 when Sterne (1937) isolated a $pXO1^{+}$ $pXO2^{-}$ variant of *B. anthracis*. Sterne (1939) developed a live spore vaccine using nonencapsulated, toxigenic spores supplemented with 0.5% saponin in 50% glycine–saline. The original formulation has remained unchanged, except for an increase in the number of spores. The vaccine is considered effective and safe for use in livestock and is still used in many countries today (Turnbull, 1991). The vaccine strain still maintains some virulence for mice and guinea pigs (Turnbull, 1991). In fact, this strain is often used as a challenge strain in mice to test novel anthrax therapeutics. Also, some domestic animals such as goats and llamas are more susceptible to the vaccine strain than are other grazing livestock (Turnbull, 1991).

Shortly after Sterne's discovery, Russian scientists also isolated strains of nonencapsulated *B. anthracis* termed STI-1 and strain no. 3. STI-1 was partially protective in guinea pigs and rabbits and, to a greater extent, in sheep. This strain was subsequently used to vaccinate 38.4 million head of livestock in 1947 in Russia and increased to 100 million in 1960. In 1960, the incidence of anthrax in Russian farm animals was compared to that of 1947, and an almost 10-fold reduction in incidence of anthrax was observed. These attenuated strains were then used to prepare an attenuated human anthrax vaccine. The human vaccine consisted of spores of STI-1 and no. 3 strains administered by scarification with 1.3×10^8 spores or subcutaneous injection with 5×10^7 spores. In 1951–1952, a clinical trial tested the efficacy of the vaccine. Residents of rural districts in the Moldavian region were vaccinated against anthrax by either scarification or subcutaneous injection. An unvaccinated segment of the population served as controls. No significant adverse effects of vaccination were reported in this study, and follow-up surveillance determined that vaccination reduced the risk of anthrax infection by 5.4 fold within the 18-month postvaccination period. Several subsequent investigations confirmed the efficacy of the attenuated spore vaccine. Also, no adverse

effects were reported in association with vaccination (Turnbull, 1991).

The Soviet Ministry of Health endorsed live anthrax vaccination by scarification in 1953 and by the subcutaneous route in 1959. Military microbiologists also experimented with a dry spore vaccine that could be aerosolized and used to safely and effectively vaccinate large numbers of individuals simultaneously; however, this route was not used for general vaccination and was reserved for emergency vaccinations (Turnbull, 1991).

The use of attenuated vaccines in western countries has not been as widely accepted for immunization of humans. Both the United States and the United Kingdom have licensed cell-free anthrax vaccines, consisting of filter-sterilized culture medium of an attenuated $pXO2^{-}$ strain of *B. anthracis* combined with aluminum hydroxide adjuvant. The U.S. vaccine, termed AVA, was licensed by the FDA (product license number 99, Bureau of Laboratories, Lansing, MI) in 1970 and consists of the culture filtrate adsorbed to aluminum hydroxide, the only vaccine adjuvant approved for use in humans in the United States. The discovery and formulation of AVA are discussed below (Turnbull, 1991).

Development of the AVA vaccine started in the 1950s when Wright et al. (1954) showed that PA, precipitated from bacterial culture with alum, could immunize and protect animals against anthrax. Isolation of a nonencapsulated, nonproteolytic derivative of *B. anthracis* strain V770 further advanced the development of an anthrax vaccine. This isolate produced greater PA levels and fewer enzymatic portions of the toxins, thereby increasing the amount of protective immunogen in the vaccine. In 1962, scientists discovered that growing the bacterium under anaerobic conditions increased the production of PA (Puziss and Wright, 1963; Wright et al., 1962). Later research by Puziss and Wright (1963) determined that PA adsorbed better to a preformed aluminum hydroxide gel, and the addition of a 1:40,000 dilution of benzethonium chloride and 0.009% formalin helped to stabilize the vaccine. This formulation provided protection from a virulent strain of *B. anthracis* in mice, guinea pigs, and rabbits. The researchers also tested human tolerance to the vaccine by injecting volunteers with 0.5 ml of the formulation at 0, 2, and 4 weeks subcutaneously into the deltoid region of the shoulder (Puziss and Wright, 1963). They reported no systemic reactions and only mild reactions at the inoculation site. The only scientific study to investigate the efficacy of the acellular anthrax vaccine was published by Brachman et al. (1962). The double-blind, controlled clinical trial was conducted between 1955 and 1959 in four goat hair mills in northeastern United States. Based on animal studies, the alum-adsorbed culture filtrate was given to 379 volunteers as a series of three initial 0.5 ml subcutaneous injections 2 weeks apart followed by three booster injections at 6-month intervals. The vaccinated individuals also received yearly boosters. In this study, 414 individuals received a placebo consisting of 0.1% alum. During the clinical evaluation of the vaccine, 21 cases of cutaneous anthrax and 5 cases of inhalational anthrax occurred in the control group, while only one case of cutaneous anthrax was reported in the vaccinated group (Brachman et al., 1962).

Today, AVA is marketed under the name BioThrax™ and is manufactured by the BioPort Corporation, Lansing, MI. The final vaccine consists of sterile bacterial culture filtrate containing PA, 1.2 mg/ml aluminum (added as aluminum hydroxide in 0.85% sodium chloride), benzethonium chloride (25 μg/ml), and formaldehyde (100 μg/ml) as preservatives. The vaccine is given as a 0.5 ml subcutaneous injection, and the recommended vaccination schedule is at 0, 2, and 4 weeks, with boosters at 6, 12, and 18 months. Yearly boosters are recommended to maintain immunity (BioThrax™ package insert).

The duration of immunity in humans is not known, and there are limited data on the antibody response to the vaccine. Two weeks after completion of the initial three injections, the vaccinated individuals had detectible antibody levels to PA; no anti-LF antibodies were detected (Turnbull et al., 1986). A cohort study of active duty military personnel receiving 1, 2, or 3 AVA injections showed that only 30% had detectible levels of antibodies to PA at 18–24 months after initial vaccination, but after subsequent injections, 99% produced detectable titers (Pittman et al., 2002a).

Because of the number of replicate injections needed in the current vaccination regimen, studies were conducted to investigate alternative vaccination strategies. Subjects given two AVA injections 4 weeks apart had comparable anti-PA antibody levels compared to individuals who received the standard regimen of three doses 2 weeks apart, suggesting that protective antibody titer may be reached with fewer doses of the vaccine (Pittman et al., 2002b). Additional studies would be needed to amend the current FDA-approved immunization schedule, but these studies will likely be performed on second-generation PA vaccines.

The data on the efficacy of AVA vaccine mostly are drawn from animal studies and the initial field trial of its alum-adsorbed precursor. Mice and guinea pigs cannot be consistently protected with AVA alone (Turnbull et al., 1986; Welkos and Friedlander, 1988). On the other hand, studies with rabbits and rhesus macaques showed 100% protection from aerosol challenge with virulent *B. anthracis* spores (Ivins et al., 1998; Pitt et al., 2001).

Vaccination with BioThrax™ is recommended for adults, who are likely to come in contact with potentially contaminated animals or animal products, such as laboratory workers, veterinarians, or others at risk of occupational exposure (Biothrax™ package insert). BioThrax™ is contraindicated for use in individuals who have developed an anaphylactic or anaphylactic-like reaction from previous inoculation with BioThrax™ or the vaccine components. The manufacturer also warns against the vaccination of pregnant women because of preliminary evidence of increased incidence of birth defects in children born to vaccinated women in the U.S. military. Individuals with a history of Guillain–Barre syndrome should not be vaccinated. The safety of the vaccine has not been established in individuals younger than 18 and older than 65.

Adverse effects of anthrax vaccination before licensure were obtained by evaluating 6985 individuals receiving the vaccine. Severe local reactions (edema or a reaction site area >120 mm) occurred after only 1% of inoculations. Three percent of vaccinated individuals experienced moderate local reactions (edema and reaction site area of 120–130 mm), while 20% reported mild reactions (edema, reddening of inoculation site, and reaction area of <30 mm). Four of the vaccine recipients reported systemic reactions (fever, chills, body aches, or nausea) after inoculation. These adverse effects were deemed acceptable for licensure of the vaccine by the FDA.

Postlicensure data are available from the Vaccine Adverse Event Reporting System (VAERS). A total of 1,859,000 doses of anthrax vaccine were distributed in the United States from January 1, 1990 to August 31, 2000. From this, 1544 cases of adverse events were reported to the VAERS and, of these, 5% were considered serious, resulting in hospitalization, disability, or death. Most reported adverse events were reactions at the injection site and some systemic reactions included headache, joint pain, muscle weakness, and itching. Two deaths occurred in people receiving the vaccine, but the inoculations were determined to be unrelated to the deaths. Less than 10 cases were reported in which serious adverse events occurred, but again the events could not be clearly linked to administration of the vaccine (CDC, 2002).

Additional studies showed that the vaccine was not associated with serious side effects, and participants did not develop side effects 25 years following vaccination. Likewise, Persian Gulf syndrome, a malady occurring in veterans of the 1991 Gulf War, could not be correlated with vaccination against anthrax, although the issue is still being debated.

In 1998, in an effort to protect military personnel against biological warfare, the U.S. Department of Defense (DoD) initiated the Anthrax Immunization Program. As a result of a lawsuit against the Pentagon, charging that the FDA licensure had not met legal requirements, a federal judge ordered the DoD to halt compulsory anthrax vaccination (Dyer, 2004). The suspension was lifted after the FDA approved Bioport's renovated manufacturing facility, allowing voluntary immunization.

Although AVA has been established as a safe, effective vaccine, there are still reservations about its side effects. Also, because the vaccine contains all proteins secreted or released from the bacteria, a chemically defined alternative is needed. The numerous doses that are needed to successfully vaccinate military personnel and at-risk civilians heralds the need for a vaccine that is stable, highly immunogenic, rapidly prepared, and cost-effective. The major vaccine component is PA, and with the advent of molecular biology researchers are now able to develop newer vaccines containing a precise amount of purified PA. Still, the need for novel and effective adjuvants remains.

After the bioterrorist events of 2001, the U.S. government conceived the BioShield program to improve public defense against biological weapons (Check, 2004). To facilitate the rapid development of new therapeutics, the FDA amended its regulations pertaining to the requirement for human clinical trials in diseases in which it is not feasible or ethical, such as with anthrax infections (Food and Drug Administration, 2002). Currently, there are four stipulations that must be met before a product can be licensed for human use based upon animal studies (Food and Drug Administration, 2002):

1. There is a reasonably well-understood pathophysiological mechanism for the toxicity of the chemical, biological, radiological, or nuclear substance and its amelioration or prevention by the product;
2. The effect is demonstrated in more than one animal species expected to react with a response predictive for humans, unless the effect is demonstrated in a single animal species that represents a sufficiently well-characterized animal model (meaning that the model has been adequately evaluated for its responsiveness) for predicting the response in humans;
3. The animal study endpoint is clearly related to the desired benefit in humans, which is generally the enhancement of survival or prevention of major morbidity; and
4. The data or information on the pharmacokinetics and pharmacodynamics of the product or other relevant data or information in animals and

humans are sufficiently well understood to allow selection of an effective dose in humans, and it is therefore reasonable to expect the effectiveness of the product in animals to be a reliable indicator of its effectiveness in humans.

ANIMAL MODELS FOR EVALUATING VACCINE EFFICACY

Rabbits and nonhuman primates are often considered the best animal models to evaluate potential anthrax vaccine candidates because the pathophysiological response to disease most closely resembles human inhalational anthrax (Fritz et al., 1995; Zaucha et al., 1998). AVA consistently protects rabbits and nonhuman primates, but protection is variable in guinea pig and mouse models (Ivins et al., 1998; Pitt et al., 2001; Turnbull et al., 1986; Welkos and Friedlander, 1988). In addition, in the mouse model, anthrax toxins are not the predominant virulence factor, and the capsule has been shown to play a major role (Welkos et al., 1993). Hence, the murine model may not be the best for evaluating antitoxic-type vaccines against anthrax. Much vaccine research is still being performed with mice and guinea pigs, because of the lower cost, availability, and ease of housing infected animals. Each vaccine must comply with FDA guidelines and will likely be tested in rabbits and nonhuman primates.

RECOMBINANT PA VACCINES

The first cloning of PA was reported by Vodkin and Leppla (1983). rPA has been expressed in *B. subtilis*, attenuated strains of *B. anthracis*, and *E. coli* (Baillie et al., 1998; Farchaus et al., 1998; Laird et al., 2004). A recent report showed that multigram quantities (2.7 g/L) of highly purified, biologically active PA could be produced from *E. coli* expressing the *pag* gene (Gwinn et al., 2005).

PA alone does not elicit a strong protective immune response and must be combined with an appropriate adjuvant. Aluminum hydroxide (Alhydrogel) is the only FDA-approved human adjuvant. Several studies have been conducted to compare AVA to rPA + Alhydrogel. Mice vaccinated with rPA did not survive subcutaneous challenge with virulent spores. Likewise, AVA did not protect the mice after two doses. rPA coupled to aluminum hydroxide provided more protection in guinea pigs than in mice. At 6 weeks after vaccination, 60% survived intramuscular challenge with 4300 spores, and 89% survived challenge after 24 weeks. Protection dropped to 25% 8 weeks after challenge with 200,000 spores. AVA protected only 50% of the animals from the increased challenge dose (Ivins et al., 1992).

rPA provided far greater protection in the rabbit model. Rabbits immunized with 100 μg of rPA combined with Alhydrogel protected 93.3% of the animals against an aerosol challenge 4 weeks after a single inoculation. The investigators showed a dose-dependent relationship between the amount of rPA and protection, and established that anti-rPA titers and toxin-neutralizing titers were reliable predictors of survival (Little et al., 2004).

rPA also effectively protected rhesus macaques (Ivins et al., 1998). Animals were immunized once with 50 μg of rPA or AVA. Twenty percent of macaques immunized with AVA or PA + Alhydrogen were bacteremic 1 week after challenge; however, all survived infection (Ivins et al., 1998). These data demonstrated that PA coupled with the FDA-approved adjuvant provides protection equivalent to that of AVA.

rPA + Alhydrogel-based anthrax vaccines produced by Vaxgen and Dynport Vaccine Company have been approved for clinical trials sponsored by the National Institute of Allergy and Infectious Disease. Dynport's rPA anthrax vaccine is currently being evaluated in a phase 1 trial at the Walter Reed Army Institute of Research/Henry M. Jackson Foundation Vaccine Clinical Research Center in Rockville, MD. The rPA vaccine, produced in *E. coli*, will be administered by two intramuscular injections 4 weeks apart. The trial will compare different doses of rPA with and without adjuvant (Alhydrogel). Vaxgen has completed a multistate phase 1 clinical trial investigating the safety and immunogenicity of three doses of rPA + Alhydrogel compared to AVA. The company reported their rPA vaccine elicited immune responses comparable to those found with AVA, with no significant safety or reactogenicity issues. Varying doses of Vaxgen's rPA vaccine, rPA102, was given to healthy volunteers at weeks 0, 4, and 8. AVA was given at weeks 0 and 4. AVA and rPA102 elicited similar neutralizing antibody titers after two injections. The third rPA102 injection increased the anti-PA antibody response. Local reactogenicity (pain) was more common among subjects receiving AVA while systemic reactogenicity (headache) was higher in rPA102 vaccinees (Gorse et al., 2006). Vaxgen is currently involved in a phase-2 multicenter randomized dose-finding trial to access the safety and immunogenicity of two inoculations with rPA over two dose ranges and four adjuvant levels. Under a Project BioShield contract, VaxGen was awarded $879.2 million in November 2004 to produce 75 million doses of vaccine. The contract was terminated for default in December 2006 (Russell, 2007).

ADJUVANTS

As stated earlier, rPA must be administered with an adjuvant to be protective. rPA combined with microbial products such as monophosphoryl lipid A, trehalose dimycolate, and the delipidated, deproteinized cell wall of skeleton of *Mycobacterium* spp. improved the protection in the mouse model when compared to AVA or rPA + Alhydrogel. rPA combined with the microbial-derived products protected 100% of the guinea pigs challenged by intramuscular injection of virulent spores. rPA + Alhydrogel protection was increased with multiple inoculations, but did not provide the level of protection afforded by the microbial adjuvants (Ivins et al., 1992).

A second study investigated the efficacy of several adjuvants combined with PA in the guinea pig model after aerosol challenge of *B. anthracis* spores. Animals were vaccinated at 0 and 4 weeks, and then challenged at 10 weeks. PA + monophosphoryl lipid A in a squalene/lecithin/Tween 20 emulsion protected 50% of the animals while AVA and PA + Alhydrogel only protected 26% and 5%, respectively (Ivins et al., 1995).

The efficacy of rPA combined with different adjuvants was also compared to AVA in rhesus macaques (Ivins et al., 1998). Animals were immunized once with 50 μg of rPA and either saponin-QS21, Alhydrogel, or monophosphoryl lipid A (MPL) in squalene/lecithin/Tween 20 emulsion (STL). Another group was given one dose of AVA. All groups showed an IgM titer that peaked 2 weeks after immunization with IgG titers peaking at 4–5 weeks post inoculation. IgG titers were highest in the group receiving PA + Alhydrogel. All groups manifested antigen-specific lymphocyte proliferation and produced toxin-neutralizing antibodies. All vaccines conferred 100% protection except PA + MPL in STL, which was 90% effective (Ivins et al., 1998). These data suggested that Alhydrogel was an efficient adjuvant in the nonhuman primate model of anthrax and would probably be as effective in humans.

There is evidence that oligodeoxynucleotides containing unmethylated CpG improve the immunogenicity of AVA in multiple animal models (Gu et al., 2007; Klinman, 2006; Klinman et al., 2006). The effect of this adjuvant on second-generation rPA vaccines has yet to be elucidated.

Other laboratories are using animal models to investigate less invasive routes of immunization such as transdermal and intranasal routes (Gaur et al., 2002; Mikszta et al., 2005). The use of transcutaneous immunization with a needle-free patch and virus expression of PA is also being explored (Iacono-Connors et al., 1991; Kenney et al., 2004). DNA vaccines encoding the *pag* gene are also being developed (Galloway and Baillie, 2004).

CAPSULAR ANTIGEN VACCINES

While vaccines containing rPA will inhibit the action of the secreted toxins, they do not counteract the antiphagocytic capsule. The poly-γ-D-glutamic acid peptides comprising the capsule are poor immunogens and must be coupled to a carrier protein to evoke an anticapsule humoral response (Schneerson et al., 2003; Wang et al., 2004). The antibodies produced are oposonigenic and should aid the host in clearing the infection (Wang et al., 2004). Chabot et al. (2004) demonstrated that vaccination with capsular antigen protected mice from a lethal challenge with an encapsulated, toxin-deficient strain of *B. anthracis*. Conjugating the capsule to a carrier protein increased IgG titers, but abrogated the protection. Further, the capsule alone evoked a higher IgM titer and increased opsonic activity. Vaccination with capsular antigen or PA alone was not protective against a virulent strain of *B. anthracis*; however, protection improved when both antigens were used together (Chabot et al., 2004). These data suggested that vaccinating against both PA and capsule might increase the effectiveness of the anthrax vaccine.

PASSIVE IMMUNIZATION

Although active immunization has been shown to be an effective way to protect against anthrax, passive immunization with anti-PA antibodies is also being explored as a new therapeutic or prophylactic approach. Antibiotics must be administered early in infection in order to be effective, and there is a "point of no return" when antibiotic therapy fails to protect the patient, presumably because of the deleterious actions of the toxins (Dixon et al., 1999). Passive immunization with anti-PA antibodies that neutralize the toxins should protect the individual from their actions. Studies in guinea pigs determined that anti-PA serum given 24 h after an intranasal challenge with fully virulent *B. anthracis* spores protected 90% of the animals (Kobiler et al., 2002). Intravenous injection of 10 mg of a high-affinity monoclonal antibody to PA 30–45 min before aerosol exposure protected 90% of the challenged rabbits. Protection was dependent on the time of administration with an 80% survival rate of the animals administered 24 h after

challenge. Only 50% treated with the antibody 36 h post infection survived the study period (Mohamed et al., 2004). Several groups are studying the protective effects of passive immunization against anthrax, and one termed AbThrax produced by Human Genome Sciences, Inc. has completed phase 1 clinical trials and moved into phase 2 (Borio and Gronvall, 2005). While passive immunization against anthrax is promising as a prophylactic/therapeutic, it is likely that future recommendations for the individuals at risk of exposure will include active immunization and antibiotic treatment, as well as human monoclonal antibodies to PA. In fact, in 2006 a 44-year-old Pennsylvania man was diagnosed with naturally acquired inhalational anthrax and treated with antibiotics, supportive care, and human anthrax immunoglobulin, produced by Cangene Corp. Once the patient was diagnosed with anthrax, the CDC recommended the use of the immunoglobulin under the Emergency Investigational Drug use protocol. The patient survived the infection; however, the role of the immunoglobulin in recovery is difficult to determine and more studies on the passive immune therapy during anthrax infections are needed (Walsh et al., 2007). Along with active and passive immunity and antibiotics, laboratories are actively developing compounds that inhibit the action of LeTx and EdTx and other novel antimicrobial therapeutics.

ALTERNATIVE ANTHRAX THERAPIES

Investigation of antitoxic compounds centers around inhibiting the enzymatic activities of both LF and EF. The molecular structures of the PA, LF, and EF proteins have been derived by X-ray crystallography, allowing for the design of inhibitors that bind optimally and specifically to the active sites of these enzymes (Drum et al., 2002; Pannifer et al., 2001; Petosa et al., 1997). Several compounds that inhibit the proteolytic activity of LF have been identified (Dell'Aica et al., 2004; Lee et al., 2004; Numa et al., 2005; Panchal et al., 2004), but only a few have been tested against anthrax infection in animal models. One hydroxamate compound (LFI), produced by Merck Research Laboratories, inhibited the activity of LeTx in vitro and protected mice from challenge with purified toxin. The compound also doubled the mean time-to-death of rabbits challenged subcutaneously with virulent spores. Interestingly, when the hydroxamate compound was coupled with suboptimal doses of ciprofloxacin, 100% of the animals survived compared with 50% survival of animals receiving antibiotic alone (Shoop et al., 2005). A clinically approved drug, adefovir dipivoxil, used to treat chronic hepatitis B infections, also blocks the adenylyl cyclase activity of EF (Shen et al., 2004), but its effectiveness as an anthrax therapy has not been investigated.

Compounds that block entry into the cell are also being investigated. One target of great interest is the furin protease that activates PA (Kacprzak et al., 2004; Peinado et al., 2004). Another approach to disrupt toxin entry is with a dominant-negative mutant of PA. Singh et al. (2001) replaced the portion of PA responsible for membrane insertion with a similar segment of a toxin produced by *Clostridium perfringens*. The resulting protein was still activated by a host furin protease, formed oligomers, and bound LF. The mutant protein failed to translocate LF into the host cell cytosol. The mutant protein inhibited the action of wild-type PA and LF in vitro and protected laboratory rats from intoxication (Singh et al., 2001). Vaccination of mice with the mutant PA produced higher antibody titers than wild-type protein, and conjugating it to poly-γ-D-glutamate produced higher titers to PA and capsule than wild-type PA combined with poly-γ-D-glutamate. This study suggested that postexposure use of the dominant-negative PA might improve anti-PA titers while simultaneously inhibiting the action of the anthrax toxins (Aulinger et al., 2005). Finally, the use of naturally occurring antibacterial agents is being investigated as possible therapy against anthrax. The lytic enzyme of the *B. anthracis* bacteriophage, γ phage, has been isolated and shown to kill the bacteria.

These novel therapeutics are still in the early stages of development, but offer new and exciting approaches to combat anthrax.

KEY ISSUES

- Anthrax outbreaks, caused by the spore-forming bacterium, *B. anthracis*, date back to antiquity. The disease occurs in herbivores worldwide, and humans are at risk of infection when handling contaminated animal products.
- The anthrax can manifest in three forms of the disease depending on the route of exposure, including cutaneous, gastrointestinal, and inhalational anthrax.
- The spores are stable and easily disseminated, which make *B. anthracis* a major bioterrorism threat. Letters sent through the U.S. Postal Service in 2001 resulted in 22 cases of anthrax and 5 deaths. This incident prompted a renewed interest in *B. anthracis* and the development of novel vaccines and therapeutic agents.

- The virulence of *B. anthracis* is dependent on the synthesis of the poly-γ-D-glutamic acid capsule, which enables the bacteria to evade phagocytosis, and two toxins, lethal toxin and edema toxin. Both toxins share a binding moiety, called PA, which facilitates toxin entry into host cells. Lethal toxin is formed when PA combines with LF, a zinc metalloprotease that cleaves mitogen-activated kinase kinases. Edema toxin is formed when EF, a calmodulin-dependent adenylyl cyclase, binds to PA.
- Currently, the only treatment for anthrax is antibiotics, which must be given early in infection to be effective.
- The FDA-licensed anthrax vaccine, AVA, has been in use since 1970. AVA comprised filter-sterilized, attenuated *B. anthracis* growth medium adsorbed to aluminum hydroxide.
- The major immunogen in AVA is PA, and anti-PA antibody titers directly correlate with protection in animal models of anthrax. Antibodies to PA inhibit the action of the toxins and may help in the clearance of the infection.
- The second-generation anthrax vaccine is based on rPA. This vaccine provides protection in animal models comparable to AVA, and is chemically defined, allowing for the administration of known doses of PA. The rPA vaccine is currently undergoing safety and immunogenicity testing in human trials.
- Passive immunization, with antibodies to PA, is also being investigated as a possible anthrax therapy.
- Vaccines against the *B. anthracis* capsule and compounds that inhibit the action of the toxins are also being investigated.

Brucellosis

Thomas A. Ficht and L. Garry Adams
College of Veterinary Medicine, Texas A&M University, College Station, TX, USA

OUTLINE

ABSTRACT

Prevention of human brucellosis has relied specifically upon reduction of animal disease, which when coupled with the presence of antibiotic therapy, has been successful in virtually eliminating brucellosis from most developed nations. Consequently, little attention has been paid to the development of human vaccines that would offer the potential for direct intervention in the event of deliberate or natural disease. Furthermore, the animal vaccines employed today are fortuitous isolates attenuated in their ability to cause abortion due to reduced

replication in reproductive tissues. Attenuation of these mutants does not extend to the reticuloendothelial disease observed in humans. Lack of genetic definition of these fortuitous isolates also limits their potential use in the development of improved vaccines, due to incomplete understanding of genetic stability, and warrants caution when applied to human use. Given the potential threat *Brucella* spp. pose to public health in both developed and underdeveloped nations, as well as the risk to front line defenders, development of human vaccine remains a critical necessity. The intracellular nature of this organism requires the stimulation of a cell-mediated immunity (Th1) favored by the use of attenuated live vectors capable of stimulating this arm of the immune system. Based on the success of "live" attenuated vaccine strains against brucellosis and other intracellular pathogens, one approach to human vaccine design is the identification of mutants of reduced persistence (survival) within macrophages, a primary target of infection and persistence. Better definition of the role of virulence determinants in survival of the organism and contribution to disease will help to define improved strains with enhanced safety and efficacy. Finally, increased knowledge of key immunogens and their role in survival will help to develop potential subunit vaccines that have provided little protection against infection with fully virulent smooth *Brucella* spp.

INTRODUCTION

Hippocrates is believed to have provided the first description of human brucellosis over two millennia ago (Eyre, 1908). Evidence preserved from the volcanic disruption near the city of Pompeii suggests that 17% of the human remains at this site had evidence of arthritic condition consistent with brucellosis (Capasso, 2002). Furthermore, the remnants of carbonized cheeses revealed forms consistent with both Lactobacillus and *Brucella* species. Luke, the physician, cites circa A.D. 63 in Acts 28:7–10 of the Bible that Paul, the apostle, healed the chief official Publius' father on the Isle of Malta who was suffering with a long-term fever consistent with the classical clinical manifestation of chronic brucellosis. Reference to a similar disease continues in works citing the post-crusades history of military and hospitaler orders of St. John, St. Lazarus, and the temple in Jerusalem. However, reliable accounts of the disease originate during the occupation of Malta by British troops circa 1860 (Marston, 1861). Bruce demonstrated that the etiologic agent of Malta Fever was a bacterium and fulfilled Koch's postulates by reproducing the disease in monkeys (Bruce, 1887, 1889). Ten years later Zammit led the group that was surprised to identify goat's milk as the source of infection rather than an insect vector (Vassallo, 1996).

Brucellosis is endemic in Mediterranean countries, and Central and South America, and is manifested as an undulant fever in humans that, if untreated, can develop into a chronic infection with symptoms persisting for several months or years (Bruce, 1888; Young, 1995). When cultured under laboratory conditions *Brucella* can form infectious aerosols, which have led to a significant number of laboratory-acquired illnesses (Miller et al., 1987; Fiori et al., 2000). In infected hosts, bacteria have been found to localize preferentially to organs that are rich in elements of the reticuloendothelial system (RES), such as liver, spleen, and lymph nodes.

The aim of research on infectious diseases is their prevention, and brucellosis is a classic example. Protection of susceptible hosts by vaccination still remains one of the best methods to accomplish this aim and early last century Bang (1906) reported that infection of cattle with virulent *Brucella abortus* often leads to immunity. Dr. Bang recommended that heifers should be vaccinated with a heavy suspension of cultured *B. abortus* sometime before first breeding. The protection afforded by this method of vaccination was determined by reduction in the rate of abortion rather than by the rate of protection against infection even though this "vaccination" procedure sometimes resulted in disease rather than prevention, but because of these problems, efforts were begun to identify strains of reduced virulence that could be used as live vaccines to provide safe protective immunity in cattle (Cunningham, 1968). Killed vaccines were also proposed as an alternative approach to the problems associated with live vaccines. Because killed *B. abortus* vaccine preparations were not effective in protecting cattle (Bang, 1906), several investigators used various combinations of live field strain isolates, doses, and inoculation routes. Among the numerous live strains developed and evaluated as vaccines are *B. abortus* Strain 19 (Buck, 1930), *B. abortus* strain 45/20 (McEwen and Roberts, 1936), *B. abortus* RB51 (Schurig et al., 1991a), mucoid variants of *Brucella suis* (Huddleston and Bennett, 1948), *Brucella melitensis* strain Rev 1 (Elberg and Faunce, 1957), and *Brucella suis* strain 2 (Bosseray and Plommet, 1990) of which only three, strain 19, RB51, and Rev 1, are currently used as live vaccines in ruminants but none are safe or efficacious for humans. Vaccination against most bacterial diseases, including brucellosis, has considerable room for improvement, since most vaccines have

been used continuously for decades with little major improvements and which is the subject of this chapter. To provide ideal protection against brucellosis, the vaccines should:

1. prevent clinical disease manifestations,
2. prevent infection in both sexes at any age,
3. not produce disease in vaccinates,
4. provide long-term protection against clinical disease with a single vaccination,
5. possess Differentiating Vaccinated from Infected Animal (DIVA) or person properties,
6. not be transmitted to other individuals,
7. be biologically stable, with no revertants under in vitro and in vivo conditions, and
8. be readily grown in large-scale fermentation technology for low cost production.

ETIOLOGIC AGENT

Brucellae are small aerobes nonmotil Gram-negative coccobacilli that are facultative intracellular pathogen (Fig. 42.1). Over the past century, several species designations have been applied to isolates with apparent preference for different animal hosts. *B. melitensis* in sheep and goats, *B. abortus* in cattle and *B. suis* in swine are all associated with human disease (Bang, 1906). The close association of "nomen"-species with a particular host is thought to indicate specific adaptation or perhaps co-evolution (Chain et al., 2005). Two naturally occurring rough species *B. canis* and *B. ovis* cause abortion in dogs and epididimytis in rams (males of the species), respectively, but are rarely associated with human infection (Carmichael and Bruner, 1968; Wallach et al., 2004). *B. neotomae* was identified in the desert wood rat (*Neotoma lepida*) (Stoenner and Lackman, 1957), and possibly as many as three species are associated with marine mammals including dolphins, porpoises, and pinnepeds (Groussaud et al., 2007). Although the latter have not been widely observed, accidental exposures in humans and experimental exposures in animals have confirmed their pathogenic behavior (Sohn et al., 2003; McDonald et al., 2006).

Genus

Brucella spp. fall within the group 2 subdivision of the α-proteobactereaceae along with the plant pathogens rhizobia and agrobacteria. Features of *Brucella* that distinguish it from most genera within the order rhizobiales are the infection of mammalian cells, a feature *Brucella* share only with *Bartonella*. The second shared feature is a streamlined genome, at least in relation to the plant pathogens. However, despite these similarities, major differences exist between *Bartonella*, an obligate intracellular pathogen and *Brucella*, a facultative intracellular pathogen. First, the genome of *Brucella* spp. is 50–100% larger than *Bartonella* spp. genomes and has preserved more of the metabolic functions shared by the plant pathogens. Correspondence between genome size and host range is also observed when comparing the host range of *B. quintana* with *B. henselae* (Alsmark et al., 2004). Extended metabolic function is therefore suspected to be responsible for the broad host range of *Brucella*, but is also capable of enhancing survival in the environment.

Differences between host species may necessitate differences in cell surface structures (cell wall) and optimal growth conditions as well as specialized mechanisms for uptake and intracellular growth of mammalian pathogens. As a result, the ability to invade mammalian hosts is a feature that may have been acquired at least in part by both *Bartonella* and *Brucella* and may be expected to exhibit nucleotide composition that is distinct from genes conserved from progenitor organisms. Several candidates exist to fulfill this role including genes encoding biosynthesis of polysaccharides, secretion systems, adhesions, and invasions (DelVecchio et al., 2002; Paulsen et al., 2002; Halling et al., 2005). However, it is possible that genes involved in uptake or invasion of mammalian cells were also present in progenitor organisms, and lost from the plant pathogens. In this case the genes would not exhibit distinctive nucleotide compositions, and would require more direct approaches for identification.

Species

Speculation concerning the origin of *Brucella* species has focused on apparent adaptation to specific hosts. Co-evolution of *Brucella* species with their preferred hosts is an alternate possibility that is consistent with currently observed host preferences. Yet, this simple interpretation appears to ignore discrepancies in the overall genetic variation observed between host species and the limited variation observed between *Brucella* spp. Obviously, host and agent do not necessarily evolve at the same rate, but the overall similarities observed among host-adapted *Brucella* species either argues for restricted genetic flexibility or recent adaptation with only minor changes. Since in most cases the timing of separation of these different host species is not known with certainty, it is difficult to draw solid conclusions concerning the co-evolution of host and agent. However, the timing of some events is more widely accepted and may be used as reference points for the discussion presented. As a start, adaptation to individual hosts may be assumed to coincide with the timing of divergence from the main mammalian branch.

Host species primarily affected by *Brucella* belong to the order *Artiodactyla* in the ungulate family that exhibited its greatest divergence during the Miocene epoch. The origin of these lines is complex and still a matter of contention, but for this discussion the results of Blair Hedges and Kumar (2003) that takes into account multiple genes has been employed. Based on this analysis, the separation of cattle from sheep and goats occurred approximately 19.6 million years ago. In contrast, the separation of cattle from swine occurred 65 million years ago. The separation of artiodactyls from the carnivores including cats and dogs occurred 82 million years ago, and pinnepeds are derived from the carnivore line. Separation of rodents was not evaluated in this study due to wide variation in results, however a safe estimate places their separation at more than 100 million years ago while lagomorphs divergence is reported at 90 million years. Cetaceans were not included in the study by Blair Hedges and Kumar, but comparison of the gene encoding artiodactyl growth hormone suggests separation approximately 40–50 million years ago (Wallis et al., 2005). Interestingly, data now suggest a divergence of *Brucella* spp. affecting dolphin and porpoise that diverged from each other more than 11 million years ago.

The timeline described above makes certain simple predictions with regard to the potential co-evolution of *Brucella* organisms and their hosts. The separation between organisms co-evolving with a given species may be expected to reflect the distances suggested by the separation between host species. This may be an unsupported assumption given the differences in growth rates and generation times of different host species, and the assumption that genetic changes take place in each species at the same rate. Furthermore, it must be realized that there is yet no real agreement among scientists concerning the exact times of mammalian divergence. Genetic analysis and the study of host–pathogen interactions would be required to confirm or refute the following predictions.

The first prediction is that *B. abortus* and *B. melitensis* should exhibit fewer differences between each other than they do with *B. suis*. Similarly, *B. ovis* with specificity for ovines should be more closely related to *B. abortus* and *B. melitensis* than to *B. suis. B. neotomae* and *B. canis* may be expected to be the two most widely diverged species assuming adaptation was initiated at the time their hosts diverged from the artiodactyls, 100 and 82 million years, respectively. Additionally, the ability of *B. melitensis* to infect both bovine and ovine/caprine species may reflect the recently shared common ancestry of these hosts or a conservation of function that provides a broader specificity. Broad specificity is a property that is especially notable in *B. suis*, which infects a range of species including lagomorphs and artiodactyls. In contrast, *B. abortus* exhibits a much more narrow host range that may reflect specific adaptation and a concomitant loss of gene function. Finally, based on the earlier assumptions cetacean isolates should have more in common with *B. suis*/*B. abortus* or *B. melitensis*, while the isolates from the pinnepeds should have more in common with *B. canis*.

Based on overall sequence analysis of the genomes of *B. melitensis*, *B. abortus*, and *B. suis*, it is clear that *B. melitensis* and *B. abortus* are more closely related (Halling et al., 2005). A finding that is consistent with their hosts diverging a mere 20 million years ago. In support of this difference 7208 SNP mutations distinguish *B. abortus* from *B. suis* and 7844 distinguish *B. melitensis* from *B. suis*, while only 6242 distinguish *B. abortus* from *B. melitensis* (Halling et al., 2005). The fact that *B. abortus* shares 6 of 7 *B. melitensis* specific ORFs (nonphage related) while also sharing 12 of 14 *B. suis*-specific ORFs is surprising given that *B. abortus* and *B. melitensis* should have co-evolved for 25 million years after diverging from *B. suis*. However, it is possible that a specific loss of *B. suis*-specific segments from *B. melitensis* occurred following the divergence of sheep/goats and cattle over the last 20 million years. Such an outcome might be argued to predict broader host specificity for *B. abortus* than for *B. melitensis*, currently a point that is debatable. Final resolution

of these issues can only be satisfied by analysis of the individual genes and their role in the survival of each species.

Of specific importance for this chapter is whether vaccination specific to each of these organisms will be necessary or more broadly based protection is possible. Although their close genetic similarity provides some promise that genus-wide protection may be readily obtained, adaptation to specific hosts could belie this simple assumption. Studies on cross-immunity with live virulent homologous and heterologous *Brucella* spp. and attenuated vaccines may also provide evidence to support approaches for developing improved live *Brucella* vaccines. Washko and Hutchings (1948) reported that cows fed *B. suis* failed to be protected against *B. abortus* challenge nor did Strain 19 protect against *B. suis* challenge in cattle or swine. *B. melitensis* rev. I protected cattle against *B. abortus* (van Drimmeln and Howell, 1964) with no evidence of rev. I shedding and goats were protected against *B. melitensis* challenge, but *B. abortus* Strain 19 was much less protective against *B. melitensis* challenge in goats. These data suggest that homologous *Brucella* spp. are usually more protective than heterologous *Brucella* spp. within a given livestock species, but in some cases heterologous *Brucella* spp. may induce protective immunity similar to the homologous *Brucella* spp. With the exception of swine, the general hierarchy of immunizing capacity of either vaccine or field strains of *Brucella* spp. for cattle, goats, and sheep is proposed to be *B. melitensis* $\geq$ *B. suis* $>$ *B. abortus* (Adams, 1990). Yet, in this regard, vaccination with *B. abortus* and *B. melitensis* have been shown to provide significant cross protection despite significant differences in clearance (Kahl-McDonagh et al., 2007).

Antigens Encoded by the Agent

A recent study evaluating protein antigens recognized by the human humoral immune response included 42 immunogenic spots (Connolly et al., 2006). Of the 42, 23 were also recognized using bovine sera from an exposed animal. Although there was no attempt to distinguish between protected and unprotected or recovering patients, previous identification using two-dimensional approaches have met with limited success identifying candidate humoral or cell-mediated immunogens (Sowa et al., 1991, 1992). Among the proteins identified were GroEL, GroES, OMP25, Omp2b porin, OMP31 and the periplasmic immunogenic proteins. Several cytoplasmic enzymes (fumarate reductase flavoprotein subunit, F0F1-type ATP synthase α-subunit) were also identified, as were the ribosomal proteins (SSU S1P, L9, L13P).

Proteins encoded in the genome of *Brucella* and recognized as immunogens include subunit and killed vaccine candidates, which have proven to be effective in animals against natural rough strains *B. ovis* and *B. canis* (Bowden et al., 2000). However, subunit and killed vaccine approaches have shown little promise against "classic" smooth organisms. Despite the use of adjuvants, conjugation to carriers, immunization ($+/-$cytokines), or alternate routes of inoculation, attempts to develop subunit vaccines have met with limited success (Winter and Rowe, 1988; Bachrach et al., 1994; Golding et al., 1994; Vemulapalli et al., 1998, 2000a; Bae and Toth, 2000; Baloglu et al., 2000). The intracellular nature of this organism requires the stimulation of a cell-mediated immunity (T helper type 1, Th1) favored by the use of attenuated live vectors capable of stimulating this arm of the immune system. For this reason, *Brucella*, like *M. bovis* BCG, has been suggested as a vector for the delivery of immunogens of other intracellular agents (Vemulapalli et al., 2000b).

IMMUNE RESPONSE

The mouse model has been used to dissect the role of several components of innate and acquired immunity in control of *Brucella* infection, and to identify *Brucella* genes that contribute to the infection process. While many genes that are required for infection and persistence in the RES have been identified using this model, little is known about the *Brucella* gene products that participate in traversing mucosal surfaces.

Studies in mice and in macrophage cell lines have contributed to our current understanding of the host response to *Brucella* infection by identifying a few host gene expression patterns. The cytokines tumor necrosis factor alpha (TNF-α), interleukin-12 (IL-12), and interferon-gamma (IFN-γ) were found to be produced by murine cells during infection and to contribute to control of intracellular *B. abortus* growth (Jiang and Baldwin, 1993; Zhan et al., 1993b). In addition, mouse macrophages and BALB/c mice were shown to produce IL-1, IL-6, and TNF-α, whereas the human monocyte/macrophage line THP-1 expressed transcripts for IL-1, IL-6, and IL-8, but not TNF-α (Dornand et al., 2002). A recent study by Splitter and colleagues used mouse microarrays to study the response of RAW264.7 macrophages to *B. abortus* infection (Eskra et al., 2003). These investigators found that *B. abortus* infection induced expression of genes associated with

inflammation, such as IL-1α, the chemokines MCP-1 and MIP-2, and TNF-α. Genes whose expression was reduced after infection, included genes related to apoptosis, vesicular trafficking, and the cell cycle (Eskra et al., 2003). While the responses of macrophage cell lines and mice to *Brucella* infection have been examined, no studies have focused on the response of mucosal surfaces to *Brucella* infection. This response is likely to be important, given that the natural route of infection of *Brucella* occurs through mucosal surfaces.

It is well established that *Brucella*-specific IgG levels become elevated during the early stages of infection in animals and humans, but there is no correlation between the appearance of these serologic responses and resolution of the infection. For *Brucella*, cellular immunity is understood to be critical for resolution of primary infection and for establishment of immunity to reinfection (Yingst and Hoover, 2003).

Considerable amounts of experimental evidence suggest that opsonization plays an important role in the early stages of *Brucella* infections (Gross et al., 1998; Eze et al., 2000). Although contact of *Brucella* with specific immunoglobulin G (IgG) enhances the brucellacidal activity of cultured macrophages, virulent strains of *B. abortus* can still resist killing by phagocytes and eventually demonstrate intracellular replication (Eze et al., 2000). Previous studies demonstrate that primary murine macrophages have limited ability to control infection with *B. melitensis*, even when activated by IFN-γ in the presence of highly opsonic concentrations of antibody and complement. The role of complement has been studied with *B. abortus* and *B. melitensis* strains, and it has been proposed that rough *Brucella* are less virulent due to their increased sensitivity to complement-mediated killing (Godfroid et al., 1998; Ugalde et al., 2000). This idea is supported by previous reports which demonstrate that disruption of the *wboA* gene in *B. abortus* and *B. melitensis* (which results in rough mutants) can bind more complement than their respective wild-type parental strains 2308 and 16M (Fernandez-Prada et al., 2001).

Neutrophils are probably the first immune cell to encounter *Brucella*. Rapid phagocytosis of *Brucella* strains by neutrophils occurs only after opsonization (Young et al., 1985). However, bacterial survival in neutrophils during early infection has been observed, suggesting that the transportation of *Brucella* to lymphoid tissues can be mediated by these cells. Finally, live virulent *Brucella* strains, but not cell wall fractions, inhibit the respiratory burst by neutrophils (Canning et al., 1985).

NK cells play a key role in host defense. They are implicated in an early immune response to a variety of pathogens. However, it has been shown that they do not control *Brucella* infection in mice (Fernandes et al., 1995). On the other hand, it was formally established that in the acute phase of the illness, the activity of the NK cells is impaired in humans developing brucellosis (Salmeron et al., 1992). A more recent study analyzed the behavior of *B. suis* in human macrophages infected in the presence of NK cells. The results suggest that NK cells are activated by *B. suis*-infected macrophages and that they inhibit the intracellular multiplication of the bacteria by lysing the infected cells, thus suggesting that NK cells could be one actor of the control of *Brucella* development in humans but not in mice (Dornand et al., 2004).

The role of dendritic cells in brucellosis is still uncertain. One report suggests that *B. abortus*, *B. melitensis*, and *B. suis* are capable of replicating in similar numbers inside human monocyte derived dendritic cells compared to macrophages. These data suggest that the bacteria may have a marked preference for DCs and that this property could support *Brucella* spreading (Billard et al., 2005).

T cells are the key players against *Brucella* infections. The major role of T cells in *Brucella* immunity can be divided into three principal functions: secretion of IFN-γ for the activation of bactericidal function in macrophages, cytotoxic T-lymphocyte activity, and contribution in IgG2a and IgG3 isotype switching (Ko and Splitter, 2003). It has been clearly demonstrated that a Th1 response is essential for resolution of the primary infection caused by *Brucella*, and the essential aspect of this response appears to be IFN-γ production (Mielke et al., 1988). The role of IFN-γ in the control of *Brucella* infections was initially demonstrated by supplementing BALB/c mice with recombinant IFN-γ. The treatment resulted in a 10-fold decrease in the number of bacteria 1 week after infection (Stevens et al., 1992). In accordance with these observations, depletion of IFN-γ by the administration of monoclonal antibodies which neutralize IFN-γ, resulted in the increase in the bacterial burden 1 week postinfection (Zhan and Cheers, 1993; Zhan et al., 1993a). The importance of IFN-γ in resolution of *Brucella* infection was recently supported by studies using BALB/c and C57BL/6 mice. C57BL/6 mice with gene deletions or disruptions in the IFN-γ, perforin or beta (2)-microglobulin genes had a decreased ability to control intracellular infections with *B. abortus* strain 2308 during the first week postinfection. However, only the IFN-γ knockout mice had a sustained inability to control the infection and this resulted in death of the mice at approximately 6 weeks postinfection (Murphy et al., 2001). In vitro studies have suggested that the mechanism by which IFN-γ enhances resistance is through activation of macrophages for

anti-*Brucella* activity, largely by promoting production of reactive oxygen intermediates (Jiang et al., 1993).

The hallmarks of human brucellosis are measurable splenomegaly with increased lympho-histiocytic cells in the spleen, a reduced percentage of splenic $CD4^+$ and $CD8^+$ T cells, and increased percentage of splenic macrophages. Splenocytes in the infected host express more mRNA for IL-2, IFN-γ, and IL-10, and less mRNA for IL-4 than uninfected suggesting a Th1 response (Baldwin et al., 1993; Zaitseva et al., 1995; Liautard et al., 1996). However, increases in IL-10 are counterproductive and may explain the virulence of this organism and the failure of some vaccines to stimulate a protective immune response (Svetic et al., 1993; Hoover et al., 1999).

Reports to date have provided clear evidence that both humoral (Plommet and Plommet, 1983; Montaraz and Winter, 1986; Montaraz et al., 1986; Winter et al., 1989) and cell-mediated immune (CMI) responses (Pavlov et al., 1982; Montaraz and Winter, 1986; Plommet and Plommet, 1987; Bosseray and Plommet, 1988; Smith et al., 1990a, 1990b) participate in protection against brucellosis. The intracellular location of *Brucella* requires the stimulation of a cell-mediated immunity (Th1) for clearance favored by the use of attenuated live vectors potent in the stimulation of this arm of the immune system. Studies demonstrate that protective immunity against brucellosis in mice is due to the combined effects of antibodies and the CMI responses mediated by the CD4 and CD8 subsets of T cells (Araya et al., 1989). In comparative analyses of infections that were performed, the virulent strain 2308 was significantly more refractory to opsonization by antibodies than the attenuated Strain 19 (Araya et al., 1989). Splenic infection by both strains caused acute as well as chronic granulomatous responses, and a severe depletion of lymphoid tissue that was most prominent 3 weeks postinfection (Araya et al., 1989; Enright et al., 1990). Thereafter, a rapid decline in bacterial numbers was observed in mice infected with strain 19, along with a decrease in the numbers of granulomas in the liver and spleen (Enright et al., 1990). In contrast, infections performed with S2308 did not result in a decrease in bacterial counts, and granulomas persisted (Enright et al., 1990).

EPIDEMIOLOGY

Human infection results from the consumption of contaminated animal products or direct exposure to aborted tissue. As a result, the prevention of human brucellosis has focused upon the reduction of animal disease, and little attention has been paid to the development of human vaccines. In the chronic form of the disease observed in humans, organisms persist in macrophage and primarily affect the lymphoreticular system (Jones and Winter, 1992). Humans are normally dead-end hosts, although anecdotal evidence suggests sexual transmission may be possible (Stantic-Pavlinic et al., 1983). Intracellular persistence within the host is the basis for human disease and the cause of reduced efficacy of antibiotic treatment.

Acute brucellosis is only observed in pregnant ruminants and is characterized by fetal/placental colonization and abortion, resulting from organism replication to high density within reproductive tissues. Ruminants that have aborted frequently become chronic shedders of the organism in the milk due to colonization of the mammary gland, a primary source of transmission. Experimental results also suggest that approximately 12% of the animals that abort due to *Brucella* infection may abort a second and sometimes a third time without detection of the organism between pregnancies, thus encouraging immediate removal from the herd (ter Huurne et al., 1993). Over the past century, several species designations have been applied to isolates originating from different hosts (Bang, 1906). Three classical species, *B. melitensis*, *B. abortus*, and *B. suis* are associated with reproductive disease (abortion) in their primary hosts, sheep/goats, cattle, and pigs, respectively. Each presents an intact O-antigen (*n*-formyl perosamine homopolymer) on their outer surface. Rough derivatives of these organisms arise spontaneously, but are typically avirulent (Schurig et al., 1991b). However, two naturally occurring rough species, *B. canis* causes abortion in dogs, and *B. ovis*, unique among *Brucella*, causes epididimytis in rams (males of the species). Serological tests indicate *B. canis* exposure occurs in 10% of all dogs in the U.S. *B. neotomae*, another identified species, was isolated only once from the desert wood rat (*N. lepida*). Over the last 10 years, there have been numerous isolations of *Brucella* organisms from marine mammals (Ewalt et al., 1994; Garner et al., 1997; Miller et al., 1998). The atypical phenotype of these isolates led to their identification as new species. However, it must be emphasized that the brucellae are considered to be a monospecific genus (Verger et al., 1985). Although certain phenotypic properties have provided a useful system for epidemiological classification of isolates their long-term stability has been questioned (Moreira-Jacob, 1963; Banai et al., 1990; Banai et al., 1991).

Of course, the diversity among these organisms and the close association of "nomen"-species with a particular host may also suggest host-specific adaptation. Although *B. melitensis* primarily affects sheep

and goats, cattle infection in endemic areas has been observed (Dafni et al., 1990). In many cases, however, such infections appear to be self-limiting, and are assumed exceptions rather than the rule. The overall similarities in the DNAs of this genus suggest that host-specific adaptations, if they exist, may only be defined by precise sequence comparison. Curiously, Bruce suggested that nothing similar to "Malta Fever" was observed in England (Bruce, 1887). Whether this was an oversight, the result of the introduction of pasteurization in 1864, or reflected differences in human virulence potential of *B. abortus* (cattle) and *B. melitensis* (sheep and goats) as reported for guinea pigs cannot be determined (Keppie et al., 1963). It is clear, however, that the organism was endemic in the United States by 1906 and is presumed to originate from cattle imported by settlers (Bang, 1906).

Significance as a Public Health Threat

An ancient disease, human brucellosis, may be the most common worldwide zoonotic bacterial infection (Fig. 42.2) (Young, 1995; Corbel, 1997; Pappas et al., 2006b), and even after over 100 years of research remains a serious challenge in the 21st century (Ariza et al., 2007). *B. melitensis* continues as a major cause of human disease worldwide, followed by *B. abortus* and *B. suis*, while rare persistent cases of *B. canis* human infection and disease by novel *Brucella* pathogens of marine mammals have also emerged. Brucellosis is re-emerging as a significant cause of travel-related disease (Memish and Balkhy, 2004).

B. melitensis represents a serious threat to worldwide animal production and public health in the Middle East, Latin America, and parts of Asia in which the organism is endemic in sheep- and/or goat-herds. Humans are infected through consumption of contaminated animal products or direct exposure to aborted tissue, and are normally dead-end hosts.

The main species affecting the U.S. is *B. abortus* in wildlife reservoirs, including bison and elk in the Greater Yellowstone Area (GYA), where it has been estimated that up to 50% of the 4000 bison in the GYA and even higher numbers of elk have been exposed or are infected with *B. abortus*. Ruminant transmission of *Brucella* occurs as a result of abortion of the fetus and/or shedding in milk. Uncontrolled growth in the reproductive organs of pregnant animals is responsible and may be related to immune suppression in these tissues (Weinberg, 1987; Smith, 1994). Persistence within the host cells (including macrophages) results in repeated abortions, between periods of apparent latency (Ray et al., 1988; ter Huurne et al., 1993). Males and non pregnant females are less susceptible. The best approach to minimize animal disease is to prevent transmission via contact with aborted material or consumption of contaminated milk. Inhibiting replication in reproductive tissues prevents the release of massive numbers of organisms into the environment. For example, S19 does not replicate in the pregnant uterus due perhaps in part to erythritol present in elevated amounts in

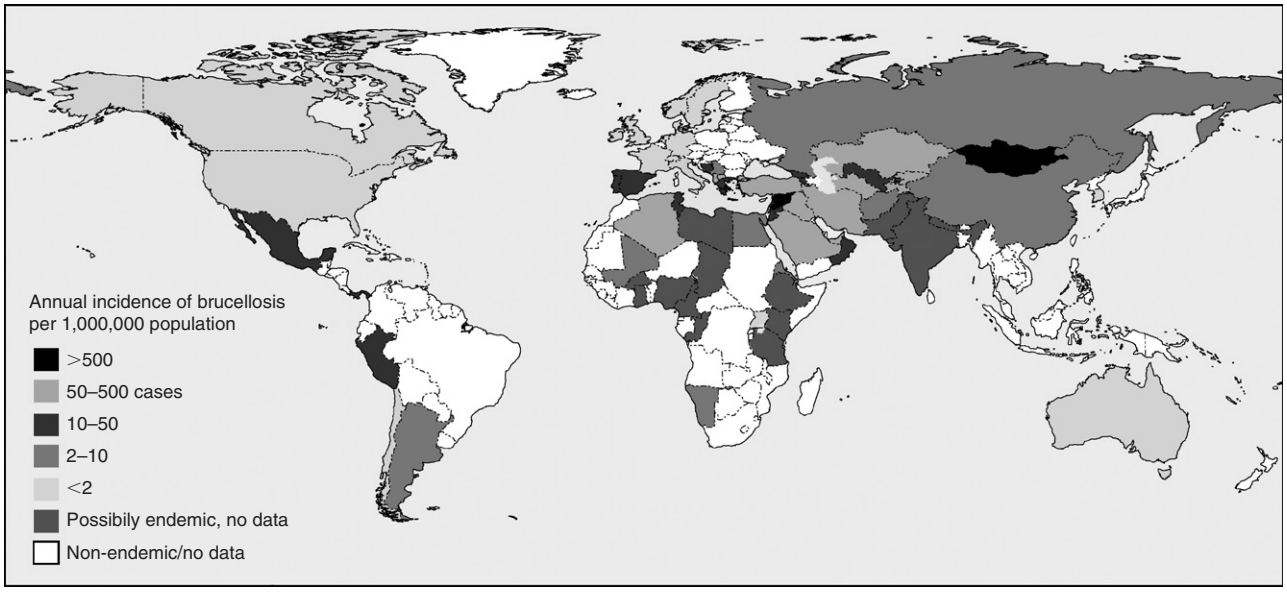

FIGURE 42.2 Worldwide distribution of human brucellosis. From Pappas et al. (2006b).

the pregnant uterus, although other defects may exist (Williams et al., 1962). Although a preferred carbon source in most *Brucella* sp., erythritol is toxic to S19 due to a gene deletion causing a toxic buildup of metabolic intermediate within the organism (Sangari et al., 1998). *B. melitensis* Rev 1 a streptomycin-independent organism isolated following back-selection from a streptomycin-dependent organism is used to protect against *B. melitensis* infections worldwide (Elberg and Faunce, 1957). Both S19 and Rev 1 provide protection in ruminants despite persistence in a percentage of vaccinates (Corner and Alton, 1981), but retain significant virulence in humans (Spink and Thompson, 1953; Bardenwerper, 1954; Spink et al., 1962). There are no reports of virulence in humans for the recently approved vaccine strain RB51, a rough derivative used with some success in ruminants (Schurig et al., 1991b), but with less success in other species (Jimenez de Bagues et al., 1995; Palmer and Cheville, 1997). The absence of O-antigen prevents development of cross-reacting immune responses that are indistinguishable from wild-type infection, but also increases the susceptibility of this strain to complement-mediated lysis, limiting survival and vaccine efficacy.

Potential as Biothreat Agent

Brucella, as Category B pathogens in the United States, have been the subject of offensive weaponization research in the recent past, because they can be readily aerosolized resulting in a high rate of morbidity with low mortality causing a prolonged incapacitating clinical disease requiring expensive long-term treatment (Pappas et al., 2006a). Very importantly, no human vaccine is currently available against this biothreat agent. If *Brucella* vaccines are developed and proven to be safe, and protect against aerosol and oral challenge in laboratory animals and nonhuman primates, these vaccines would be a deterrent to these biothreat agents. According to one study, the use of *Brucella* as a weapon was calculated to pose a substantial financial risk (less than anthrax or tularemia, but significant) (Kaufmann et al., 1997). *Brucella* organisms can be delivered via aerosol to infect humans (Kaufmann et al., 1980) with an infectious dose of fewer than 10–100 organisms (1000 cfu infectious dose assumed in economic impact study). Infection incapacitates human hosts with mostly flu-like symptoms, but will result in death if left untreated (Young, 1995).

The financial impact study did not attempt to determine the threshold at which financial risk may pose a risk to national security. Nor did the study outline scenarios in which the use of one organism might be favored over the use of others. The study did underscore the need to invest in research in all understudied organisms to prevent their use in this manner and suggested that decreased study of these organisms increase the potential consequences resulting from their use as weapons. Bioengineering poses the additional risk of introducing antibiotic resistance, rendering ineffective the most successful form of treatment.

CLINICAL DISEASE

Nonspecific, but characteristic symptoms of human brucellosis include pyrexia, diaphoresis, fatigue, loss of appetite, and muscle or joint pain. Depression, cephalalgia, and irritability also frequently occur. Infection of bones or joints occurs in about one in three patients, causing localized inflammation and edema. Some may also have cough, chest pain, and stomach upset. Although about one in four patients with brucellosis have respiratory symptoms, thoracic radiographs usually appear normal (Lubani et al., 1989; Madkour, 1989). Symptoms have also been described to recur years after the original infection. Chronic illness may result in infection of secondary tissues, including heart and brain, if the disease is left untreated. Brucellosis is most frequently acquired by man through contact with infected livestock and consumption of unpasteurized dairy products. Brucellosis in humans is often difficult to recognize and may present as an acute fever, or as a chronic or localized infection that is best diagnosed by culturing the bacterium from blood or other infected tissues. Due to the slow growth of *Brucella*, cultures may require several weeks for positive identification. Infection may also be diagnosed indirectly via detection of anti-*Brucella*-specific antibodies in patients' blood. Disease may begin abruptly or gradually from 3 days to several months after exposure. Less common sites of infection are the male reproductive system, brain, and heart valves. Symptoms often last for 3–6 months, but occasionally persist for a year or longer. Patients infected for a long time frequently experience weight loss, and many patients temporarily improve, then relapse (Ariza et al., 1986). Recurrence of human disease may be related to a latent form of survival demonstrated to occur at low frequency in at least one study (Ray et al., 1988; ter Huurne et al., 1993).

While brucellosis, like typhoid fever, is a nonenteric disease in which systemic illness is more common than localized disease, there have been reports from human cases of patchy mucosal hyperemia within the digestive tract, ulcerations of Peyer's patches, and acute ileitis (Petrella and Young, 1988; Sohn et al., 2003; McDonald et al., 2006). Furthermore, an

association has been reported between ingestion of *Brucella* and specific digestive system complaints, including diarrhea and abdominal pain (Thapar and Young, 1986). Hence, whether it causes pathology in a particular case, *B. abortus* must pass the mucosal barrier of the gastrointestinal tract to cause systemic infection and target to the RES. Currently, very little is known about this process. A study in calves suggested that *B. abortus* is able to enter the lamina propria by transepithelial migration via lymphoepithelial cells (analogous to M cells) of the ileal Peyer's patches (Ackermann et al., 1988), a portal of entry shared by other pathogens, such as *Salmonella typhimurium* and *Mycobacterium avium* subsp. *paratuberculosis* (Santos et al., 2002). Although reports in the literature continue to suggest a link between brucellosis and abortion in women, direct isolation of the organism from human fetuses is seldom reported (Khan et al., 2001). Changes in hormone profiles are thought to contribute to these different outcomes whether through stress or suppressed immune function in the host or changes to the organism (Bienvenu and Young, 1962; Meyer, 1976; Ramirez-Romero, 1998).

In its natural bovine host, *B. abortus* infection is transmitted via the alimentary tract. *B. abortus* infection in the gravid cow causes late gestational abortion or perinatal death, and licking of aborted fetuses and placental tissue, or ingestion of organisms in the milk by calves result in contact of *B. abortus* with the mucosa of the gastrointestinal tract. The disease caused by this group of organisms may be divided into two types based on the course of disease and symptomology. Acute brucellosis observed in ruminants is characterized by fetal/placental colonization and abortion, resulting from replication to high density within reproductive tissues. Ruminants that have aborted frequently become chronic shedders of the organism in the milk due to colonization of the mammary gland. This form of the disease is not observed in humans. Chronic brucellosis is characterized by infection of the lymphatics and RES and is observed in nonpregnant ruminants, mice, and humans. Differences in the two forms of disease are attributable to the target cells infected. Trophoblasts are preferentially colonized in acute disease while the organism persists in macrophages during chronic disease (Jones and Winter, 1992).

TREATMENT

Treatment of human brucellosis remains complex, requiring protracted administration of more than one antibiotic which is mostly based on the principles applied half a century ago with few modifications being made even today despite the emergence of new antibiotic classes and different therapeutic approaches (Ariza et al., 2007). The Ioannina Recommendations panel suggested that the optimal treatment of uncomplicated brucellosis should be based on a 6-week regimen of doxycycline combined either with streptomycin for 2–3 weeks, or rifampicin for 6 weeks (Castillo et al., 1989; Ariza et al., 2007). Ruminants and mice will usually clear such infection, but humans require treatment with antibiotics to prevent sequelae that may include neurological and cardiac involvement (Young, 1995). Two recent studies have shown that the doxycycline–rifampin regimen is preferred by both clinicians and patients (Pappas et al., 2006c, 2007), even when they are aware of the relative superiority of the alternative regimen. The fact that doxycycline–rifampin is an all-oral regimen may allow for better implementation in clinical practice in areas with less well-developed health infrastructure, because it eliminates the need for parenteral administration of streptomycin as part of the doxycycline–streptomycin regimen. The cure is neither certain nor rapid, since the intracellular location reduces antibiotic efficacy and some affected individuals may require re-treatment if symptoms return.

PATHOGENESIS

Brucella spp. infect hosts principally by penetrating the natural mucosa from which it disseminates via bacteremia throughout the body particularly the RES and reproductive systems (Fig. 42.3). An experimental infection found that the oral cavity-pharynx and the intestine were the two main portals of entry for oral infection of *B. abortus* in calves (Carpenter, 1924). Conjunctivae, intranasal mucosa, and vagina were also permeable to *Brucella* infection (Plant et al., 1986; Meador and Deyoe, 1989; Mense et al., 2001). The evaluation of the invasion process of *B. abortus* through calf intestinal Peyer's patches revealed that lymphoepithelial, but not enteroabsorptive cells, engulfed individual brucellae that remain inside vesicles, phagolysosomes, and large vacuoles (Ackermann et al., 1988). After transepithelial migration, many brucellae were observed alive inside neutrophils, mononuclear phagocytes, or free in the interstitium and lymphatic vessels of lamina propria. The invasion process via conjunctiva was accompanied by a submucosal inflammatory reaction with the bacterium consistently cultured from the parotid lymph node 2–4 days postinoculation (Enright, 1990). These observations suggest that *Brucella* invade the host by

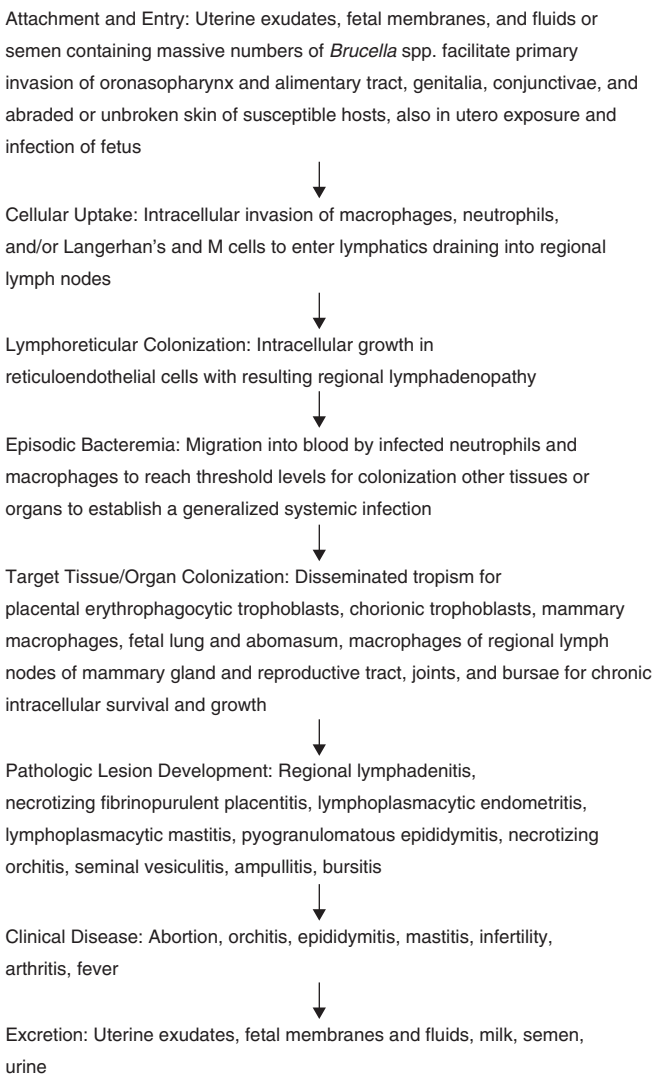

FIGURE 42.3 Composite schema of *Brucella* attachment, invasion, metastasis, dissemination, systemic disease, clinical disease, and excretion.

transepithelial migration, then escape into the submucosa and disseminate free or inside phagocytic cells to regional lymph nodes by lymphatic drainage.

In addition to in vivo studies required for full understanding of *Brucella* pathogenesis, in vitro assays performed on cell lines or primary cultures are informative for a more complete understanding of the host–agent relationship. The bacterial adhesion to cell membrane is an essential first step in the establishment of infection (Salyers and Whit, 2002). *Brucella* attach as a single organism to cultured epithelial cell lines via receptor molecules containing sialic acid or sulfated residues, and at 8h postinfection begin to form microcolonies which subsequently become larger with extended time (Castaneda-Roldan et al., 2004). It has been demonstrated that rough strains are more adherent and invasive to nonphagocytic cells than smooth ones (Detilleux et al., 1990), in part because the O-polysaccharide structure of the *Brucella* outer membrane protein obscures nonspecific ligands and consequently decreases the ability of the bacteria to bind the cell surface. Within a few minutes after binding nonprofessional phagocytic cells, *Brucella* are internalized by receptor-mediated phagocytosis (Detilleux et al., 1990, 1991). Detailed studies have shown that the *Brucella* uptake by epitheloid-like cells is not a passive but an active mechanism, where the bacteria induces its own internalization by activating small GTPases of the Rho subfamily (i.e., Rho, Rac, Cdc42) and modulate rearrangements of the host cell actin cytoskeleton and microtubules (Guzman-Verri et al., 2001). However, only a limited number of nonprofessional phagocytic cells in a monolayer are permissive to invasion (Detilleux et al., 1990; Pizarro-Cerda et al.,

1998a), suggesting heterogeneous susceptibility and/or invasiveness among cells and bacteria, respectively.

After in vivo invasion of nonprofessional phagocytic cells, such as trophoblasts, *Brucella* localize and replicate within the rough endoplasmic reticulum without restricting basic cellular functions. However, after extensive intracellular replication infected cells develop signs of degeneration and necrosis, leading to a release of free bacteria into the media and the infection of the other cells proceeds (Anderson et al., 1986). In vitro studies have found that during the first minutes after invasion, virulent *Brucella* transiently interact with an intracellular compartment related to the early endocytic network that is gradually transformed in a multimembranous autophagic vacuole. Later, *Brucella* are delivered into a rough endoplasmic reticulum–like compartment in the perinuclear area, where massive intracellular replication occurs (Detilleux et al., 1990; Pizarro-Cerda et al., 1998a). The benefits for the pathogen of being associated with the endoplasmic reticulum of nonprofessional phagocytic host cell, an event also observed in *Toxoplasma gondii* (Sinai and Joiner, 1997; Sinai et al., 1997), have not yet been identified, although the hypothesis of taking advantage of utilizing metabolites synthesized or translocated to this compartment is an attractive concept (Gorvel and Moreno, 2002). The Type IV-Secretion System (T4SS) encoded by *virB* operon in virulent *Brucella* controlling the intracellular trafficking, bypassing late-endosomal compartments and avoids its degradation by inhibiting phagosome–lysosome fusion in nonprofessional phagocytic cells (Pizarro-Cerda et al., 1998b; Comerci et al., 2001).

Once infected, natural hosts and humans can remain infected for life. After translocating the epithelium layer, *Brucella* are endocytosed by local macrophages and transported to the regional lymph nodes. Failure to destroy the bacteria at this stage results in dissemination to organs that are rich in elements of the RES, such as spleen, bone marrow, and lymph nodes (Enright et al., 1990). The chronic nature of the disease lies in the ability of virulent Brucellae to survive and replicate inside macrophages (Roop et al., 2004). On the contrary, as observed in nonprofessional phagocytic cells, differences in mechanisms of binding and entering of each individual bacterium into macrophages determines its fate within intracellular compartments and the outcome of the infection (Campbell et al., 1994; Rittig et al., 2001; Watarai et al., 2002). Opsonized *Brucella* bind professional phagocytic cells through complement and Fc receptors, whereas nonopsonized organisms seem to bind via lectin, fibronectin, and/or other unknown receptors (Campbell et al., 1994; Rittig et al., 2001). More recently, other papers have addressed the possibility that lipid rafts could serve as docking sites for nonopsonized *Brucella* to stabilize the bacteria–macrophage interaction previous to internalization (Naroeni and Porte, 2002; Watarai et al., 2002).

As soon as the bacteria contact the macrophage membrane, F-actin and annexin I–associated structures transiently accumulate beneath or around the pathogen, regardless of whether the bacteria were previously opsonized or not (Kusumawati et al., 2000). Phagocytosis occurs within a few minutes after contact, when opsonized *Brucella*, but not nonopsonized, induce major morphological changes in the macrophages cell membrane consisting on membrane ruffles that surround and capture the bacteria, in a zipper-like interaction between receptors and ligands (Kusumawati et al., 2000; Rittig et al., 2001). The initial formation of two types of *Brucella*-containing phagosomes, one tightly fitting, representing the survival-permitting compartment, and other spacious, representing the killing compartment, was observed after *Brucella* engulfment (Arenas et al., 2000; Rittig et al., 2001). The delayed phagocytosis observed in wild-type *Brucella* compared with *virB* mutant was interpreted as a necessary time for the fully virulent pathogen to alter the plasma membrane in order to create a specialized organelle permissive for survival and replication (Watarai et al., 2002; Bellaire et al., 2005). These *Brucella*-containing phagosomes briefly interact with early-endosomal compartments, and at 1 h postinfection colocalize with late-endosomal markers in cell lines (Arenas et al., 2000; Bellaire et al., 2005) but not in primary macrophages (Celli et al., 2003). Simultaneously, the delivery of protons by the ATPase proton pump to the phagosome membrane causes a rapid acidification inside the vacuole, a condition necessary during the early phase of infection for survival and replication of *Brucella* in macrophages (Porte et al., 1999; Arenas et al., 2000; Rittig et al., 2001; Bellaire et al., 2005). Paradoxically, the number of *Brucella* inside macrophages decreases in the first hours postinfection and only few phagocytosed organisms are capable of surviving, redirecting their intracellular trafficking, and replicating inside phagosomes, a process highly dependent on a functional T4SS (Arenas et al., 2000; Rittig et al., 2001; Celli et al., 2003; Bellaire et al., 2005; He et al., 2006). This initial killing is probably due to the capability of macrophages to generate toxic oxygen-dependent mechanisms during phagocytosis (Harmon et al., 1989).

After the adaptation phase, *Brucella* replication is initiated, however the *Brucella*-replicative niche in macrophages is controversial. It has been observed that *Brucella* replicates inside compartments with

phagolysosomal characteristics (Arenas et al., 2000), endoplasmic reticulum-like compartments (Celli et al., 2003; Bellaire et al., 2005), and nonacidic phagosomes (Bellaire et al., 2005). Among all the differences reported, replication inside phagolysosome vacuoles is the most curious, because experimental evidence seems to support the proposal that *Brucella* intracellular survival in macrophages results from an inhibition of *Brucella*-containing phagosome and lysosome membrane fusion (Porte et al., 1999; Naroeni et al., 2001; Celli et al., 2003). However, the reported differences in *Brucella* intracellular trafficking within macrophages may in part be due to different cells (primary cultures vs. cell lines, human vs. mouse origin), *Brucella* strains, and conditions used (opsonized vs. nonopsonized bacteria).

In addition to macrophages and cells of the RES, *Brucella* have a major predilection for the gravid uterus ultimately causing abortion with huge numbers of organisms being expelled in the fetus and fetal fluids. In the ruminant placenta, *Brucella* replicate initially in the phagosomes of erythrophagocytic trophoblasts of the placentome and later in the rough endoplasmic reticulum of the periplacentomal chorioallantoic trophoblasts (Anderson et al., 1986). The subsequent invasion of the fetus and replication in placental cotyledons leads to extensive placentitis and abortion. Despite the important role that trophoblasts play in brucellosis, there is no detailed description of how *Brucella* invade and intracellularly traffic.

VACCINES

Prevention of human brucellosis has always relied upon reduction of animal disease. Consequently, little attention has been paid to the development of human vaccines. The animal vaccine strains employed today are fortuitous isolates attenuated in ability to cause abortion due to reduced replication in reproductive tissues. The attenuation of these mutants does not extend to reticuloendothelial disease observed in mice and in humans. Furthermore, the lack of genetic definition of fortuitous isolates limits the usefulness of vaccine strains, preventing complete description of their stability (Schurig et al., 1991b; Sangari et al., 1998).

Development of human vaccine strains must rely on different approaches. The best approach to human vaccine design has not been experimentally identified, however, reduced persistence (survival) within macrophages represents a better approach given the limited success observed using subunit and killed vaccines (Schurig et al., 2002). To date, functions targeted for inactivation are based on observations with other bacterial pathogens that typically cause acute infections. The chronic nature of brucellosis in humans suggests other approaches are warranted. Animal vaccine strains defective in important "virulence" determinants (O-antigen, SOD, heat shock proteins) often attenuate the survival of the organism either too severely or not severely enough (Latimer et al., 1992; Elzer et al., 1996; Robertson et al., 1996; Bellaire et al., 1999). This may result from sensitivity to extracellular killing mechanisms (O-antigen mutants) or sensitivity to macrophage killing activities prominent in early infection (SOD, stress response proteins). Better definition of the role of virulence determinants in brucellosis is required.

The potential reluctance of the general population to use live vaccines is based on safety issues and such thinking must not be used to deter the development of products based on otherwise sound scientific principles. The use of such vaccines in humans can be expected under extreme circumstances, such as protection against biological terrorism or biological warfare. Starting with the work of Louis Pasteur, live vaccines have offered the best possible solution for immune protection. Use in humans requires that safety be determined beyond a shadow of doubt. This is one of the reasons that we have proposed the construction of double-knockout mutants. Questions concerning the safety of such products warrant future testing in primate models or in *scid* mice expressing a reconstituted human immune system.

For this reason, numerous studies have explored gene functions necessary for persistence within macrophages using random mutagenesis (Allen et al., 1998; Hong et al., 2000; Lestrate et al., 2000; Ficht, 2002; Lestrate et al., 2003; Delrue et al., 2004; Wu et al., 2006a). In this approach, genes required for survival have been classified according to the duration of survival of the resulting mutant. Gene functions required early in the process reduce survival at both 2 and 8 weeks postinfection; although some may recover these are excluded from additional analysis (Hong et al., 2000). Gene functions required for long-term survival appear normal at 2 weeks, but are greatly reduced after 8 weeks. Examination of the vaccine potential of each group of organisms in the mouse model have revealed a direct correlation between survival and immune protection that will be explored in later sections of this chapter.

Of the currently available vaccine strains, only *B. abortus* S19 and *B. melitensis* Rev 1 have been tested in humans (Spink and Thompson, 1953; Spink et al., 1962). Rev 1 was found to be unsuitable for human use with 2/3 of the "volunteers" exhibiting symptoms

of disease and colonization by the organism (Spink et al., 1962). In contrast, a subculture of S19 referred to as 19-BA provided results that may be more encouraging. Two volunteers (12%) exhibited symptoms of disease and the organism was only isolated from one. Strain 19-BA was originally used to vaccinate at least three million people in the Soviet Union (Vershilova, 1961), and investigators concluded that there were more problems due to hypersensitivity than to persistence of the organism. Eight percent complained of headache and malaise, and 2% showed signs of febrile illness. As a result of this vaccination program, a 60% decline (1952–1958) in human brucellosis was reported during a period when animal brucellosis exhibited no decline, and the investigators recommended the use of strain 19-BA in endemic areas. Although efficacious, vaccines with these side effects cannot be tolerated given the current knowledge of bacterial pathogenesis and the ability to manipulate microbial genomes. Reports of adverse reactions in humans also cast doubt on the recently approved vaccine strain RB51, a rough derivative used with some success in ruminants (Ashford et al., 2004). The absence of O-antigen prevents development of cross-reacting immune responses that are indistinguishable from wild-type infection, but also increases the susceptibility of this strain to host killing mechanisms limiting survival and vaccine efficacy (Jimenez de Bagues et al., 1995; Palmer and Cheville, 1997).

The pursuit for an ideal vaccine for eradicating brucellosis has kept scientists busy for nearly a century now, as the criteria for an ideal *Brucella* vaccine are very difficult to achieve. Before achieving clinical reality, the hurdles an ideal *Brucella* vaccine needs to overcome are to: (a) be harmless to the recipient, even on accidental inoculation; (b) be able to induce long-term immunity after one administration; (c) have minimal influence on diagnostic methods such as serologic tests; (d) prevent infection in both sexes, prevent abortion; and (e) be inexpensive, easily produced, stable, and of consistent quality.

In recent years, a stable rough variant of virulent *B. abortus* S2308 designated RB51 (Schurig et al., 1991b) was developed that has one advantage over other vaccines in that it does not stimulate the formation of serum-specific antibodies (Schurig et al., 1991b; Cheville et al., 1992; Tobias et al., 1992). However, the level of protection it affords against smooth virulent strains is lower than that conferred by the current live attenuated smooth vaccine strains (Roop et al., 1991; Samartino and Enright, 1992; Tobias et al., 1992), and inoculation of high doses (10^{10} organisms) leads to placental and fetal colonization of pregnant cattle. Unpublished data also suggests that in several developing countries where the challenge dose of *B. abortus* is very high, RB51 does not protect animals from brucellosis as effectively as strain 19. Besides causing abortion in reindeer and elk, it sometimes also localizes in the uterine trophoblasts of pregnant cows, and is shed in the milk of infected animals.

The use of available vaccines, Strain 19 and RB51, has been disappointing in that they are not sufficiently efficacious in bison, elk, or other species (Cook et al., 2002; Davis and Elzer, 2002; Elzer et al., 2002; Kreeger et al., 2002; Elzer et al., 2003; Olsen et al., 2003). Due to the shear numbers of elk (>30,000), it is not feasible to evaluate a parenteral delivery system in this population in which neither S19 nor RB51 are adequately efficacious (Cook et al., 2002; Kreeger et al., 2002).

Vaccines in Development

Given the potential threat this organism poses and the demonstrated potential for immune protection, the development of human vaccine strains appears to be a viable approach. However, better definition of the role of virulence determinants in survival of the organism and contribution to disease is required. For this reason, over the past 10 years we have characterized gene functions necessary for persistence within macrophages using transposon mutagenesis. In this approach, genes required for survival have been classified according to survival characteristics of deficient mutants (Hong et al., 2000; Wu et al., 2006b). Mutants are generally characterized as having early (rapid) and late (delayed) clearance. Examination of the vaccine potential of these mutants in the mouse model reveals improved immune protection associated with prolonged survival (Kahl-McDonagh et al., 2006; Kahl-McDonagh and Ficht, 2006). The use of live attenuated vaccines will require demonstration of safety as well as efficacy as addressed below.

Prospects for Future Vaccine Candidates

Two factors have been explored as measures of vaccine potential. The first is the safety of the candidate measured by reduced colonization and the absence of side effects. However, a direct relationship between survival and immune protection has been demonstrated in the mouse model (Kahl-McDonagh and Ficht, 2006). Yet, persistence enhances the possibility that the vaccine will colonize additional tissues. The solution is to enhance persistence of highly attenuated (safe) vaccines, and a promising approach has been the use of microencapsulation (A. Arenas-Gamboa, unpublished) in comparison with the standard *B. melitensis*

vaccine strain Rev 1 (Alton and Elberg, 1967; Elberg, 1981). Efficacy trials will evaluate vaccine candidates that have demonstrated significant immune protection in the mouse model. The second factor is the ability of the organism to induce a protective immune response.

Signature-tagged mutants have been identified using a survival-based strategy in the mouse model of infection (Hong et al., 2000; Wu et al., 2006b). Attenuated survival is subsequently confirmed based on clearance from the spleens of mice more rapidly than parental wild-type using either mixed infections (mutant:wild-type) or individual strains in the mouse model. Knockout mutants are then constructed to simplify potential field release with minimal environmental impact. The immune potential of vaccine candidates with different survival characteristics; rapid (1–2 weeks) versus delayed (>6 weeks) is evaluated in mice protection against colonization and persistence as a measure of efficacy. Mutants providing protection equivalent or superior to currently available vaccines are then selected for evaluation in the goat model (Kahl-McDonagh et al., 2006; Kahl-McDonagh and Ficht, 2006). Using this model, evaluation may be made between protection against clinical signs, infection (colonization), and abortion or premature birth of the kid. Current candidates of interest include Δ*luxR*, Δ*mucR*, and Δ*asp24* deletion mutants (Table 42.1). The choice of these mutants is based on preliminary results in which Δ*asp24* mutants persisted in the host, but provided elevated levels of protective immunity in mice and goats (Kahl-McDonagh et al., 2006; Kahl-McDonagh and Ficht, 2006). Examination of immune correlates in these animals will help to describe immune protection against brucellosis. Δ*luxR* mutants are rapidly cleared from the host, but still provide significant levels of protection. However, the Δ*luxR* mutants have also been shown to provide enhanced protection when delivered in microencapsulated form and have the added advantage of not stimulating (or preventing) splenomegaly when delivered in either format. These features of immune protection and safety make Δ*luxR* mutants ideal candidates for testing in nonhuman primates. Recently, DNA vaccines have been developed that are beginning to demonstrate a level of protection which may prove useful (Cassataro et al., 2005; Gonzalez-Smith et al., 2006; Luo et al., 2006).

TABLE 42.1 Candidate vaccine *Brucella* mutants

Vaccine candidate	Secondary mutation	Phenotypic difference	Outcome/status
B. melitensis Δ*luxR*	None	Mutant highly attenuated; controls T4SS expression	IP and oral vaccination enhanced by encapsulation
	Δ*virB12*	Provides diagnostic marker	No effect on virulence; no change
	Δ*virB*	No additional effect on virulence; primary and secondary mutations affect same virulence genes	Reversion to virulence reduced; no change
	Δ*manBA*	Distinct virulence mechanism; aggregate defects	Attenuation enhanced; reversion to virulence reduced
	Δ*mucR*	Distinct virulence regulon; aggregate defects	Attenuation enhanced; reversion to virulence reduced

Formulation and Microencapsulation

Oral or intranasal vaccine is relatively easy to distribute, low cost compared to parenteral immunization, simplifies multiple dosing, and has the potential for stimulation of mucosal immunity. Microencapsulation of *Brucella* antigens has been used successfully to provide immune protection in the mouse model of brucellosis (Murillo et al., 2001, 2002a, 2002b, 2002c). Microencapsulation provides advantages over delivery of vegetative or lyophilized *Brucella* vaccines. The microcapsules protect the vaccine, enhance the immune response via delivery to preferential sites, and allow exposure modulation (i.e., controlled release). Capsules of 5μm diameter, delivered orally, typically enter Peyer's patches of the intestines, travel to local lymph nodes and to the spleen. Capsules of larger diameter typically reside in M cells of Peyer's patches and elicit a local immune response. The technique is also expected to increase the shelf life of vaccines. Microencapsulation takes advantage of the properties of early mutants, i.e., rapid clearance with minimal side effects, and is expected to enhance immunity through sustained release. Double-mutants represent additional potential candidates for microencapsulation, due to their elevated attenuation there typically is little induction of a protective immune response. Additional features that may be explored include pulse-release in response to specific

environments (low pH, reducing environment, etc.) or targeting to specific cell types.

A number of processes based on established technologies have recently been adapted for use as encapsulants for living cells to permit transplantation (Young et al., 2002). Hydrogel formation has been employed to encapsulate living cells in bioremediation applications (Russell et al., 2003), for live cell entrapment (Young et al., 2002; Russell et al., 2003), or for protein drug delivery (Qiu et al., 2003). PEG gels provide a protective environment for the cell mechanically blocking attack by cells of the immune system in cases of transplantation (Young et al., 2002). The pore size and therefore the release rate from the capsule will depend on the length of the PEG polymer utilized for the matrix. PEG-based spheres will be formed from a solution of PEG-diacrylate-575, a comonomer (allylamine, acrylic acid, or acrylamide) and living cells (Mellott et al., 2001). Pentaerythritol triacrylate (PETA) will serve as a cross-linking agent and 2,2′-dimethoxy-2-phenyl-acetophenone (DMPA) as photo-initiator for production of methyl radicals for cross-linking. This method has proven to be safe and efficient for the encapsulation of proteins and living cells (Mellott et al., 2001). An alternate hydrogel method utilizes thiol-containing PEG-copolymer injected as a liquid containing the payload (viable cells) and forms a polymer after injection due to the formation of disulfide cross-links in the reducing tissue environment. This depot slowly releases (2–4 weeks) the cellular payload as hydrolysis of the matrix occurs (Qiu et al., 2003).

Rationale for Second and Third New Generation Vaccines

Adams (1990) reviewed the future development of live, attenuated vaccines, and proposed that optimal immunity against *Brucella* spp. will require: (1) antibodies for immune clearance, and (2) sensitized T-helper-cells and delayed hypersensitivity T cells of the macrophage activating type are required for containment, killing, and elimination of *Brucella* spp., thus identification of B-cell and T-cell epitopes and/or modified virulence factors for effective delivery to the host was the next logical step. Furthermore, because the predominant natural exposure in brucellosis is per os, oral delivery of the immunogen to the gut-associated lymphoid tissue (GALT) that stimulates generalized secretory, humoral, and cellular immune responses is the optimal route for vaccination (Adams, 1990). A newer approach consists of identifying diagnostic immunodominant protein antigens and deleting the corresponding genes in the current live attenuated smooth *Brucella* strains. Mutants constructed thus should not induce antibody responses against these target proteins that will be immunodominant in infection and therefore good candidates for conventional serological tests. The introduction of stable and genetic or phenotypic markers used to replace the genes of interest should allow the newly constructed vaccine strain from being differentiated from field isolates, the so-called DIVA vaccines. *B. abortus* S19 mutants deleted for copper–zinc superoxide dismutase (CuZnSOD) or a 31 kDa protein have been constructed and have provided protective immunity against *B. abortus* in cattle similar to the response evoked by the parental strain (Cheville et al., 1993). However, the proteins chosen were not immunodominant in infected cattle and therefore inappropriate as diagnostic antigens.

The caprine model is proposed to be the next optimal model to evaluate gene deletion mutants previously characterized in the mouse model. Strains selected for high levels of protection induced in mice will then be evaluated for safety and efficacy in nonpregnant goats. Subsequent experiments should evaluate protective immunity induced against challenge with virulent organisms. The caprine model offers a natural ruminant host that is inexpensive, accessible, and can provide early-stage evaluation of vaccines with disease symptoms similar to those experienced in humans. However, the nonhuman primate model is the optimal model to evaluate protection against clinical signs that occur in human brucellosis as well as protection against infection. The caprine experiments provide optimal data to select the most appropriate vaccine candidate for nonhuman primate studies as well as reducing the number of nonhuman primates required for potency testing. Evaluations should include overall health, body temperature, pulse, respiration, leukocytosis, bacteremia, and colonization of selected tissues. The best candidates evaluated in both hosts are then used to provide support under the "two animal" U.S. Food and Drug Administration rule for projected Phase I testing.

Nonhuman Primates

Other species were examined for use in this protocol as a substitute for nonhuman primates. The first is the use of the goat model described above. The symptoms experienced in the goat model are similar to those observed in humans. A large amount of work performed previously was conducted in mice; however, these animals do not clinically duplicate brucellosis

as seen in humans. In order for this project to test the safety and efficacy of a vaccine for human use, a nonhuman primate model must be used. There are no suitable nonhuman primate animal models, computer models, nor are there any in vitro tests, which can replace the rhesus monkey (*Macaca mullatta)* to evaluate the efficacy of *Brucella* vaccines. Rhesus monkeys, rather than cynomolgus monkeys, are preferable based on earlier studies and the availability of human monoclonal antibodies that cross-react against rhesus monkey proteins. This permits phenotyping immunological cell populations and measurement of cytokines in the rhesus monkeys and direct correlation with humans. These monoclonal antibodies, designed for human use, have been demonstrated to work in this species.

Early studies demonstrated that rhesus monkeys could be infected orally using whole agar slants or milk from infected animals (Huddleson and Hallman, 1929). In a recent report of USAMRIID studies (Mense et al., 2004), rhesus monkeys were shown to be susceptible to aerosol infection by *B. melitensis* strain 16M, and that the cellular and humoral immune responses correlate with clinical observations. Exposed animals became bacteremic and febrile following aerosol challenge, and the time from challenge to bacteremia appeared inversely related to the challenge dose. Histopathologic abnormalities were directly related to dose using morphometric techniques. Furthermore, spleen weights increased with increasing aerosol exposure dose. This is consistent with human disease where the lymphoreticular system is also a known target with *Brucella* infection (Spink and Thompson, 1953; Spink et al., 1962). Data from USAMRIID studies established that nonhuman primates could also be infected with virulent *B. melitensis* strain 16M by the intragastric route, and this infection may involve organs other than the digestive tract proper. Intragastric administration of 10^{12} CFU of the virulent 16M strain led to profound bacteremia and extensive tissue infection. It is anticipated that candidate vaccine strains will be initially delivered by intranasal inoculation and immune responses monitored both before and after challenge (Chen and Elberg, 1976). Microencapsulation may be expected to enhance protection via controlled release and boosting of the protective immune response and may permit the use of reduced vaccine doses.

SUMMARY OF VACCINE RESEARCH AIMS

Current genetic tools permit the development of novel *Brucella* vaccine candidates derived through deletion of virulence factors and subsequent removal of antibiotic resistance marker genes. The defined nature of targeted mutations is expected to simplify interpretation of safety and efficacy compared with the use of fortuitously derived spontaneously attenuated organisms. Evaluation in multiple hosts is expected to provide support for safety and efficacy in nonhuman primates. The identification of vaccine candidates should be based on the predictive capabilities of mouse and guinea pig models supported in another study prior to testing in goats and nonhuman primates to estimate safety and efficacy for future human testing. Combining multiple genetic mutations in a single organism is expected to enhance safety while maintaining a significant level of protection and preventing reversion to virulence. Immune parameters will be characterized with the intent of determining the correlation between mutation in specific genes, survival, and immune protection. Finally, timed release of viable vaccine strains through microencapsulation may enhance vaccine safety and efficacy by combining two features of *Brucella* vaccines that are usually incompatible, i.e., extreme attenuation and persistence within the host.

KEY ISSUES

- Brucellosis is a serious disease threat to human and animal populations in underdeveloped countries.
- The progress made in the control of animal brucellosis over the last 50 years, has prevented the development of improved strategies to directly control human disease.
- The continued public health threat posed by brucellosis is a direct result of the cycle of human poverty that results in self-reliance on small, local animal herds.
- The high infectivity, potential for aerosol delivery, and lack of human intervention strategies are characteristics of a biothreat agent.
- Development of improved vaccines may be expected to improve public health and economic standing of underdeveloped countries.
- Development of improved vaccines may be expected to provide protection for at-risk personnel in the war against terror.
- Development of significant levels of protection has only been associated with live attenuated vaccines; characterization of the genes necessary for intracellular survival will aid in the development of safe and efficacious vaccine strains.

- Understanding the mechanism(s) of interaction between host and agent is essential to the development of improved intervention strategies.
- An optimally attenuated *Brucella* vaccine may be used as a vector to deliver genes derived from other pathogens.

ACKNOWLEDGMENTS

The authors thank Dr. Angela Arenas, Dr. Melissa M. Kahl-McDonagh, Dr. Carlos A. Rossetti, and Dr. Allison Rice-Ficht for their thoughtful discussions, development of conceptual approaches, and their contributions to this manuscript.

OUTLINE

ABSTRACT

Burkholderia mallei and *Burkholderia pseudomallei* are gram-negative bacteria that cause two distinct diseases, glanders and melioidosis, respectively. Based on DNA sequence and 16S rRNA sequence comparisons, these organisms are closely related, and Multi-Locus Sequence Typing (MLST) suggests that *B. mallei* has evolved as a clonal derivative of *B. pseudomallei. B. mallei* is an obligate parasite of equines and was relatively common throughout the world until the early 20th century and the development of motorized transportation. Human glanders is usually a consequence of contact with infected animals. Acute glanders is usually fatal without medical intervention. The chronic form of the disease may present clinically with swollen lymph nodes, ulcerating nodules, and subcutaneous abscesses. *B. pseudomallei* is widely distributed throughout tropical countries. Unlike

B. mallei, the bacterium can survive outside of a mammalian host and be found in soil and water. Melioidosis affects animals and humans, has a diverse range of symptoms similar to those of glanders, and can be fatal in the acute septicemic form. In endemic areas, *B. pseudomallei* infection is a major cause of hospitalization, and the popularity of worldwide travel has led to increased numbers of cases being reported in non-endemic areas such as Europe and North America. There has been some effort to develop a vaccine against *B. pseudomallei* and *B. mallei*. The close genetic relatedness of the two species suggests that one vaccine may be effective against both diseases. The availability of the genome sequence data should help in the search for a new vaccine by facilitating the identification of potentially protective subunits.

INTRODUCTION

The aim of this chapter is to provide an insight into the biology of two closely related potential biowarfare/bioterrorism agents, *Burkholderia mallei* and *Burkholderia pseudomallei*. Recent genome and epidemiological analyses of these organisms suggest that *B. mallei* has diverged from *B. pseudomallei*. Both organisms cause diseases that affect humans and animals, cause similar clinical symptoms, and are inherently very resistant to a wide range of antibiotics. Despite the similarities, there are some differences. *B. mallei* is believed to be unable to survive outside of a mammalian host, whereas *B. pseudomallei* can be isolated from the environment in endemic areas. There are also differences in the presence of genes associated with virulence, such as type three secretion systems (TTSS), and a family of proteins related to hemagglutinins and invasins (Tiyawisutsri et al., 2007; Rainbow et al., 2002). Our understanding of the molecular basis of disease caused by both agents is rapidly developing, and there is an increasing understanding of virulence mechanisms. Genome sequencing and microarray technology has also identified organism-specific genes potentially involved in pathogenesis. In this chapter, we will consider both glanders and melioidosis, review the recent advances in our knowledge of the organisms, and discuss the potential to produce a vaccine.

HISTORY OF GLANDERS

Glanders is one of the oldest diseases known to mankind and was first described by Aristotle (Wilkinson, 1981). The disease terminology comes from the Greek word "melis" and its Latin derivative "malleus," meaning "severe disease." *B. mallei* was first isolated by Loeffler and Schutz in Germany in 1882, closely followed by Bouchard, Charrin, and Capitan in the same year (Steele, 1979). The organism is a gram-negative aerobic bacillus and is believed to be an obligate mammalian pathogen with solipeds as the natural reservoirs of infection (Pitt, 1990; Sanford, 1996).

The lethal nature of glanders renders *B. mallei* an ideal biological warfare/bioterrorism agent, and there are several reports of its use in this way. It is generally believed that glanders was deliberately spread during World War I by the Germans to infect a large number of Russian horses and mules on the Eastern front (Wheelis, 1998). This had a detrimental effect on the supply of convoys and troops and artillery movement, which were dependent on the horses and the mules. Possibly as a consequence of this dispersal of *B. mallei*, cases of human glanders in Russia increased after World War I. During World War II, the Japanese were believed to have infected horses, civilians, and prisoners of war with glanders at the Pinfang Institute in China. *B. mallei* was also studied by the United States as a biological warfare agent during the 1940s but not apparently weaponized. The former Soviet Union reportedly weaponized *B. mallei* and deployed it in Afghanistan during the 1980s (Alibek, 1999). Glanders has mostly been eradicated from the West since aggressive control measures were enforced in the early 20th century (Steele, 1979; Derbyshire, 2002). However, cases of glanders still periodically occur in certain parts of Asia, the Middle East, northern Africa, and various Mediterranean regions (Benenson, 1995; Kovalev, 1971).

HISTORY OF MELIOIDOSIS

In Rangoon, in 1911, Whitmore and Krishnaswami recorded several cases of a fatal septicemic disease in morphine addicts and neglected inhabitants of the town. After conducting a postmortem on the first victim, they observed a caseous consolidation of the lungs with the presence of abscesses in other organs including spleen, liver, and kidney. They initially described it as a glanders-like disease but were unsatisfied that the bacterium they isolated from the patient was actually glanders as the victim did not have close contact with horses. Subsequently, they conducted a series of experiments, including culturing on peptone agar and potato slopes, and performed virulence studies in guinea pigs. Although

the bacterium was similar to the glanders bacillus, there were several differences. The organism isolated was motile, did not induce the characteristic Strauss reaction, and grew rapidly on agar. They concluded that they had identified a new bacterium that was closely related to *B. mallei* (Whitmore and Krishnaswami, 1912; Whitmore, 1913). Several more cases of the disease were described in Rangoon in the following years, and postmortem studies conducted on the victims showed the characteristic symptoms described above (Krishnaswami, 1917). Shortly after this, cases of melioidosis were reported in Malaya in animals at the Institute for Medical Research in Kuala Lumpur (Stanton and Fletcher, 1932). The disease was named melioidosis, derived from the Greek words "melis," which means distemper of asses, and "eidos," which means resemblance (Stanton and Fletcher, 1921).

B. pseudomallei is regarded as a potential biowarfare/bioterrorism agent and appears on the category B list of critical agents published by the U.S. Centers for Disease Control and Prevention. Cases of melioidosis were reported during and after World War II and in soldiers fighting in Vietnam (White, 2003). Melioidosis cases from the Vietnam war often presented as a chronic infection, and reactivation of the disease occurred many years after exposure (Rubin et al., 1963; Sanford and Moore, 1971). *B. pseudomallei* is also a major veterinary pathogen with several outbreaks in zoos. The most infamous case "Affaire du Jardin des Plantes" involved an outbreak in large mammals of the Paris zoological gardens. The infection was disseminated by a panda donated by Mao Ze Dong to President Pompidou (Dance and White, 1996).

Until recently, there were only a few reports of melioidosis cases in South and East Asia probably because of insufficient diagnostic facilities. The first reported case in Thailand was in 1955. Three more cases were reported by 1966 and, 20 years later, over 800 documented cases (White, 2003). Melioidosis is now recognized as an important human infection in Southeast Asia and northern Australia (Currie et al., 2000; Puthucheary et al., 1992). The number of cases of melioidosis that occurs globally is thought to be underestimated with many cases not being diagnosed (White, 2003).

ETIOLOGICAL AGENTS

B. mallei is a gram-negative, nonmotile, aerobic, rod-shaped bacterium, 0.3–0.8 μm in width and 2–5 μm in length (Timoney et al., 1988). The bacteria often stain irregularly and do not appear to have capsules or form spores. Electron microscopy of the bacteria has revealed a capsule-like structure covering the bacteria. This capsule has been shown to be a major virulence factor of *B. mallei* and is thought to protect against harsh environmental factors (Deshazer et al., 2001). The organism grows aerobically in ordinary media and anaerobically only in the presence of nitrate. The organism is slow to grow on glycerol agar, typically requiring 48 h at 37°C.

B. pseudomallei is a gram-negative, motile, non-spore-forming bacillus, 0.4–0.6 μm in width and 2–5 μm in length. The bacteria exhibit a characteristic bipolar staining and are seen singly, in pairs, or very occasionally in chains (Pitt, 1990). The organism grows aerobically in many simple media and will grow under strictly anaerobic conditions in a complex medium containing nitrate. The range of organic compounds that may be used as sole sources of carbon and energy is exceptionally wide, making *B. pseudomallei* one of the most nutritionally versatile members of the genus *Burkholderia*. The form and color of growth on solid media is highly variable, and colonies can range in structure from extreme rough to mucoid and in color from cream to bright orange (Redfearn et al., 1966; Chantratita et al., 2007). Figure 43.1 illustrates the differing colony morphologies on Ashdown agar. Chantratita et al. (2007) suggest that a particular colonial type (type II) is adapted to persistence, resulting in a low-virulence state. It has been shown that virulence is dependent on the presence of the capsular antigen (Atkins et al., 2002; Reckseidler et al., 2001). *B. pseudomallei* has been shown to secrete an abundant slime layer made up of polysaccharides. This layer has been termed the "glycocalyx," and it is thought that bacterial cells may live and divide within

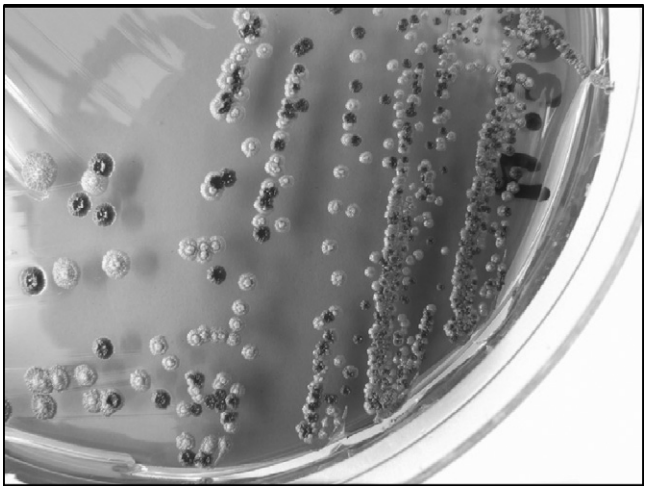

FIGURE 43.1 *B. pseudomallei* colonies on Ashdown media, kindly donated by Narisara Chantratita and Sharon Peacock, Mahidol University, Thailand.

it, protected from unfavorable environmental factors (Kanai and Kondo, 1994).

CLASSIFICATION

B. mallei and *B. pseudomallei* have previously been assigned to the genus *Bacillus*, *Acinetobacter*, *Loefferella*, *Actinobacillus*, *Malleomyces*, or *Pfeifferella* (NCBI Taxonomy). Most recently, based on their 16S ribosomal nucleic acid sequences, DNA homology, cellular lipid and fatty acid composition, and phenotypic characteristics, they were known as *Pseudomonas mallei* and *Pseudomonas pseudomallei* (Leelarasamee and Bovornkitti, 1989). Currently, these species are classified in the genus *Burkholderia*, which is named after U.S. microbiologist Walter Burkholder, who first described *Burkholderia cepecia*, formerly known as *Pseudomonas cepecia* (Yabuuchi et al., 1992).

The genome sequence of *B. pseudomallei* strain K96243 reveals that it is one of the largest prokaryotic genomes comprising two chromosomes of 4.07 and 3.17 Mb (Holden et al., 2004). The larger chromosome carries genes associated with housekeeping functions involved in processes such as cell growth and metabolism, and the smaller chromosome is thought to encode genes required for adaptation and survival in different environments. This proposal is also supported by the finding that genes important during the early phase growth of *B. pseudomallei* in vitro are preferentially located on chromosome 1, whereas genes involved in stationary-phase growth are biased toward chromosome 2 (Rodrigues et al., 2006). There is significant intraspecies diversity that is attributed to either DNA acquisition or loss (Ou et al., 2005). An unusual feature of the *B. pseudomallei* genome is the presence of 16 genomic islands, which make up 6.1% of the entire genome, and is thought to be acquired by horizontal gene transfer. These genome islands are absent in the *B. mallei* genome, which is smaller than that of *B. pseudomallei*, consisting to two chromosomes of 3.51 and 2.32 Mb (Nierman et al., 2004). The presence of a number of insertion sequence elements is thought to have mediated the extensive deletions and rearrangements of the genome relative to that of *B. pseudomallei* (Nierman et al., 2004). The genome downsizing supports previous Multi-Locus Sequence Typing (MLST)-derived conclusions that *B. mallei* has evolved from *B. pseudomallei* (Godoy et al., 2003). Subtractive hybridization between *B. mallei* and *B. pseudomallei* has identified several DNA fragments specific to the latter, which may provide functional detection tools (Monastyrskaya et al., 2004).

PROTECTIVE IMMUNE RESPONSE

The immunological basis of resistance against *B. pseudomallei* infection is poorly understood. However, limited studies in healthy humans exposed to *B. pseudomallei* in endemic areas or patients with overt disease indicate activation of both humoral and cell-mediated arms of the immune system. Individuals naturally exposed to *B. pseudomallei* develop antibodies that increase in titer during acute disease. Indeed, serodiagnostic tests for melioidosis depend on the development of antibodies to *B. pseudomallei* (Ashdown, 1987; Dance, 1991). The levels of IgA, IgM, and IgG antibodies to *B. pseudomallei* correlate with the severity of the disease (Wiersinga et al., 2006). Charuchaimontri et al. (1999) have reported that high levels of antibody to lipopolysaccharide II (LPS II) (now considered to be LPS) in humans suffering from melioidosis correlate with survival.

Experimental studies in mice also suggest that antibodies may play important roles in protection from disease. The immunization of mice with capsular polysaccharide or LPS can protect mice against challenge with *B. pseudomallei* (Nelson et al., 2004), suggesting a role for antibodies in protection. Polyclonal antibodies to LPS can protect diabetic rats against infection caused by *B. pseudomallei* (Brett and Woods, 1996), and in a previously reported study, four protective monoclonal antibodies (mabs) were identified (Jones et al., 2002), which were directed against capsular polysaccharide (antibodies 3VEI5 and 4VA5), LPS (antibody CC6), or an unidentified protein (antibody 4VH7). These antibodies were able to protect mice against an i.p. challenge with 10^4 cfu (approximately 250 LD50 doses) of *B. pseudomallei* strain NCTC4845 (Jones et al., 2002). Similar protection has been reported by Bottex et al. (2005) with a mab directed against the capsular polysaccharide and evaluated in an outbred strain of mice. Both capsular polysaccharide and LPS have been shown to be key virulence factors of *B. pseudomallei*. An antibody against these polysaccharides is reported to be opsonizing and to promote killing by polymorphonuclear leukocytes (PMNs) (Ho et al., 1997). Combinations of protective mabs provided protection, evidenced as an increased time to death, against an i.p. challenge with 10^6 cfu of *B. pseudomallei* (Jones et al., 2002).

Patients with severe melioidosis have high levels of pro-inflammatory cytokines (such as IL-12, IL-18, TNF, IFNγ, IL-15, and IL-6), immunoregulatory cytokines (such as IL-10), as well as granzymes A and B [components of natural killer (NK) cell and cytotoxic-T cell lytic granules], indicating extensive activation

of the cellular immune compartment. Reportedly asymptomatic but seropositive individuals tend to show stronger cellular adaptive responses compared to individuals with clinical melioidosis, suggesting a key role for cellular immunity in the control of infection (Barnes et al., 2004). These observations are supported by experimental models of melioidosis in mice that have begun to identify the mechanisms of immunity (Haque et al., 2006; Holden et al., 2004; Santanirand et al., 1999). Nevertheless, detailed immunological knowledge of human infection is poor compared to many other infections, and there has been no previous attempt at a broader analysis of immune changes during acute infection. $CD8^+$ T cells have been shown in *B. pseudomallei* infections to be an important source of early IFNγ via a bystander activation pathway (Lertmemongkolchai et al., 2001). In the murine model of disease, $CD4^+$ T cells, rather than $CD8^+$ T cells, are strongly implicated in the control of infection (Haque et al., 2006). However, there is apparently no association between HIV infection and susceptibility to melioidosis, which questions the role of $CD4^+$ T cells in resistance to melioidosis in humans (Wiersinga et al., 2006).

The immune responses to infection with *B. mallei* are even less well understood. In solipeds, it is clear that antibody responses develop during infection since serodiagnostic tests are used to monitor possible cases of disease (Neubauer et al., 2005). In the murine model of disease, passive administration of monoclonal antibodies against LPS provides protection against an aerosol challenge with *B. mallei*, although sterile immunity was not achieved (Trevino et al., 2006). However, the ability of *B. mallei* to replicate inside host cells suggests that cellular responses might be evoked and linked to a protective response.

EPIDEMIOLOGY

Although glanders was once widespread throughout the world, it has been successfully eradicated by test and slaughter programs (van Zijderveld and Bongers, 2000). Sporadic cases of glanders occur in parts of Asia, Africa, countries in the former Soviet Union, Mexico, South America, and the Middle East (Fig. 43.2) (Arun et al., 1999; Scholz et al., 2006).

Melioidosis, on the other hand, is widespread (Fig. 43.3), and an excellent review of the epidemiology of the disease has been published (Cheng and Currie, 2005). Melioidosis in humans is reported

FIGURE 43.2 Worldwide distribution of *B. mallei*.

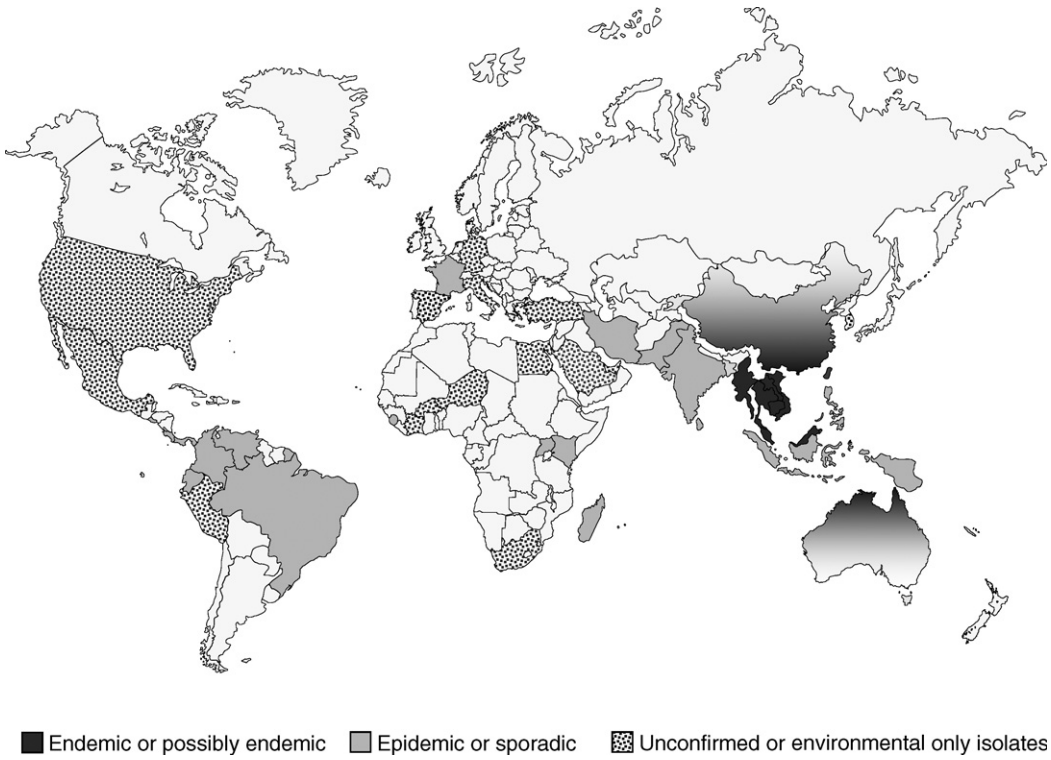

FIGURE 43.3 Worldwide distribution of *B. pseudomallei*.

mainly in northeastern Thailand, Singapore, and northern Australia, with sporadic cases occurring in surrounding areas. Cases reported from other parts of the world are usually associated with travelers returning from endemic countries (Dance et al., 1999; Nieminen and Vaara, 2005). More recently, there has been an increase in cases reported in South America probably due to the growing awareness of melioidosis and improved diagnostic methods (Inglis et al., 2006; Aardema et al., 2005).

CLINICAL DISEASE

Glanders

The incubation period of glanders ranges from 10 to 14 days, and there is some evidence that the disease may remain latent (Fritz et al., 2000). The disease can manifest itself in four forms dependent on the route of exposure: local cutaneous, pulmonary, septicemic, and chronic forms (Waag and Deshazer, 2004). Initial symptoms include fever, malaise, muscle aches, and headache. The cutaneous form is a localized infection with pus-forming ulcerations on the skin, which may spread over the body. Infections associated with mucous membranes of the nose, trachea, pharynx, and lungs results in purulent ulceration. The pulmonary form is associated with pneumonia, pulmonary abscesses, and pleural effusions. Chest X-rays reveal localized infections in the lobes of the lungs. The septicemic form is fatal, resulting in death within a few days if untreated. The chronic form, also known as farcy, is associated with multiple abscess formation in muscles of the arms and legs, or in the spleen, liver, and joints. Even with treatment at this stage, there is a high fatality rate with frequent relapses of infection.

Melioidosis

The incubation period of melioidosis is normally 2–3 days, but there are reports of the disease developing up to 60 years after exposure (Arakawa, 1990; Ngauy et al., 2005). The clinical spectrum of melioidosis is extremely diverse, consisting of four forms of disease: acute fulminant septicemia, subacute illness, chronic infection, and subclinical disease. The disease may be localized or disseminated, and virtually any organ may be affected. Depending on whether the disease is acute or chronic, melioidosis can mimic other bacterial infections, including typhoid, malaria, tuberculosis,

and septicemia from other common bacterial organisms (Ip et al., 1995; Everett and Nelson, 1975).

The importance of early diagnosis and treatment has been stressed in the management of acute septicemic melioidosis. However, symptoms are so varied and the demise of the patient so rapid that, unless a clinician is alert to the possibility of a *B. pseudomallei* infection, the disease may be wrongly diagnosed (Arakawa, 1990). The acute septicemic form is usually associated with an underlying disease or condition such as diabetes, alcoholism, or immunodeficiency and, despite current antibiotic regimes, carries a high mortality rate (50–75%) (Majid, 1990).

Lesions apparent during the progression of melioidosis were shown to contain a large number of infiltrating cells, mainly macrophages, many of which contained phagocytosed bacilli (Wong et al., 1995). Most of the bacillary cells were surrounded by an electron-dense substance and had a clear halo between the substance and the cell wall (Narita et al., 1982). Following uptake, ingested *B. pseudomallei* escape from the vacuoles, possibly as a result of bacterium-mediated vacuolar membrane damage (Harley et al., 1994).

Each clinical case of melioidosis may represent the outcome of one of three possible processes: primary infection, reinfection, or reactivation of latent disease. Primary infection appears almost inevitable in children in northeast Thailand, where approximately 80% have developed antibodies to *B. pseudomallei* by the age of 4 years. Nearly all these infections appear to be asymptomatic or subclinical. In most cases, adult melioidosis results from reinfection or reactivation of latent infections (Maharjan et al., 2005; Suputtamongkol et al., 1994). Serological studies in Malaysia also found a high incidence of antibodies to *B. pseudomallei*, presumably due to mild, unrecognized, or inapparent infections (Strauss et al., 1969). *B. pseudomallei* infections are also prevalent in animals, and cases have been reported in captive dolphins, sheep, pigs, and goats (Currie et al., 1994; Dance, 1991; Vedros et al., 1988).

TREATMENT

Early positive laboratory diagnosis and appropriate chemotherapy are essential for the successful management of glanders and melioidosis. If these prerequisites are met, then the prognosis of these diseases are good and fatalities are limited to those patients who present with overwhelming, fulminating septicemia, which cannot be halted by current medical treatment (Ashdown et al., 1980). The antibiotic susceptibility profile of *B. mallei* and *B. pseudomallei* are similar, and both pathogens are susceptible in vitro to ceftazidime, imipenem, meropenem, and doxycycline (Kenny et al., 1999).

The small number of human cases of glanders means that there is limited information about antibiotic treatment, although sulfadiazine has been found to be effective in experimental animals and humans (Batmanov, 1993). An accidental exposure of a microbiologist to *B. mallei* provided an insight into the treatment and management of glanders (Srinivasan et al., 2001; Waag and Deshazer, 2004). The infection was not controlled by cephalosporin or clarithromycin, and symptoms returned after completion of the course of antibiotics. Intravenous tobramycin and doxycycline were more effective in controlling the infection, but lesions formed in the liver contained *B. mallei*. Treatment with imipenem and doxycycline, followed by oral doxycycline and azithromycin, resulted in resolution of the lesions in the spleen and the liver of the patient. There was no reported spread of the disease to whom the patient came in contact (Waag and Deshazer, 2004).

The conventional treatment regimen for melioidosis infections in Thailand was a combination of chloramphenicol, doxycycline, and cotrimoxazole (Dance et al., 1989). Fluoroquinolone antibiotics were found to be inappropriate for the treatment of melioidosis (Winton et al., 1988). Trials carried out in the 1980s recommended ceftazidime as the antibiotic of choice to replace the use of high doses of chloramphenicol, doxycycline, trimethoprim–sulfamethoxazole, and sometimes kanamycin (Chau et al., 1986). Ceftazidime, widely used as a single drug treatment against *Pseudomonas aeruginosa* septicemia, is safe, well tolerated, and highly active against *B. pseudomallei* in vitro, and its use in the treatment of melioidosis has halved the mortality of severe cases (White et al., 1989). The case fatality rate is still high (≈40%), with an increasing number of reports of resistance to currently used drug treatments (Dance et al., 1991; Godfrey et al., 1991). The treatment of choice is high-dose intravenous ceftazidime, meropenem, or imipenem/cilastatin administered for 10–14 days (or longer as clinically indicated), followed by oral trimethoprim–sulfamethoxazole–doxycyline for 12–20 weeks (Wuthiekanun and Peacock, 2006). Treatment of melioidosis patients who presented with septic shock in Australia with meropenem and granulocyte colony-stimulating factor (G-CSF) resulted in a large reduction in mortality from 95% to 10% (Cheng et al., 2004). However, this may be associated with improved intensive-care management during the study period. To address this issue, a randomized, placebo-controlled trial of G-CSF treatment has been conducted in Thailand (Peacock, 2006).

PATHOGENESIS

The pathogenic mechanisms of *B. mallei* and *B. pseudomallei* remain unclear, reflecting the various clinical presentations of both diseases. Current knowledge suggests that a complex interaction of a number of factors influence the course and nature of diseases. These factors include the size of the infectious dose, the route of infection, host factors, and bacterial virulence determinants. Although some virulence determinants in both *B. pseudomallei* and *B. mallei* have been identified, they are poorly characterized.

B. pseudomallei is reported to produce several toxic factors. Culture filtrates were found to contain both toxic and proteolytic activity and a heat-stable molecule with classical endotoxin activity (Colling et al., 1958; Heckly and Nigg, 1958). Further characterization showed the presence of a heat-labile exotoxin that is thought to suppress cellular immune functions (Heckly, 1964; Yahya, 1995). The production of hemolysin appears to be linked to population density. Well-isolated colonies of *B. pseudomallei* appear completely nonhemolytic; however, smaller colonies in a crowded environment are hemolytic (Ashdown, 1990; Liu, 1957).

Other putative extracellular virulence determinants include a 36-kDa protease (Sexton et al., 1994). Metalloproteases have been identified in many bacterial species and often play roles in the pathogenesis of disease (Kooi and Sokol, 1996). Cell-associated virulence determinants include pili and the extracellular polysaccharide (Brett et al., 1994). The flagella of *B. pseudomallei* have been suggested to play roles in virulence. However, nonmotile mutants are reported to be fully virulent in the diabetic rat model of disease but attenuated by the intranasal BALB/c mouse model and in the nematode model of infection (Essex-Lopresti et al., 2005; Deshazer et al., 1997). Therefore, the role of flagella in disease in humans is not clear.

TTSS play an important role in intracellular invasion and survival of gram-negative facultative intracellular pathogens. A type III secretion apparatus has been identified in *B. pseudomallei*, which shows strong homology to the *Salmonella enterica* pathogenicity island 1 (SPI-1) (Rainbow et al., 2002; Stevens et al., 2002). It has been demonstrated that mutations in *B. pseudomallei* genes involved in TTSS3 affect host cell invasion, resulting in bacteria being confined to endocytic vesicles (Stevens et al., 2002, 2003). Interestingly, strains of *B. pseudomallei* with mutations in TTSS3 demonstrated varying degrees of attenuation in animal models of infections (Stevens et al., 2004). TTSS are also thought to be important in facilitating cell-to-cell spread of *B. mallei* (Ribot and Ulrich, 2006). More recently, in *B. mallei*, a type VI secretion system has been identified and shown to be important for virulence in the hamster model of glanders infection (Schell et al., 2007). Furthermore, a protein secreted by the type VI secretion system showing homology to the hemolysin-coregulated protein (Hcp) family was recognized by glanders antisera, indicating that this protein is expressed in vivo (Schell et al., 2007).
